To Ruth and Daniel,
with all my love.

Brief Contents

Preface xvii
Acknowledgments xix
Guided Tour xxiii

1 Keys to the Study of Chemistry 1
2 The Components of Matter 38
3 Stoichiometry of Formulas and Equations 86
4 The Major Classes of Chemical Reactions 134
5 Gases and the Kinetic-Molecular Theory 176
6 Thermochemistry: Energy Flow and Chemical Change 224
7 Quantum Theory and Atomic Structure 256
8 Electron Configuration and Chemical Periodicity 290
9 Models of Chemical Bonding 328
10 The Shapes of Molecules 365
11 Theories of Covalent Bonding 398
12 Intermolecular Forces: Liquids, Solids, and Phase Changes 424
13 The Properties of Mixtures: Solutions and Colloids 488
Interchapter: A Perspective on the Properties of the Elements 541
14 Periodic Patterns in the Main-Group Elements 552
15 Organic Compounds and the Atomic Properties of Carbon 616
16 Kinetics: Rates and Mechanisms of Chemical Reactions 672
17 Equilibrium: The Extent of Chemical Reactions 722
18 Acid-Base Equilibria 766
19 Ionic Equilibria in Aqueous Systems 814
20 Thermodynamics: Entropy, Free Energy, and the Direction of Chemical Reactions 863
21 Electrochemistry: Chemical Change and Electrical Work 902
22 The Elements in Nature and Industry 960
23 The Transition Elements and Their Coordination Compounds 1002
24 Nuclear Reactions and Their Applications 1044

Appendix A Common Mathematical Operations in Chemistry A-1
Appendix B Standard Thermodynamic Values for Selected Substances at 298 K A-5
Appendix C Equilibrium Constants at 298 K A-8
Appendix D Standard Electrode (Half-Cell) Potentials at 298 K A-11
Appendix E Answers to Selected Problems A-12

Glossary G-1
Credits C-1
Index I-1

Detailed Contents

Preface xvii

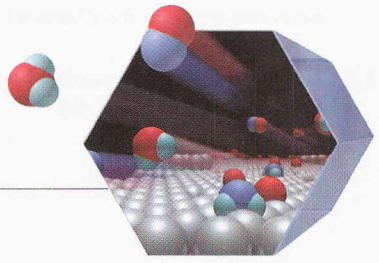
Guided Tour xxiii



1 CHAPTER

Keys to the Study of Chemistry 1

1.1 Some Fundamental Definitions 2
The Properties of Matter 2
The Three States of Matter 4
The Central Theme in Chemistry 5
The Importance of Energy in the Study of Matter 6

1.2 Chemical Arts and the Origins of Modern Chemistry 8
Prechemical Traditions 8
The Phlogiston Fiasco and the Impact of Lavoisier 9

1.3 The Scientific Approach: Developing a Model 10

1.4 Chemical Problem Solving 12
Units and Conversion Factors in Calculations 12
A Systematic Approach to Solving Chemistry Problems 14

1.5 Measurement in Scientific Study 16
General Features of SI Units 16
Some Important SI Units in Chemistry 17

1.6 Uncertainty in Measurement: Significant Figures 25
Determining Which Digits Are Significant 26
Significant Figures in Calculations 27
Precision, Accuracy, and Instrument Calibration 29

Chapter Perspective 30

Chemical Connections to Interdisciplinary Science: CHEMISTRY PROBLEM SOLVING IN THE REAL WORLD 31

For Review and Reference 32
Problems 33

2 CHAPTER

The Components of Matter 38

2.1 Elements, Compounds, and Mixtures: An Atomic Overview 39

2.2 The Observations That Led to an Atomic View of Matter 41
Mass Conservation 41
Definite Composition 42
Multiple Proportions 43

2.3 Dalton's Atomic Theory 44
Postulates of the Atomic Theory 44
How the Theory Explains the Mass Laws 44
The Relative Masses of Atoms 45

2.4 The Observations That Led to the Nuclear Atom Model 45
Discovery of the Electron and Its Properties 45
Discovery of the Atomic Nucleus 47

2.5 The Atomic Theory Today 49
Structure of the Atom 49
Atomic Number, Mass Number, and Atomic Symbol 50
Isotopes and Atomic Masses of the Elements 50

Tools of the Laboratory: MASS SPECTROMETRY 52

A Modern Reassessment of the Atomic Theory 53

2.6 Elements: A First Look at the Periodic Table 54

2.7 Compounds: Introduction to Bonding 57
The Formation of Ionic Compounds 60
The Formation of Covalent Compounds 60
The Elements of Life 61

2.8 Compounds: Formulas, Names, and Masses 62
Types of Chemical Formulas 62
Some Advice about Learning Names and Formulas 62
Names and Formulas of Ionic Compounds 63
Names and Formulas of Binary Covalent Compounds 68
An Introduction to Naming Organic Compounds 69
Molecular Masses from Chemical Formulas 70

Gallery: PICTURING MOLECULES 72

2.9 Mixtures: Classification and Separation 73

Tools of the Laboratory: BASIC SEPARATION TECHNIQUES 74

Chapter Perspective 76
For Review and Reference 77
Problems 78

3 CHAPTER

Stoichiometry of Formulas and Equations 86

3.1 The Mole 87
Defining the Mole 87
Molar Mass 89
Interconverting Moles, Mass, and Number of Chemical Entities 90
Mass Percent from the Chemical Formula 93

3.2 Determining the Formula of an Unknown Compound 94
Empirical Formulas 95
Molecular Formulas 96
Chemical Formulas and Molecular Structures 99

3.3 Writing and Balancing Chemical Equations 101

3.4 Calculating Amounts of Reactant and Product 105
Stoichiometrically Equivalent Molar Ratios from the Balanced Equation 106
Chemical Reactions That Occur in a Sequence 109
Chemical Reactions That Involve a Limiting Reactant 110
Chemical Reactions in Practice: Theoretical, Actual, and Percent Yields 114

3.5 Fundamentals of Solution Stoichiometry 116
Expressing Concentration in Terms of Molarity 117
Mole-Mass-Number Conversions Involving Solutions 117
Preparing and Diluting Molar Solutions 118
Stoichiometry of Chemical Reactions in Solution 120

Chapter Perspective 122
For Review and Reference 123
Problems 125

4 CHAPTER

The Major Classes of Chemical Reactions 134

4.1 The Role of Water as a Solvent 135
The Polar Nature of Water 135
Ionic Compounds in Water 136
Covalent Compounds in Water 138

4.2 Writing Equations for Aqueous Ionic Reactions 140

4.3 Precipitation Reactions 141
The Key Event: Formation of a Solid from Dissolved Ions 141
Predicting Whether a Precipitate Will Form 142

4.4 Acid-Base Reactions 144
The Key Event: Formation of H_2O from H^+ and OH^- 145
Acid-Base Titrations 146
Proton Transfer: A Closer Look at Acid-Base Reactions 148

4.5 Oxidation-Reduction (Redox) Reactions 150
The Key Event: Movement of Electrons Between Reactants 150
Some Essential Redox Terminology 151
Using Oxidation Numbers to Monitor the Movement of Electron Charge 151
Balancing Redox Equations 154
Redox Titrations 155

4.6 Elements in Redox Reactions 158

4.7 Reversible Reactions: An Introduction to Chemical Equilibrium 165

Chapter Perspective 167
For Review and Reference 167
Problems 169

5 CHAPTER

Gases and the Kinetic-Molecular Theory 176

5.1 An Overview of the Physical States of Matter 177

5.2 Gas Pressure and Its Measurement 179
Laboratory Devices for Measuring Gas Pressure 179
Units of Pressure 181

5.3 The Gas Laws and Their Experimental Foundations 183
The Relationship Between Volume and Pressure: Boyle's Law 183
The Relationship Between Volume and Temperature: Charles's Law 184
The Relationship Between Volume and Amount: Avogadro's Law 186
Gas Behavior at Standard Conditions 187
The Ideal Gas Law 188
Solving Gas Law Problems 189

5.4 Further Applications of the Ideal Gas Law 193
The Density of a Gas 193
The Molar Mass of a Gas 194
The Partial Pressure of a Gas in a Mixture of Gases 195

5.5 The Ideal Gas Law and Reaction Stoichiometry 198

5.6 The Kinetic-Molecular Theory: A Model for Gas Behavior 200
How the Kinetic-Molecular Theory Explains the Gas Laws 200
Effusion and Diffusion 205
The Chaotic World of Gases: Mean Free Path and Collision Frequency 206

Chemical Connections to Planetary Science: STRUCTURE AND COMPOSITION OF EARTH'S ATMOSPHERE 207

5.7 Real Gases: Deviations from Ideal Behavior 210
Effects of Extreme Conditions on Gas Behavior 210
The van der Waals Equation: The Ideal Gas Law Redesigned 212

Chapter Perspective 213
For Review and Reference 213
Problems 216

6 CHAPTER

Thermochemistry: Energy Flow and Chemical Change 224

6.1 Forms of Energy and Their Interconversion 225
The System and Its Surroundings 225
Energy Flow to and from a System 226
Heat and Work: Two Forms of Energy Transfer 227
The Law of Energy Conservation 229
Units of Energy 229
State Functions and the Path Independence of the Energy Change 230

6.2 Enthalpy: Heats of Reaction and Chemical Change 232
The Meaning of Enthalpy 232
Comparing ΔE and ΔH 232
Exothermic and Endothermic Processes 233
Some Important Types of Enthalpy Change 234

6.3 Calorimetry: Laboratory Measurement of Heats of Reaction 235
Specific Heat Capacity 235
The Practice of Calorimetry 236

6.4 Stoichiometry of Thermochemical Equations 238

6.5 Hess's Law of Heat Summation 240

6.6 Standard Heats of Reaction (ΔH^0_{rxn}) 242
Formation Equations and Their Standard Enthalpy Changes 242
Determining ΔH^0_{rxn} from ΔH^0_f Values of Reactants and Products 243

Chemical Connections to Environmental Science: THE FUTURE OF ENERGY USE 245

Chapter Perspective 248
For Review and Reference 248
Problems 250

7 CHAPTER

Quantum Theory and Atomic Structure 256

7.1 The Nature of Light 257
The Wave Nature of Light 258
The Particle Nature of Light 262

7.2 Atomic Spectra 264
The Bohr Model of the Hydrogen Atom 265
The Energy States of the Hydrogen Atom 266

Tools of the Laboratory: SPECTROPHOTOMETRY IN CHEMICAL ANALYSIS 269

7.3 The Wave-Particle Duality of Matter and Energy 271
The Wave Nature of Electrons and the Particle Nature of Photons 271
The Heisenberg Uncertainty Principle 274

7.4 The Quantum-Mechanical Model of the Atom 275
The Atomic Orbital and the Probable Location of the Electron 275
Quantum Numbers of an Atomic Orbital 277
Shapes of Atomic Orbitals 280
Energy Levels of the Hydrogen Atom 283

Chapter Perspective 283
For Review and Reference 283
Problems 285

8 CHAPTER

Electron Configuration and Chemical Periodicity 290

8.1 Development of the Periodic Table 291

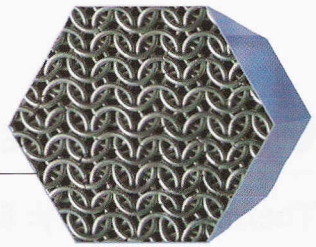
8.2 Characteristics of Many-Electron Atoms 292
The Electron-Spin Quantum Number 292
The Exclusion Principle 293
Electrostatic Effects and Energy-Level Splitting 294

8.3 The Quantum-Mechanical Model and the Periodic Table 296
Building Up Periods 1 and 2 296
Building Up Period 3 298
Electron Configurations Within Groups 300
The First *d*-Orbital Transition Series: Building Up Period 4 300
General Principles of Electron Configurations 302
Unusual Configurations: Transition and Inner Transition Elements 303

8.4 Trends in Three Key Atomic Properties 305
Trends in Atomic Size 305
Trends in Ionization Energy 309
Trends in Electron Affinity 312

8.5 Atomic Structure and Chemical Reactivity 313
Trends in Metallic Behavior 313
Properties of Monatomic Ions 316

Chapter Perspective 322
For Review and Reference 322
Problems 324



9 CHAPTER

Models of Chemical Bonding 328

9.1 Atomic Properties and Chemical Bonds 329
The Three Types of Chemical Bonding 329
Lewis Electron-Dot Symbols: Depicting Atoms in Chemical Bonding 331

9.2 The Ionic Bonding Model 332
Energy Considerations in Ionic Bonding: The Importance of Lattice Energy 333
Periodic Trends in Lattice Energy 335
How the Model Explains the Properties of Ionic Compounds 337

9.3 The Covalent Bonding Model 339
The Formation of a Covalent Bond 339
Properties of a Covalent Bond: Bond Energy and Bond Length 341
How the Model Explains the Properties of Covalent Substances 343

Tools of the Laboratory: INFRARED SPECTROSCOPY 345

9.4 Bond Energy and Chemical Change 347
Changes in Bond Strength: Where Does ΔH^{0}_{rxn} Come From? 347
Using Bond Energies to Calculate ΔH^{0}_{rxn} 347
Relative Bond Strengths in Fuels and Foods 350

9.5 Between the Extremes: Electronegativity and Bond Polarity 351
Electronegativity 351
Polar Covalent Bonds and Bond Polarity 353
The Partial Ionic Character of Polar Covalent Bonds 354
The Continuum of Bonding Across a Period 355

9.6 An Introduction to Metallic Bonding 357
The Electron-Sea Model 357
How the Model Explains the Properties of Metals 358

Chapter Perspective 360
For Review and Reference 360
Problems 361

10 CHAPTER

The Shapes of Molecules 365

10.1 Depicting Molecules and Ions with Lewis Structures 366
Using the Octet Rule to Write Lewis Structures 366
Resonance: Delocalized Electron-Pair Bonding 369
Formal Charge: Selecting the More Important Resonance Structure 371
Lewis Structures for Exceptions to the Octet Rule 372

10.2 Valence-Shell Electron-Pair Repulsion (VSEPR) Theory and Molecular Shape 375
Electron-Group Arrangements and Molecular Shapes 376
The Molecular Shape with Two Electron Groups (Linear Arrangement) 377
Molecular Shapes with Three Electron Groups (Trigonal Planar Arrangement) 377
Molecular Shapes with Four Electron Groups (Tetrahedral Arrangement) 378
Molecular Shapes with Five Electron Groups (Trigonal Bipyramidal Arrangement) 380
Molecular Shapes with Six Electron Groups (Octahedral Arrangement) 381
Using VSEPR Theory to Determine Molecular Shape 383
Molecular Shapes with More Than One Central Atom 384

Gallery: MOLECULAR BEAUTY: ODD SHAPES WITH USEFUL FUNCTIONS 386

10.3 Molecular Shape and Molecular Polarity 387
Bond Polarity, Bond Angle, and Dipole Moment 387
The Effect of Molecular Polarity on Behavior 389

Chapter Perspective 389

Chemical Connections to Sensory Physiology: MOLECULAR SHAPE, BIOLOGICAL RECEPTORS, AND THE SENSE OF SMELL 390

For Review and Reference 392
Problems 393

11 CHAPTER

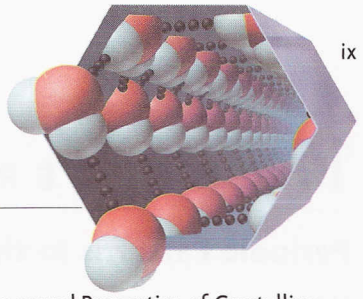
Theories of Covalent Bonding 398

11.1 Valence Bond (VB) Theory and Orbital Hybridization 399
The Central Themes of VB Theory 399
Types of Hybrid Orbitals 400

11.2 The Mode of Orbital Overlap and the Types of Covalent Bonds 406
Orbital Overlap in Single and Multiple Bonds 406
Orbital Overlap and Molecular Rotation 409

11.3 Molecular Orbital (MO) Theory and Electron Delocalization 409
The Central Themes of MO Theory 410
Homonuclear Diatomic Molecules of the Period 2 Elements 412
MO Description of Some Heteronuclear Diatomic Molecules 417
MO Descriptions of Benzene and Ozone 418

Chapter Perspective 419
For Review and Reference 419
Problems 421



12 CHAPTER

Intermolecular Forces: Liquids, Solids, and Phase Changes 424

12.1 An Overview of Physical States and Phase Changes 425

12.2 Quantitative Aspects of Phase Changes 428
Heat Involved in Phase Changes: A Kinetic-Molecular Approach 428
The Equilibrium Nature of Phase Changes 430
Phase Diagrams: Effect of Pressure and Temperature on Physical State 434

12.3 Types of Intermolecular Forces 436
Ion-Dipole Forces 437
Dipole-Dipole Forces 438
The Hydrogen Bond 439
Polarizability and Charge-Induced Dipole Forces 440
Dispersion (London) Forces 441

12.4 Properties of the Liquid State 443
Surface Tension 443
Capillarity 444
Viscosity 445

Gallery: PROPERTIES OF LIQUIDS 446

12.5 The Uniqueness of Water 445
Solvent Properties of Water 447
Thermal Properties of Water 447
Surface Properties of Water 447
The Density of Solid and Liquid Water 448

12.6 The Solid State: Structure, Properties, and Bonding 449
Structural Features of Solids 449

Tools of the Laboratory: X-RAY DIFFRACTION ANALYSIS AND SCANNING TUNNELING MICROSCOPY 455
Types and Properties of Crystalline Solids 456
Amorphous Solids 460
Bonding in Solids: Molecular Orbital Band Theory 460

12.7 Advanced Materials 464
Electronic Materials 464
Liquid Crystals 466
Ceramic Materials 469
Polymeric Materials 472
Nanotechnology: Designing Materials Atom by Atom 477

Chapter Perspective 479
For Review and Reference 480
Problems 481

13 CHAPTER

The Properties of Mixtures: Solutions and Colloids 488

13.1 Types of Solutions: Intermolecular Forces and Predicting Solubility 490
Intermolecular Forces in Solution 490
Liquid Solutions and the Role of Molecular Polarity 491
Gas Solutions and Solid Solutions 494

13.2 Intermolecular Forces and Biological Macromolecules 495
The Structure of Proteins 495
The Structure of the Cell Membrane 498
The Structure of DNA 500
The Structure of Cellulose 501

13.3 Why Substances Dissolve: Understanding the Solution Process 502
Heats of Solution and Solution Cycles 502
Heats of Hydration: Ionic Solids in Water 503
The Solution Process and the Change in Entropy 505

13.4 Solubility as an Equilibrium Process 507
Effect of Temperature on Solubility 508
Effect of Pressure on Solubility 509

13.5 Quantitative Ways of Expressing Concentration 510
Molarity and Molality 510
Parts of Solute by Parts of Solution 512
Interconverting Concentration Terms 514

13.6 Colligative Properties of Solutions 515
Colligative Properties of Nonvolatile Nonelectrolyte Solutions 516

Gallery: COLLIGATIVE PROPERTIES IN INDUSTRY AND BIOLOGY 521
Using Colligative Properties to Find Solute Molar Mass 523
Colligative Properties of Volatile Nonelectrolyte Solutions 524
Colligative Properties of Strong Electrolyte Solutions 525

13.7 The Structure and Properties of Colloids 527

Chemical Connections to Sanitary Engineering: SOLUTIONS AND COLLOIDS IN WATER PURIFICATION 529

Chapter Perspective 531
For Review and Reference 531
Problems 534

INTERCHAPTER

A Perspective on the Properties of the Elements 541

Topic 1 The Key Atomic Properties 542

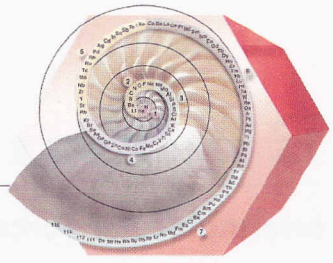
Topic 2 Characteristics of Chemical Bonding 544

Topic 3 Metallic Behavior 546

Topic 4 Acid-Base Behavior of the Element Oxides 547

Topic 5 Redox Behavior of the Elements 548

Topic 6 Physical States and Phase Changes 550



14 CHAPTER

Periodic Patterns in the Main-Group Elements 552

14.1 Hydrogen, the Simplest Atom 553
Where Does Hydrogen Fit in the Periodic Table? 553
Highlights of Hydrogen Chemistry 554

14.2 Trends Across the Periodic Table: The Period 2 Elements 555

14.3 Group 1A(1): The Alkali Metals 558
Why Are the Alkakli Metals Soft, Low Melting, and Lightweight? 558
Why Are the Alkali Metals So Reactive? 558
The Anomalous Behavior of Lithium 559

14.4 Group 2A(2): The Alkaline Earth Metals 562
How Do the Physical Properties of the Alkaline Earth and Alkali Metals Compare? 562
How Do the Chemical Properties of the Alkaline Earth and Alkali Metals Compare? 562
The Anomalous Behavior of Beryllium 563
Diagonal Relationships: Lithium and Magnesium 563
Looking Backward and Forward: Groups 1A(1), 2A(2), and 3A(13) 563

14.5 Group 3A(13): The Boron Family 566
How Do the Transition Elements Influence Group 3A(13) Properties? 566
What New Features Appear in the Chemical Properties of Group 3A(13)? 566
Highlights of Boron Chemistry 570
Diagonal Relationships: Beryllium and Aluminum 572

14.6 Group 4A(14): The Carbon Family 572
How Does the Bonding in an Element Affect Physical Properties? 572
How Does the Type of Bonding Change in Group 4A(14) Compounds? 576
Highlights of Carbon Chemistry 576
Highlights of Silicon Chemistry 578
Diagonal Relationships: Boron and Silicon 579
Looking Backward and Forward: Groups 3A(13), 4A(14), and 5A(15) 579

Gallery: SILICATE MINERALS AND SILICONE POLYMERS 580

14.7 Group 5A(15): The Nitrogen Family 583
What Accounts for the Wide Range of Physical Behavior in Group 5A(15)? 583
What Patterns Appear in the Chemical Behavior of Group 5A(15)? 586
Highlights of Nitrogen Chemistry 587
Highlights of Phosphorus Chemistry: Oxides and Oxoacids 590

14.8 Group 6A(16): The Oxygen Family 591
How Do the Oxygen and Nitrogen Families Compare Physically? 591
How Do the Oxygen and Nitrogen Families Compare Chemically? 594
Highlights of Oxygen Chemistry: Range of Oxide Properties 596
Highlights of Sulfur Chemistry: Oxides, Oxoacids, and Sulfides 596
Looking Backward and Forward: Groups 5A(15), 6A(16), and 7A(17) 598

14.9 Group 7A(17): The Halogens 598
What Accounts for the Regular Changes in the Halogens' Physical Properties? 598
Why Are the Halogens So Reactive? 598
Highlights of Halogen Chemistry 602

14.10 Group 8A(18): The Noble Gases 605
How Can Noble Gases Form Compounds? 605
Looking Backward and Forward: Groups 7A(17), 8A(18), and 1A(1) 605

Chapter Perspective 607
For Review and Reference 607
Problems 608

15 CHAPTER

Organic Compounds and the Atomic Properties of Carbon 616

15.1 The Special Nature of Carbon and the Characteristics of Organic Molecules 617
The Structural Complexity of Organic Molecules 618
The Chemical Diversity of Organic Molecules 618

15.2 The Structures and Classes of Hydrocarbons 620
Carbon Skeletons and Hydrogen Skins 620
Alkanes: Hydrocarbons with Only Single Bonds 623
Constitutional Isomerism and the Physical Properties of Alkanes 625
Chiral Molecules and Optical Isomerism 627
Alkenes: Hydrocarbons with Double Bonds 628

Chemical Connections to Sensory Physiology: GEOMETRIC ISOMERS AND THE CHEMISTRY OF VISION 630
Alkynes: Hydrocarbons with Triple Bonds 631
Aromatic Hydrocarbons: Cyclic Molecules with Delocalized π Electrons 632
Variations on a Theme: Catenated Inorganic Hydrides 633

Tools of the Laboratory: NUCLEAR MAGNETIC RESONANCE (NMR) SPECTROSCOPY 634

15.3 Some Important Classes of Organic Reactions 634
Types of Organic Reactions 634
The Redox Process in Organic Reactions 637

15.4 Properties and Reactivities of Common Functional Groups 638
Functional Groups with Only Single Bonds 638
Functional Groups with Double Bonds 643
Functional Groups with Single and Double Bonds 645
Functional Groups with Triple Bonds 649

15.5 The Monomer-Polymer Theme I: Synthetic Macromolecules 650
Addition Polymers 651
Condensation Polymers 652

15.6 The Monomer-Polymer Theme II: Biological Macromolecules 653
Sugars and Polysaccharides 653
Amino Acids and Proteins 655
Nucleotides and Nucleic Acids 658

Chapter Perspective 661

Chemical Connections to Genetics: DNA SEQUENCING AND THE HUMAN GENOME PROJECT 662

For Review and Reference 664
Problems 666

16 CHAPTER

Kinetics: Rates and Mechanisms of Chemical Reactions 672

16.1 Factors That Influence Reaction Rate 674

16.2 Expressing the Reaction Rate 675
Average, Instantaneous, and Initial Reaction Rates 676
Expressing Rate in Terms of Reactant and Product Concentrations 678

16.3 The Rate Law and Its Components 679

Tools of the Laboratory: MEASURING REACTION RATES 680

Determining the Initial Rate 681
Reaction Order Terminology 682
Determining Reaction Orders 683
Determining the Rate Constant 685

16.4 Integrated Rate Laws: Concentration Changes over Time 686
Integrated Rate Laws for First-, Second-, and Zero-Order Reactions 686
Determining the Reaction Order from the Integrated Rate Law 688
Reaction Half-Life 689

16.5 The Effect of Temperature on Reaction Rate 692

16.6 Explaining the Effects of Concentration and Temperature 694
Collision Theory: Basis of the Rate Law 694
Transition State Theory: Molecular Nature of the Activated Complex 697

16.7 Reaction Mechanisms: Steps in the Overall Reaction 700
Elementary Reactions and Molecularity 701
The Rate-Determining Step of a Reaction Mechanism 702
Correlating the Mechanism with the Rate Law 703

16.8 Catalysis: Speeding Up a Chemical Reaction 706
Homogeneous Catalysis 707
Heterogeneous Catalysis 708

Chemical Connections to Enzymology: KINETICS AND FUNCTION OF BIOLOGICAL CATALYSTS 709

Chemical Connections to Atmospheric Science: DEPLETION OF THE EARTH'S OZONE LAYER 711

Chapter Perspective 712
For Review and Reference 712
Problems 714

17 CHAPTER

Equilibrium: The Extent of Chemical Reactions 722

17.1 The Equilibrium State and the Equilibrium Constant 723

17.2 The Reaction Quotient and the Equilibrium Constant 726
Writing the Reaction Quotient 727
Variations in the Form of the Reaction Quotient 728

17.3 Expressing Equilibria with Pressure Terms: Relation Between K_c and K_p 733

17.4 Reaction Direction: Comparing Q and K 734

17.5 How to Solve Equilibrium Problems 736
Using Quantities to Determine the Equilibrium Constant 736
Using the Equilibrium Constant to Determine Quantities 739
Mixtures of Reactants and Products: Determining Reaction Direction 743

17.6 Reaction Conditions and the Equilibrium State: Le Châtelier's Principle 745
The Effect of a Change in Concentration 746
The Effect of a Change in Pressure (Volume) 748
The Effect of a Change in Temperature 750
The Lack of Effect of a Catalyst 752

Chemical Connections to Cellular Metabolism: DESIGN AND CONTROL OF A METABOLIC PATHWAY 754

Chemical Connections to Industrial Production: THE HABER PROCESS FOR THE SYNTHESIS OF AMMONIA 755

Chapter Perspective 756
For Review and Reference 757
Problems 759

18 CHAPTER

Acid-Base Equilibria 766

18.1 Acids and Bases in Water 768
Release of H^+ or OH^- and the Classical Acid-Base Definition 768
Variation in Acid Strength: The Acid-Dissociation Constant (K_a) 769
Classifying the Relative Strengths of Acids and Bases 772

18.2 Autoionization of Water and the pH Scale 773
The Equilibrium Nature of Autoionization: The Ion-Product Constant for Water (K_w) 773
Expressing the Hydronium Ion Concentration: The pH Scale 775

18.3 Proton Transfer and the Brønsted-Lowry Acid-Base Definition 777
The Conjugate Acid-Base Pair 778
Relative Acid-Base Strength and the Net Direction of Reaction 780

18.4 Solving Problems Involving Weak-Acid Equilibria 782
Finding K_a Given a Concentration 783
Finding Concentration Given K_a 784
The Effect of Concentration on the Extent of Acid Dissociation 785
The Behavior of Polyprotic Acids 786

18.5 Weak Bases and Their Relation to Weak Acids 788
Molecules as Weak Bases: Ammonia and the Amines 788
Anions of Weak Acids as Weak Bases 791
The Relation Between K_a and K_b of a Conjugate Acid-Base Pair 791

18.6 Molecular Properties and Acid Strength 793
Trends in Acid Strength of Nonmetal Hydrides 793
Trends in Acid Strength of Oxoacids 794
Acidity of Hydrated Metal Ions 794

18.7 Acid-Base Properties of Salt Solutions 796
Salts That Yield Neutral Solutions 796
Salts That Yield Acidic Solutions 796
Salts That Yield Basic Solutions 797
Salts of Weakly Acidic Cations and Weakly Basic Anions 798

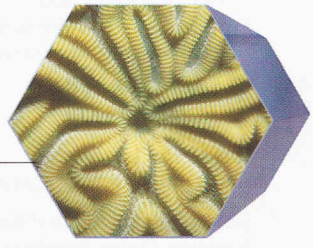
18.8 Generalizing the Brønsted-Lowry Concept: The Leveling Effect 799

18.9 Electron-Pair Donation and the Lewis Acid-Base Definition 800
Molecules as Lewis Acids 801
Metal Cations as Lewis Acids 802

Chapter Perspective 804
For Review and Reference 804
Problems 806

19 CHAPTER

Ionic Equilibria in Aqueous Systems 814



19.1 Equilibria of Acid-Base Buffer Systems 815
How a Buffer Works: The Common-Ion Effect 816
The Henderson-Hasselbalch Equation 820
Buffer Capacity and Buffer Range 821
Preparing a Buffer 822

19.2 Acid-Base Titration Curves 824
Monitoring pH with Acid-Base Indicators 824
Strong Acid–Strong Base Titration Curves 825
Weak Acid–Strong Base Titration Curves 827
Weak Base–Strong Acid Titration Curves 830
Titration Curves for Polyprotic Acids 830
Amino Acids as Biological Polyprotic Acids 831

19.3 Equilibria of Slightly Soluble Ionic Compounds 832
The Ion-Product Expression (Q_{sp}) and the Solubility-Product Constant (K_{sp}) 833
Calculations Involving the Solubility-Product Constant 834
The Effect of a Common Ion on Solubility 837
The Effect of pH on Solubility 838

Chemical Connections to Geology: CREATION OF A LIMESTONE CAVE 840

Predicting the Formation of a Precipitate: Q_{sp} vs. K_{sp} 841

Chemical Connections to Environmental Science: THE ACID-RAIN PROBLEM 842

19.4 Equilibria Involving Complex Ions 844
Formation of Complex Ions 844
Complex Ions and the Solubility of Precipitates 846
Complex Ions of Amphoteric Hydroxides 848

19.5 Ionic Equilibria in Chemical Analysis 850
Selective Precipitation 850
Qualitative Analysis: Identifying Ions in Complex Mixtures 851

20 CHAPTER

Thermodynamics: Entropy, Free Energy, and the Direction of Chemical Reactions 863

20.1 The Second Law of Thermodynamics: Predicting Spontaneous Change 864
Limitations of the First Law of Thermodynamics 865
The Sign of ΔH Cannot Predict Spontaneous Change 866
Freedom of Particle Motion and Dispersal of Particle Energy 867
Entropy and the Number of Microstates 867
Entropy and the Second Law of Thermodynamics 870
Standard Molar Entropies and the Third Law 871

20.2 Calculating the Change in Entropy of a Reaction 875
Entropy Changes in the System: Standard Entropy of Reaction (ΔS°_{rxn}) 875
Entropy Changes in the Surroundings: The Other Part of the Total 877
The Entropy Change and the Equilibrium State 878

Chemical Connections to Biology: DO LIVING THINGS OBEY THE LAWS OF THERMODYNAMICS? 879

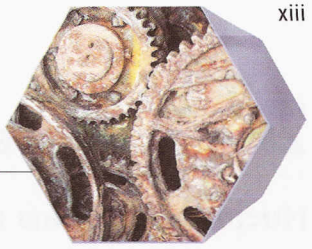
Spontaneous Exothermic and Endothermic Reactions: A Summary 880

20.3 Entropy, Free Energy, and Work 881
Free Energy Change and Reaction Spontaneity 881
Calculating Standard Free Energy Changes 882
ΔG and the Work a System Can Do 884
The Effect of Temperature on Reaction Spontaneity 886
Coupling of Reactions to Drive a Nonspontaneous Change 888

Chemical Connections to Biological Energetics: THE UNIVERSAL ROLE OF ATP 889

20.4 Free Energy, Equilibrium, and Reaction Direction 890

Chapter Perspective 894
For Review and Reference 894
Problems 896



21 CHAPTER

Electrochemistry: Chemical Change and Electrical Work 902

21.1 Redox Reactions and Electrochemical Cells 903
A Quick Review of Oxidation-Reduction Concepts 903
Half-Reaction Method for Balancing Redox Reactions 904
An Overview of Electrochemical Cells 908

21.2 Voltaic Cells: Using Spontaneous Reactions to Generate Electrical Energy 909
Construction and Operation of a Voltaic Cell 910
Notation for a Voltaic Cell 912
Why Does a Voltaic Cell Work? 913

21.3 Cell Potential: Output of a Voltaic Cell 914
Standard Cell Potentials 915
Relative Strengths of Oxidizing and Reducing Agents 917

21.4 Free Energy and Electrical Work 923
Standard Cell Potential and the Equilibrium Constant 923
The Effect of Concentration on Cell Potential 926
Changes in Potential During Cell Operation 927
Concentration Cells 928

21.5 Electrochemical Processes in Batteries 932
Primary (Nonrechargeable) Batteries 932
Secondary (Rechargeable) Batteries 933
Fuel Cells 935

21.6 Corrosion: A Case of Environmental Electrochemistry 936
The Corrosion of Iron 936
Protecting Against the Corrosion of Iron 938

21.7 Electrolytic Cells: Using Electrical Energy to Drive Nonspontaneous Reactions 939
Construction and Operation of an Electrolytic Cell 939
Predicting the Products of Electrolysis 941
The Stoichiometry of Electrolysis: The Relation Between Amounts of Charge and Product 944

Chemical Connections to Biological Energetics: CELLULAR ELECTROCHEMISTRY AND THE PRODUCTION OF ATP 947

Chapter Perspective 949
For Review and Reference 949
Problems 952

22 CHAPTER

The Elements in Nature and Industry 960

22.1 How the Elements Occur in Nature 961
Earth's Structure and the Abundance of the Elements 961
Sources of the Elements 965

22.2 The Cycling of Elements Through the Environment 966
The Carbon Cycle 966
The Nitrogen Cycle 968
The Phosphorus Cycle 970

22.3 Metallurgy: Extracting a Metal from Its Ore 973
Pretreating the Ore 973
Converting Mineral to Element 974
Refining and Alloying the Element 977

22.4 Tapping the Crust: Isolation and Uses of the Elements 978
Producing the Alkali Metals: Sodium and Potassium 978
The Indispensable Three: Iron, Copper, and Aluminum 980
Mining the Sea: Magnesium and Bromine 987
The Many Sources and Uses of Hydrogen 988

22.5 Chemical Manufacturing: Two Case Studies 992
Sulfuric Acid, the Most Important Chemical 992
The Chlor-Alkali Process 994

Chapter Perspective 996
For Review and Reference 996
Problems 997

23 CHAPTER

The Transition Elements and Their Coordination Compounds 1002

23.1 Properties of the Transition Elements 1004
Electron Configurations of the Transition Metals and Their Ions 1004
Atomic and Physical Properties of the Transition Elements 1006
Chemical Properties of the Transition Metals 1007

23.2 The Inner Transition Elements 1010
The Lanthanides 1010
The Actinides 1011

23.3 Highlights of Selected Transition Metals 1012
Chromium 1012
Manganese 1013
Silver 1014
Mercury 1016

23.4 Coordination Compounds 1017
Complex Ions: Coordination Numbers, Geometries, and Ligands 1018
Formulas and Names of Coordination Compounds 1020
A Historical Perspective: Alfred Werner and Coordination Theory 1022
Isomerism in Coordination Compounds 1023

23.5 Theoretical Basis for the Bonding and Properties of Complexes 1026
Application of Valence Bond Theory to Complex Ions 1026
Crystal Field Theory 1028

LIST OF MARGIN NOTES

This icon in the text indicates a related application, study aid, or historical note appearing in the margin.

Chapter 1
The Incredible Range of Physical Change 5
Scientific Thinker Extraordinaire [Lavoisier] 9
A Great Chemist Yet Strict Phlogistonist [Priestley] 10
Everyday Scientific Thinking 12
How Many Barleycorns from His Majesty's Nose to His Thumb? [Inexact units] 16
How Long Is a Meter? 17
Central Importance of Measurement in Science [Lord Kelvin] 25

Chapter 2
Immeasurable Changes in Mass 42
Dalton's Revival of Atomism 44
Atoms? Humbug! [Famous skeptics] 45
The Familiar Glow of Colliding Particles [Signs, aurora, and TV] 46
Naming an Element 50
The Heresy of Radioactive "Transmutation" 53

Chapter 3
Imagine a Mole of . . . [Amazing comparisons] 87
A Rose by Any Other Name [Natural product formulas] 95
Limiting Reactants in Everyday Life 111

Chapter 4
Displacement Reactions Inside You [Protein metabolism] 145
Space-Age Combustion Without a Flame [Fuel cells] 163

Chapter 5
Atmosphere-Biosphere Redox Interconnections 177
POW! P-s-s-s-t! POP! [Familiar effects of gas behavior] 178
Snowshoes and the Meaning of Pressure 179
The Mystery of the Suction Pump 180
Breathing and the Gas Laws 187
Gas Density and Human Disasters 193
Up, Up, and Away! [Hot-air balloons] 194
Preparing Nuclear Fuel 205
Danger on Molecular Highways [Molecular motion] 206

Chapter 6
Wherever You Look There Is a System 225
Thermodynamics in the Kitchen 227
The Tragic Life of the First Law's Discoverer [von Mayer] 229
Your Personal Financial State Function [Checkbook analogy] 231
Imagine an Earth Without Water [Specific heat capacity] 238

Chapter 7
Hooray for the Human Mind [Major events around 1900] 257
Electromagnetic Emissions Everywhere 259
Rainbows and Diamonds 261
Ping-Pong Photons [Analogy for photoelectric effect] 263
What Are Stars and Planets Made Of? 268
"He'll Never Make a Success of Anything" [Einstein] 271
The Electron Microscope 272
Uncertainty Is Unacceptable? [Famous skeptics] 275
A Radial Probability Distribution of Apples 277

Chapter 8
Mendeleev's Great Contribution 291
Moseley and Atomic Number 292
Baseball Quantum Numbers [Analogy with stadium seat] 293
Packing 'Em In [Nuclear charge and atomic size] 308

Chapter 9
The Remarkable Insights of G. N. Lewis 332
The Amazing Malleability of Gold 358

Chapter 10
A Purple Mule, Not a Blue Horse and a Red Donkey [Resonance hybrid] 370
Deadly Free-Radical Activity 373

Chapter 12
Environmental Flow [Solid, liquid, and gas flow] 426
A Cooling Phase Change [Sweating and panting] 427
Cooking Under Low or High Pressure 434
The Remarkable Behavior of a Supercritical Fluid (SCF) 435
A Diamond Film on Every Pot 460
Solar Cells 464
One Strand or Many Pieces? 472

Chapter 13
A Greener Approach to Working with Organic Solvents 493
Waxes for Home and Auto 495
The Hardness and Softness of Soaps 498
Hot Packs, Cold Packs, and Self-Heating Soup 505
A Saturated Solution Is Like a Pure Liquid and Its Vapor 507
Scuba Diving and Soda Pop 510
Unhealthy Ultralow Concentrations [Pollutants] 512
"Soaps" in Your Small Intestine [Bile salts] 527
From Colloid to Civilization [River deltas] 531

Chapter 14
Fill 'Er Up with Hydrogen? Not Soon 555
Versatile Magnesium 562
Lime: The Most Useful Metal Oxide 562
Gallium Arsenide: The Next Wave of Semiconductors 566
Borates in Your Labware 570
CFCs: The Good, the Bad, and the Strong 577
Hydrazine, Nitrogen's Other Hydride 586
Nitric Oxide: A Biochemical Surprise 588
The Countless Uses of Phosphates 590
Match Heads, Bug Sprays, and O-Rings 591
Selenium and Xerography 594
Hydrogen Peroxide: Hydrazine's Cousin 595
Acid from the Sky 596
HF: Unusual Structure, Familiar Uses 602
Pyrotechnic Perchlorates 604

Chapter 15
"Organic Chemistry Is Enough to Drive One Mad" [Wohler] 617
Chiral Medicines 628
Aromatic Carcinogens 633
Pollutants in the Food Chain [PCBs and DDT] 640
A Pungent, Pleasant Banquet [Carboxylic acids and esters] 647
Polysaccharide Skeletons of Lobsters and Roaches 654

Chapter 16
The Significance of *R* [Dimensional analysis] 693
Sleeping Through the Rate-Determining Step 702
Catalytically Cleaning Your Car's Exhaust 708

Chapter 17
The Universality of Le Châtelier's Principle 746
Temperature-Dependent System [Similar math expressions] 752
Catalyzed Perpetual Motion? 752

Chapter 18
Pioneers of Acid-Base Chemistry 767

Chapter 20
A Checkbook Analogy for Heating the Surroundings 877
The Greatness and Obscurity of J. Willard Gibbs 881
The Wide Range of Energy Efficiency 885

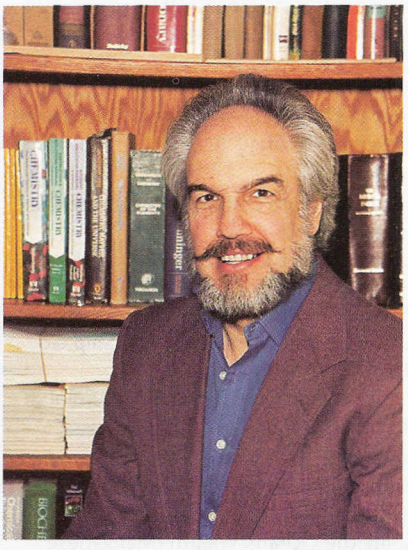
Chapter 21
The Electrochemical Future Is Here 903
Which Half-Reaction Occurs at Which Electrode? 909
Electron Flow and Water Flow 913
The Pain of a Dental Voltaic Cell 923
Walther Hermann Nernst (1864–1941) 926
Concentration Cells in Your Nerve Cells 930
Minimicroanalysis 931
Father of Electrochemistry and Much More [Michael Faraday] 945

Chapter 22
Phosphorus from Outer Space [Meteorite sources] 970
Phosphorus Nerve Poisons 972
Panning and Fleecing for Gold 974
A Plentiful Oceanic Supply of NaCl 979
Was It Slag That Made the Great Ship Go Down? [Titanic] 981
Energy Received and Returned [Aluminum batteries] 985

Chapter 23
A Remarkable Laboratory Feat [Isolating lanthanides] 1010
Sharing the Ocean's Wealth [Manganese nodules] 1014
Mad as a Hatter [Mercury poisoning] 1017
Grabbing Ions [Chelates] 1020
Anticancer Geometric Isomers 1024

Chapter 24
The Tiny, Massive Nucleus 1046
Her Brilliant Career [Marie Curie] 1047
The Little Neutral One [Neutrinos] 1049
The Case of the Shroud of Turin 1058
How Old Is the Solar System? 1059
The Powerful Bevatron 1061
Naming Transuranium Elements 1062
A Tragic Way to Tell Time in the Dark [Painting watch dials] 1063
Risk of Radon 1065
Modeling Radiation Risk 1066
The Force That Binds Us [Strong force] 1071
Lise Meitner (1878–1968) 1074
"Breeding" Nuclear Fuel 1077

About the Author and Consultants



Martin S. Silberberg received a B.S. in Chemistry from the City University of New York and a Ph.D. in Chemistry from the University of Oklahoma. He then accepted a research position in analytical biochemistry at the Albert Einstein College of Medicine in New York City, where he studied neurotransmitter metabolism in Parkinson's disease. Following his years in research, Dr. Silberberg joined the faculty of Simon's Rock College of Bard, a liberal arts college known for its excellence in teaching small classes of highly motivated students. As head of the Natural Sciences Major and Director of Premedical Studies, he taught courses in general chemistry, organic chemistry, biochemistry, and liberal-arts chemistry. The close student contact afforded him insights into how students learn chemistry, where they have difficulties, and what strategies can help them succeed. In 1983, Dr. Silberberg applied these insights in a broader context by establishing a text writing, editing, and consulting company. Before writing his own text, he worked as a consulting and development editor on chemistry, biochemistry, and physics texts for several major college publishers. He resides with his wife and son in the Pioneer Valley near Amherst, Massachusetts, where he enjoys the rich cultural and academic life of the area and relaxes by cooking, gardening, and hiking.

Dr. Silberberg is very grateful to his consultants, whose advice and insight have helped optimize this text for a variety of students from diverse learning environments.

Randy Duran is Professor of Chemistry within the Butler Polymer Laboratory and Adjunct Professor of Materials Science at the University of Florida. In addition to teaching general chemistry and advanced courses in physical and polymer chemistry, Dr. Duran directs an active research program in the area of polymer surfaces and interfaces.

Charles G. Haas, emeritus Professor of Chemistry at The Pennsylvania State University, earned his Ph.D. at the University of Chicago under the supervision of Norman Nachtrieb. During his 38-year career at Penn State, he taught general chemistry, undergraduate and graduate inorganic chemistry, and courses in chemical education for public school teachers at all levels. His research focuses on the chemistry of transition metals and coordination compounds.

Arlan D. Norman served as Professor of Chemistry and Biochemistry at the University of Colorado at Boulder, where he taught general and inorganic chemistry for 33 years, concentrating on molecular graphics, modeling, and visualization techniques. He is now founding Dean of Western Washington University's newly formed College of Sciences and Technology.

IS CHEMISTRY CHANGING?

As in any dynamic, modern science, theories in chemistry are refined to reflect new data, established ideas are applied to new systems, and connections are forged with other sciences to uncover new information. But chemistry, as the science of matter and its changes, is central to so many other sciences—physical, biological, environmental, medical, and engineering—that it must evolve continuously to enable their progress. Designing "greener" ways to make plastics, fuels, and other commodities, monitoring our atmosphere and oceans to predict the effects of their changing compositions, comprehending our genetic makeup to develop novel medicines and disease treatments, and synthesizing nanomaterials with revolutionary properties are among the countless areas in which chemistry is evolving.

Nevertheless, the basic concepts of chemistry still form the essence of the course. The mass laws and the mole concept still apply to the amounts of substances involved in a chemical reaction. Atomic properties, and the periodic trends and types of bonding derived from them, still determine molecular structure—which in turn still governs the forces between molecules and the resulting physical behavior of substances. And the central concepts within the fields of kinetics, equilibrium, and thermodynamics still account for the dynamic aspects of chemical change.

The challenge for a modern chemistry text, then, is to do two jobs at once: present the fundamental principles clearly and show how they apply to the newly emerging areas of chemistry. Like chemistry itself, the Fourth Edition of ***Chemistry: The Molecular Nature of Matter and Change*** has evolved in important ways to meet this challenge. Read on to learn how we've enhanced this edition to continue to meet the changing needs of students and instructors.

WHAT SETS THIS BOOK APART?

Respected and emulated through three editions, ***Chemistry: The Molecular Nature of Matter and Change*** has set—and then raised—the standard for general chemistry texts. And while the content has been continually updated to reflect the changing impact of chemistry in the world, the mechanisms of the text—the teaching approaches that are so admired—have remained the same. Three hallmarks make this text the market leader:

1. Visualizing chemical models—macroscopic to molecular
2. Thinking logically to solve problems
3. Applying ideas to the real world.

Visualizing Chemical Models: Macroscopic to Molecular

Because chemistry deals with observable changes in the world around us that are caused by unobservable atomic-scale events, a size gap of mind-boggling proportions must be spanned. Throughout the text, concepts are explained first at the macroscopic level and then from a molecular point of view, with the text's groundbreaking illustrations placed next to the discussion to bring the point home for today's visually oriented students.

Thinking Logically to Solve Problems

The problem-solving approach, based on a widely accepted, four-step method, is introduced in Chapter 1 and employed *consistently* throughout the text. It encourages students to first plan a logical approach to a problem, and only then proceed to solve it mathematically. The check, a step universally recommended by instructors, fosters the habit of assessing the reasonableness and magnitude of the answer. For practice and reinforcement, each worked problem is followed immediately by a similar one, for which an abbreviated solution is given at the end of the chapter.

Applying Ideas to the Real World

An understanding of modern chemistry influences a person's attitudes about public policy issues, such as climate change, health care, and agricultural methods, and also explains everyday phenomena, such as the spring in a running shoe, the display of a laptop screen, and the fragrance of a rose. Today's students may enter one of the emerging chemistry-related, hybrid fields—biomaterials science or planetary geochemistry, for example—and their text should point out the relevance of chemical concepts to such career directions. Chemical Connections, Tools of the Laboratory, Galleries, and margin notes are up-to-date pedagogic features that complement the text content.

EMBRACING CHANGE: HOW WE EVALUATED YOUR NEEDS

Just as the applications of chemistry change, so do your needs in the classroom. Martin Silberberg and McGraw-Hill listened—and responded. They invited instructors like you from across the nation—with varying teaching styles, class sizes, and student background—to provide feedback through reviews and focus groups. This feedback was then used to carefully revise and mold this new edition of ***Chemistry: The Molecular Nature of Matter and Change***,

resulting in new topic coverage, succinct and logical presentation, and expanded treatment in key areas.

WHAT'S NEW IN THE FOURTH EDITION?

Enhancements to this Edition

Annotated Instructor Edition

Created to help you optimize use of the text, the annotated edition uses the margins to cite journal articles and lecture demonstrations, to display icons for transparencies, online resources, figures and tables, worked problems, and animations that are available to you, and to show content related to other fields (biological, engineering, environmental/green chemistry, and organic chemistry), as well as to indicate the general level of difficulty of each homework problem.

Integration of Organic and Biochemistry

In response to students' strong interest in biology-related material, applications of mainstream chemical concepts to bio-organic topics are incorporated into many chapters, including new discussions in Chapters 2, 3, 13, and 15 (see below). All of these discussions are clearly identified, so they can be skipped or included as you wish.

Integration of Green Chemistry

This strong new research direction to develop substances and processes with only benign effects on the environment receives coverage, including homework problems, in Chapters 3, 6, 13, 15, and 16 (see below). These discussions are identified and can be skipped or included as you wish.

Molecular-View Sample Problems

A new type of conceptual sample problem is introduced that finally teaches students how to look at simple molecular scenes and think through qualitative and quantitative problems based on them. These 10 new exercises—five sample problems and their five follow-up problems—appear in Chapters 2, 3, 5, 13, and 17.

Electron Density Art

Striking new art based on the latest quantum-mechanical calculations depicts the distribution of electron density in covalent bonds. These illustrations appear in Chapters 7, 9, 11, 14, and 16.

End-of-Chapter Problems

Over 275 new problems appear, many at the challenging level, with applications from biology, organic chemistry, engineering, and environmental science. Several new molecular-scene problems have also been included.

In This Chapter...

At the end of its introduction, each chapter includes this short preview that orients the student to the sequence of main topics and correlates with the chapter outline.

Changes to Individual Chapters

Chapter 2 briefly introduces the naming and structures of organic compounds and discusses the elements found in living systems in the context of the periodic table.

Chapter 3 introduces isomers in terms of molecular formulas and discusses percent yield in the multistep synthesis of medicines. The green-chemistry concept of atom economy is discussed, with a sample calculation.

Chapter 4 highlights the role of water in aqueous systems and emphasizes the activity series of metals in the context of redox reactions.

Chapter 6 brings up the green chemistry of fuels and new energy sources and updates the essay on climate change and alternative energy.

Chapter 9 has been greatly improved with art and discussions that clarify the importance of covalent bonding and trends in electronegativity. Coverage of foods and fuels has been revised and moved here from Chapter 6; it now complements the full treatment of bond energy. And the essay on IR spectroscopy now includes isomers, with new art.

Chapter 12 emphasizes the universal importance of dispersion forces and summarizes all intermolecular forces with new art.

Chapter 13 includes a major new section on how intermolecular forces stabilize the structures of proteins, nucleic acids, polysaccharides, and cell membranes, with striking new art. A new margin note discusses the role of greener solvents in syntheses.

Chapter 15 includes carbon-skeleton formulas in discussions (and problems) to prepare students for organic chemistry courses. In the biopolymer section, the structural hierarchy of proteins is covered, and a unique, new essay pays homage to the remarkable achievement of the Human Genome Project by describing the chemistry of DNA sequencing.

Chapter 16 describes the transition state with new art and updates coverage of catalytic hydrogenation and ozone depletion.

Chapter 20 has been completely rewritten to reflect a new approach to the coverage of entropy. The vague notion of "disorder" (with analogies to macroscopic systems) has been replaced with the idea that entropy is related to the dispersal of a system's energy and the freedom of motion of its particles. Also clarified are the characteristics of a reversible process and the connection between free energy and equilibrium.

Chapter 21 extends the consistent method for determining cell potential and updates coverage of batteries and fuel cells.

Appendices have been greatly expanded to include extensive tables of thermodynamic and equilibrium data.

Acknowledgments

My deepest appreciation goes to all the academic and research chemists who have generously contributed their time and expertise to improving the text. Once again, I was extremely fortunate to have the meticulous eyes of Dorothy B. Kurland reviewing every chapter and each new homework problem. The following experts helped me keep specific content areas up-to-date and accurate: Ronald J. Gillespie of McMaster University for advice on the new electron-density relief maps and Michel Rafat of the University of Manchester Institute of Science and Technology for providing data for these illustrations and many useful discussions regarding them; Deborah Exton of the University of Oregon for new coverage of green chemistry; Jonathan Kurland of Dow Chemical Company for essays on fuels (Chapter 6), ozone depletion (Chapter 16), acid rain (Chapter 19), and numerous other points of industrial and atmospheric chemistry; Chad Mirkin and Sungho Park of Northwestern University for advice on nanotechnology (Chapter 12); Steven A. Soper of Louisiana State University and Bruce A. Roe of the University of Oklahoma for the new essay on DNA sequencing (Chapter 15); Frank Lambert of Occidental College for insightful advice and comments on the coverage of entropy (Chapters 13 and 20); Stewart Strickler of the University of Colorado–Boulder for in-depth help in revising the coverage of entropy and free energy (Chapters 13, 20, 21); and John Newman of the University of California/Berkeley and Perla Balbuena of the University of South Carolina for the coverage of batteries and fuel cells (Chapter 21).

Special thanks go to Rich Bauer of Arizona State University and Sue Nurrenbern of Purdue University for their helpful reviews of the new molecular sample problems and to the professors who contributed many of the excellent new homework problems: Joseph Bularzik, Sarina Ergas of the University of Massachusetts–Amherst, Rich Langley of Stephen F. Austin State University, S. Walter Orchard of Tacoma Community College, Jeanette K. Rice of Georgia Southern University, and Marcy Whitney of the University of Alabama.

Modern texts are served by a battery of supplements, and this one is very lucky to have supplement authors so committed to accuracy and clarity for student and instructor. John Pollard of the University of Arizona researched and coordinated all of the annotations that appear in the Annotated Instructor's Edition of this text. Elizabeth Bent Weberg wrote a superb *Student Study Guide*. Rich Langley of Stephen F. Austin University diligently prepared the *Instructor Solutions Manual* and *Student Solutions Manual*. S. Walter Orchard of Tacoma Community College updated the *Test Bank*. Christina Bailey of California Polytechnic University again provided the excellent PowerPoint Lecture Outlines that appear on the Digital Content Manager CD.

I am especially grateful for the support of the Board of Advisors, a select group of chemical educators dedicated to helping make this text the optimum teaching tool. The board contributed insightful comments during the revision that shaped this edition in many significant ways.

So many exceptional publishing professionals played key roles in this new edition, and I owe them my warmest gratitude. Heading the McGraw-Hill Higher Education team with their friendship and support were Editorial Director Kent Peterson and Sponsoring Editor Thomas Timp. When my previous Development Editor Joan Weber moved to other projects, she deftly passed this one into the able hands of Development Editor Donna Nemmers; Donna handled innumerable text and supplement details with her unusual mix of warmth and competence. Project Manager Peggy Selle engineered countless production details with consummate experience and skill. Senior Designer David Hash supervised the striking new design by freelancers Jamie O'Neal and Michael Goodman. And Marketing Manager Tami Hodge developed exciting new ways to present the book and supplements to the academic community.

A wonderful group of expert freelancers contributed as well. Jane Hoover did a masterful copyediting job, and Katie Aiken and Janelle Pregler followed with superb proofreading. Michael Goodman again performed his magic on in-text molecular art and the cover. And the remarkable Karen Pluemer somehow managed to coordinate all the complex interactions with publisher and freelancers, while keeping me on schedule and sane.

Finally, in far more ways than I could ever begin to say here, I am indebted to my son Daniel and wife Ruth for their love and confidence. Daniel, now 16, has become an accomplished artist, and he drafted initial designs for several key pieces of art, including the cover, before the illustrators took over. As in past editions, Ruth played numerous essential roles—laying out the student-friendly pages of text, art, and tables, collaborating on style and design, editing new text and art, checking all page proofs, and, in general, helping author and publisher maintain the highest standards of quality and consistency throughout the project.

LEARNING CHEMISTRY JUST GOT EASIER

Success starts here.

Take this guided tour for *Chemistry: The Molecular Nature of Matter and Change,* Fourth Edition, and you'll see how to get the most out of your textbook!

Chapter Opener

The opener provides a thought-provoking figure and legend that relate to a main topic of the chapter.

Concepts and Skills to Review

This unique feature helps you prepare for the upcoming chapter by referring to key material from earlier chapters that you should understand *before* you start reading this one.

A Select Few Particles of solid lead(II) iodide swirling through a sodium nitrate solution are the products of this precipitation reaction, an example of one of a handful of major reaction classes. Distinguishing the key features of these classes and learning the role of water in many of them form the focus of the chapter.

4

The Major Classes of Chemical Reactions

4.1 The Role of Water as a Solvent
Polar Nature of Water
Ionic Compounds in Water
Covalent Compounds in Water
4.2 Writing Equations for Aqueous Ionic Reactions
4.3 Precipitation Reactions
The Key Event: Formation of a Solid
Predicting Whether a Precipitate Will Form
4.4 Acid-Base Reactions
The Key Event: Formation of Water
Acid-Base Titrations
Proton Transfer in Acid-Base Reactions
4.5 Oxidation-Reduction (Redox) Reactions
The Key Event: Movement of Electrons
Redox Terminology
Oxidation Numbers
Balancing Redox Equations
Redox Titrations
4.6 Elements in Redox Reactions
4.7 Reversible Reactions: An Introduction to Chemical Equilibrium

Rapid chemical changes occur among gas molecules as sunlight bathes the atmosphere or lightning rips through a stormy sky. Aqueous reactions go on unceasingly in the gigantic containers we know as oceans. And, in every cell of your body, thousands of reactions taking place right now allow you to function. Indeed, the amazing variety in nature is largely a consequence of the amazing variety of chemical reactions.

Of the millions of chemical reactions occurring in and around you, we have examined only a tiny fraction so far, and it would be impossible to examine them all. Fortunately, it isn't necessary to catalog every reaction, because when we survey even a small percentage of reactions, a few major patterns emerge.

IN THIS CHAPTER . . . We examine the underlying nature of the three most common reaction processes. One of our main themes is aqueous reaction chemistry, so we first investigate how the molecular structure of water influences its crucial role as a solvent in these reactions. We see how to use ionic equations to describe reactions. We focus in turn on precipitation, acid-base, and oxidation-reduction reactions, examining why they occur and how to quantify them. We classify several important types of oxidation-reduction reactions that include elements as reactants or products. The chapter ends with an introductory look at the reversible nature of all reactions.

4.1 THE ROLE OF WATER AS A SOLVENT

Many reactions take place in aqueous solution, and our first step toward comprehending these reactions is to understand how water acts as a solvent. The role a solvent plays in a reaction depends on its chemical nature. Some solvents play a passive role, dispersing the dissolved substances into individual molecules but doing nothing further. Water plays a much more active role, interacting strongly with the substances and, in some cases, even reacting with them. To understand this active role, we'll examine the structure of water and how it interacts with ionic and covalent solutes.

The Polar Nature of Water

Of the many thousands of reactions that occur in the environment and in organisms, nearly all take place in water. Water's remarkable power as a solvent results from two features of its molecules: *the distribution of the bonding electrons* and *the overall shape.*

Recall from Section 2.7 that the electrons in a covalent bond are shared between the bonded atoms. In a covalent bond between identical atoms (as in H_2, Cl_2, O_2, etc.), the sharing is equal, so no imbalance of charge appears (Figure 4.1A). On the other hand, in covalent bonds between nonidentical atoms, the sharing is unequal: one atom attracts the electron pair more strongly than the other. For reasons discussed in Chapter 9, an O atom attracts electrons more strongly than an H atom. Therefore, in each O—H bond in water, the shared electrons spend more time closer to the O atom (Figure 4.1B).

This unequal distribution of negative charge creates partially charged "poles" at the ends of each O—H bond. The O end acts as a slightly negative pole (represented by the red shading and the δ−), and the H end acts as a slightly positive pole (represented by the blue shading and the δ+). Figure 4.1C indicates the bond's polarity with a *polar arrow* (the arrowhead points to the negative pole and the tail is crossed to make a "plus").

The H—O—H arrangement forms an angle, so the water molecule is bent. The combined effects of its bent shape and its polar bonds make water a **polar molecule:** the O portion of the molecule is the partially negative pole, and the region midway between the H atoms is the partially positive pole (Figure 4.1D).

Concepts & Skills to Review
before you study this chapter

- names and formulas of compounds (Section 2.8)
- nature of ionic and covalent bonding (Section 2.7)
- mole-mass-number conversions (Section 3.1)
- molarity and mole-volume conversions (Section 3.5)
- balancing chemical equations (Section 3.3)
- calculating amounts of reactants and products (Section 3.4)

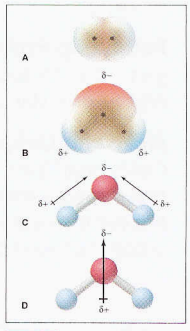

Figure 4.1 Electron distribution in molecules of H_2 and H_2O. A, In H_2, the identical nuclei attract the electrons equally. The central region of higher electron density (red) is balanced by the two outer regions of lower electron density (blue). **B,** In H_2O, the O nucleus attracts the shared electrons more strongly than the H nucleus. **C,** In this ball-and-stick model, a polar arrow points to the negative end of each O—H bond. **D,** The two polar O—H bonds and the bent shape give rise to the polar H_2O molecule.

Chapter Outline and *In This Chapter*

Each chapter begins with an outline that shows the sequence of topics and subtopics. And, at the end of the introduction, a paragraph called *In This Chapter* ties the main topics to the outline.

SOLVING PROBLEMS, STEP BY STEP

Using this clear and thorough problem-solving approach, you'll learn to think through chemistry problems logically and systematically.

Sample Problems

A worked-out problem appears whenever an important new concept or skill is introduced. The step-by-step approach is shown consistently for every sample problem in the text.

Steps

Plan
analyzes the problem so that you can use what is known to find what is unknown. This approach develops the habit of thinking through the solution *before* performing calculations.

Solution
shows the calculation steps *in the same order* as they are discussed in the plan.

Check
fosters the habit of going over your work quickly to make sure that the answer is reasonable, chemically and mathematically—a great way to avoid careless errors.

Comment
provides an additional insight, alternative approach, or common mistake to avoid.

Follow-up Problem
gives you immediate practice by presenting a similar problem.

NEW and Unique to This Text!
Conceptual (picture) problems apply this stepwise strategy to help you interpret molecular scenes and solve problems based on them.

Problem-Solving Roadmaps

are block diagrams—specific to the problem and shown alongside the Solution—that lead you visually through the needed calculation steps.

SAMPLE PROBLEM 5.2 Applying the Volume-Pressure Relationship

Problem Boyle's apprentice finds that the air trapped in a J tube occupies 24.8 cm^3 at 1.12 atm. By adding mercury to the tube, he increases the pressure on the trapped air to 2.64 atm. Assuming constant temperature, what is the new volume of air (in L)?

Plan We must find the final volume (V_2) in liters, given the initial volume (V_1), initial pressure (P_1), and final pressure (P_2). The temperature and amount of gas are fixed. We convert the units of V_1 from cm^3 to mL and then to L, rearrange the ideal gas law to the appropriate form, and solve for V_2. We can predict the direction of the change: since P increases, V will decrease; thus, $V_2 < V_1$. (Note that the roadmap has two parts.)

Solution Summarizing the gas variables:

$P_1 = 1.12$ atm $P_2 = 2.64$ atm
$V_1 = 24.8\ cm^3$ (convert to L) V_2 = unknown T and n remain constant

Converting V_1 from cm^3 to L:

$$V_1 = 24.8\ cm^3 \times \frac{1\ mL}{1\ cm^3} \times \frac{1\ L}{1000\ mL} = 0.0248\ L$$

Arranging the ideal gas law and solving for V_2: At fixed n and T, we have

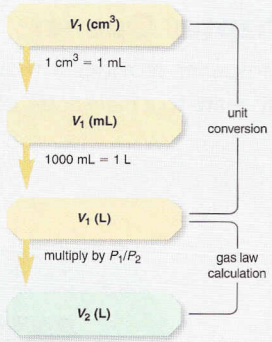
$$\frac{P_1V_1}{\cancel{nT}_1} = \frac{P_2V_2}{\cancel{nT}_2} \quad \text{or} \quad P_1V_1 = P_2V_2$$

$$V_2 = V_1 \times \frac{P_1}{P_2} = 0.0248\ L \times \frac{1.12\ atm}{2.64\ atm} = 0.0105\ L$$

Check As we predicted, $V_2 < V_1$. Let's think about the relative values of P and V as we check the math. P more than doubled, so V_2 should be less than $\frac{1}{2}V_1$ ($0.0105/0.0248 < \frac{1}{2}$).

Comment Predicting the direction of the change provides another check on the problem setup: To make $V_2 < V_1$, we must multiply V_1 by a number *less than* 1. This means the ratio of pressures must be *less than* 1, so the larger pressure (P_2) must be in the denominator, P_1/P_2.

FOLLOW-UP PROBLEM 5.2 A sample of argon gas occupies 105 mL at 0.871 atm. If the temperature remains constant, what is the volume (in L) at 26.3 kPa?

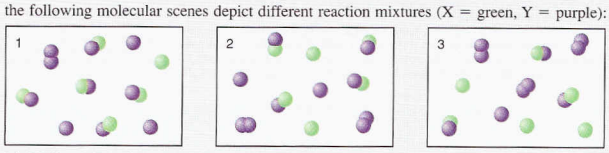


SAMPLE PROBLEM 17.14 Determining Equilibrium Parameters from Molecular Scenes

Problem For the reaction,

$$X(g) + Y_2(g) \rightleftharpoons XY(g) + Y(g) \qquad \Delta H > 0$$

the following molecular scenes depict different reaction mixtures (X = green, Y = purple):



(a) If $K_c = 2$ at the temperature of the reaction, which scene represents the mixture at equilibrium?
(b) Will the reaction mixtures in the other two scenes proceed toward reactants or toward products to reach equilibrium?
(c) For the mixture at equilibrium, how will a rise in temperature affect $[Y_2]$?

Plan **(a)** We are given the balanced equation and the value of K_c and must choose the scene representing the mixture at equilibrium. We write the expression for Q_c, and for

Brief Solutions to Follow-up Problems

5.1 P_{CO_2} (torr) = (753.6 mmHg − 174.0 mmHg) $\times \frac{1\ torr}{1\ mmHg}$
= 579.6 torr

P_{CO_2} (Pa) = 579.6 torr $\times \frac{1\ atm}{760\ torr} \times \frac{1.01325\times10^5\ Pa}{1\ atm}$
$= 7.727\times10^4$ Pa

P_{CO_2} (lb/in^2) = 579.6 torr $\times \frac{1\ atm}{760\ torr} \times \frac{14.7\ lb/in^2}{1\ atm}$
$= 11.2\ lb/in^2$

5.2 P_2 (atm) = 26.3 kPa $\times \frac{1\ atm}{101.325\ kPa} = 0.260$ atm

V_2 (L) = 105 mL $\times \frac{1\ L}{1000\ mL} \times \frac{0.871\ atm}{0.260\ atm} = 0.352$ L

5.3 T_2 (K) = 273 K $\times \frac{9.75\ cm^3}{6.83\ cm^3} = 390.$ K

5.4 P_2 (torr) = 793 torr $\times \frac{35.0\ g - 5.0\ g}{35.0\ g} = 680.$ torr

(There is no need to convert mass to moles because the ratio of masses equals the ratio of moles.)

5.5 $n = \frac{PV}{RT} = \frac{1.37\ atm \times 438\ L}{0.0821\ \frac{atm\cdot L}{mol\cdot K} \times 294\ K} = 24.9$ mol O_2

Mass (g) of O_2 = 24.9 mol $O_2 \times \frac{32.00\ g\ O_2}{1\ mol\ O_2} = 7.97\times10^2$ g O_2

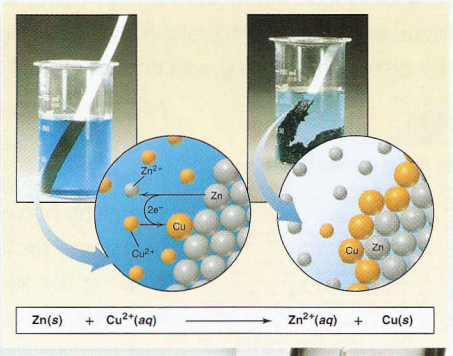
Brief Solutions to Follow-up Problems

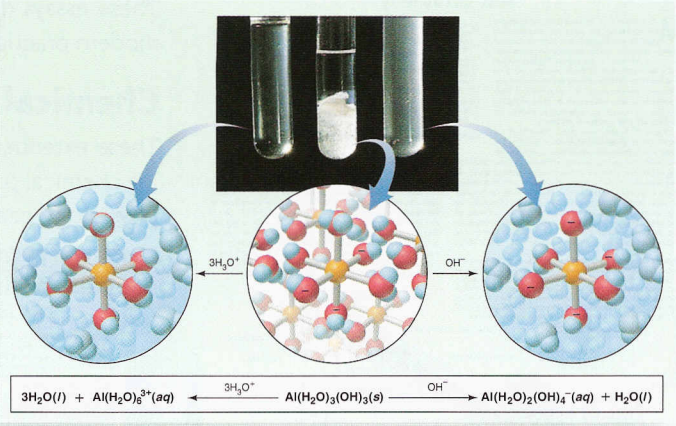
provide multistep solutions at the end of the chapter, not just a one-number answer at the back of the book. This fuller treatment is an excellent way for you to reinforce your problem-solving skills.

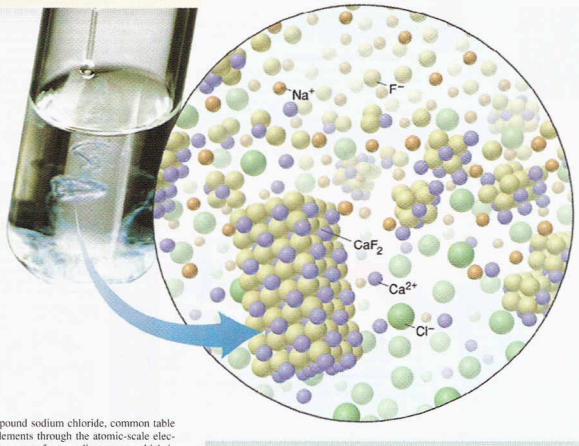
DESIGNED TO HELP YOU "SEE" CHEMISTRY

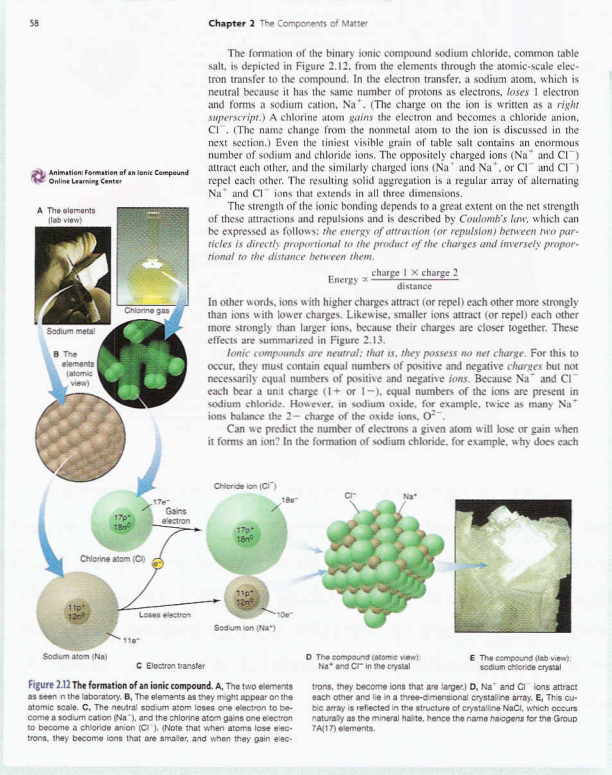
Three-Level Illustrations

A Silberberg hallmark, these illustrations provide macroscopic and molecular views of a process that help you connect these two levels of reality with each other and with the chemical equation that describes the process in symbols.









58

Chapter 2 The Components of Matter

The formation of the binary ionic compound sodium chloride, common table salt, is depicted in Figure 2.12, from the elements through the atomic-scale electron transfer to the compound. In the electron transfer, a sodium atom, which is neutral because it has the same number of protons as electrons, *loses* 1 electron and forms a sodium cation, Na^+. (The charge on the ion is written as a *right superscript*.) A chlorine atom *gains* the electron and becomes a chloride anion, Cl^-. (The name change from the nonmetal atom to the ion is discussed in the next section.) Even the tiniest visible grain of table salt contains an enormous number of sodium and chloride ions. The oppositely charged ions (Na^+ and Cl^-) attract each other, and the similarly charged ions (Na^+ and Na^+, or Cl^- and Cl^-) repel each other. The resulting solid aggregation is a regular array of alternating Na^+ and Cl^- ions that extends in all three dimensions.

The strength of the ionic bonding depends to a great extent on the net strength of these attractions and repulsions and is described by *Coulomb's law*, which can be expressed as follows: *the energy of attraction (or repulsion) between two particles is directly proportional to the product of the charges and inversely proportional to the distance between them.*

$$\text{Energy} = \frac{\text{charge 1} \times \text{charge 2}}{\text{distance}}$$

In other words, ions with higher charges attract (or repel) each other more strongly than ions with lower charges. Likewise, smaller ions attract (or repel) each other more strongly than larger ions, because their charges are closer together. These effects are summarized in Figure 2.13.

Ionic compounds are neutral; that is, they possess no net charge. For this to occur, they must contain equal numbers of positive and negative *charges* but not necessarily equal numbers of positive and negative *ions*. Because Na^+ and Cl^- each bear a unit charge (1+ or 1−), equal numbers of the ions are present in sodium chloride. However, in sodium oxide, for example, twice as many Na^+ ions balance the 2− charge of the oxide ions, O^{2-}.

Can we predict the number of electrons a given atom will lose or gain when it forms an ion? In the formation of sodium chloride, for example, why does each

A, The two elements as seen in the laboratory. **B,** The elements as they might appear on the atomic scale. **C,** The neutral sodium atom loses one electron to become a sodium cation (Na^+), and the chlorine atom gains one electron to become a chloride anion (Cl^-). (Note that when atoms lose electrons, they become ions that are smaller, and when they gain electrons, they become ions that are larger.) **D,** Na^+ and Cl^- ions attract each other and lie in a three-dimensional crystalline array. **E,** This cubic array is reflected in the structure of crystalline NaCl, which occurs naturally as the mineral halite, hence the name *halogens* for the Group 7A(17) elements.

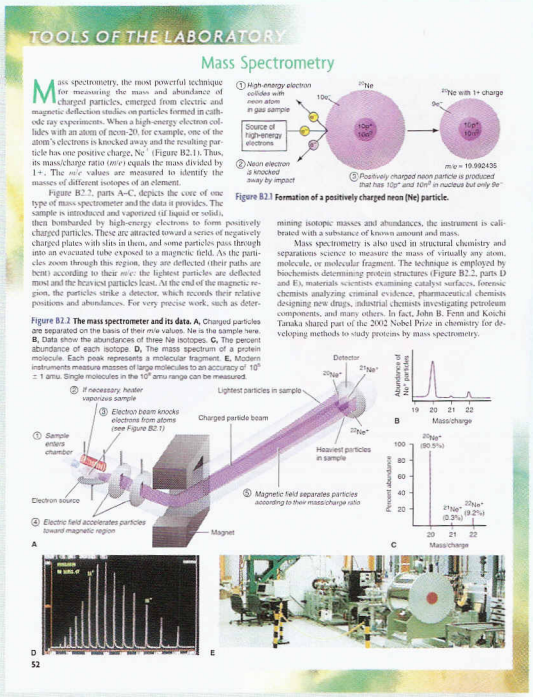
Cutting-Edge Molecular Models

Author and artist worked side by side and employed the most advanced computer-graphic software to provide accurate molecular-scale models and vivid scenes. Included in the Fourth Edition are many new pieces of molecular art as well as newly designed electron-density illustrations.

Page Layout

Author and pager collaborated on page layout to ensure that all figures and tables are as close as possible to their related text. In some cases, art is wrapped by text so that you can read about concepts and see them depicted simultaneously.

MAKING CHEMISTRY "REAL" THROUGH MODERN APPLICATIONS



TOOLS OF THE LABORATORY

Mass Spectrometry

Mass spectrometry, the most powerful technique for measuring the mass and abundance of charged particles, emerged from electric and magnetic deflection studies on particles formed in cathode ray experiments. When a high-energy electron collides with an atom of neon-20, for example, one of the atom's electrons is knocked away and the resulting particle has one positive charge, Ne^+ (Figure B2.1). Thus, its mass/charge ratio (m/e) equals the mass divided by 1+. The m/e values are measured to identify the masses of different isotopes of an element.

Figure B2.2, parts A–C, depicts the core of one type of mass spectrometer and the data it provides. The sample is introduced and vaporized (if liquid or solid), then bombarded by high-energy electrons to form positively charged particles. These are attracted toward a series of negatively charged plates with slits in them, and some particles pass through into an evacuated tube exposed to a magnetic field. As the particles zoom through this region, they are deflected (their paths are bent) according to their m/e: the lightest particles are deflected most and the heaviest particles least. At the end of the magnetic region, the particles strike a detector, which records their relative positions and abundances. For very precise work, such as determining isotopic masses and abundances, the instrument is calibrated with a substance of known amount and mass.

Mass spectrometry is also used in structural chemistry and separations science to measure the mass of virtually any atom, molecule, or molecular fragment. The technique is employed by biochemists determining protein structures (Figure B2.2, parts D and E), materials scientists examining catalyst surfaces, forensic chemists analyzing criminal evidence, pharmaceutical chemists designing new drugs, industrial chemists investigating petroleum components, and many others. In fact, John B. Fenn and Koichi Tanaka shared part of the 2002 Nobel Prize in chemistry for developing methods to study proteins by mass spectrometry.

Figure B2.2 The mass spectrometer and its data. A, Charged particles are separated on the basis of their m/e values. Ne is the sample here. B, Data show the abundances of three Ne isotopes. C, The percent abundance of each isotope. D, The mass spectrum of a protein molecule. Each peak represents a molecular fragment. E, Modern instruments measure masses of large molecules to an accuracy of 10^{-5} ± 1 amu. Single molecules in the 10^6 amu range can be measured.

Figure B2.3 Formation of a positively charged neon (Ne) particle.

52

Tools of the Laboratory

These essays describe the key instruments and techniques that chemists use in modern practice to obtain the data that underlie their theories.

Chemical Connections

These extended essays show the interdisciplinary nature of chemistry by applying chemical principles discussed in the text to related scientific fields, including physiology, geology, biochemistry, engineering, and environmental science.

CHEMICAL CONNECTIONS to Genetics

DNA Sequencing and the Human Genome Project

As a result of one of the most remarkable scientific achievements in modern times, we now know our complete genetic makeup, the sequence of the 3 billion nucleotide base pairs in the DNA of the entire human genome! The potential benefits for medical science and for an understanding of our relationship with other creatures are profound.

As is true of so many large scientific endeavors, the Human Genome Project (www.genome.gov) began as a vision of forward-thinking scientists meeting at a conference—in 1986, at the Cold Spring Harbor Symposium in New York. In 1988, after much debate over feasibility—and even advisability—the U.S. Congress funded the $3-billion, 15-year program. Government scientists worked independently of, but in parallel with, private researchers at Celera Genomics, and in early 2003, the project was completed.

Central to this accomplishment is *DNA sequencing*, the process used to determine the identity and order of bases. Sequencing is an indispensable tool in molecular biology and biochemical genetics research. The process usually begins with a series of enzymatic and cloning steps to prepare the sample, but we will focus on the chemical steps that yield the final result.

An Overview of DNA Sequencing

The genome consists of DNA molecules; segments of their chains are the genes, the functional units of heredity. The DNA exists in each cell's nucleus as tightly coiled threads arranged, in the human, into 23 pairs of chromosomes (Figure B15.6). A given chromosome may have 100 million nucleotide bases, but the sequencing process can handle, at one time, DNA fragments only about 2000 bases long. Therefore, the chromosome is first broken into pieces by enzymes that cleave at specific sites. Then, through a variety of "amplification" methods, many copies of the individual DNA "target" fragments are made. After each target fragment has been sequenced, the data are interpreted to give a continuous sequence that represents the structure of the entire chromosome.

Steps in the Sequencing

Once a DNA target fragment is prepared, either of two methods are used to sequence it. We'll introduce the first and detail the second because it is much more common today.

1. *The Maxam-Gilbert chemical cleavage method* uses chemical reactions to break the DNA at specific locations. The total amount of the DNA target fragment is divided into four samples, and each is labeled with phosphorus-32, a radioactive "tag" that will make the final product easy to visualize. Each of the four samples is treated with reactants under conditions of temperature, concentration, and acidity that will cleave the DNA in characteristic ways. For instance, dimethylsulfate ($CH_3OSO_2OCH_3$) followed by heating cleaves the chain at a guanine (G). The cleavage products in each tube are then separated by size (length) through gel electrophoresis (discussed below). Photographic film placed on the gel is exposed by the radioactive tags in the cleavage products. The result is a series of dark bands, from which the sequence of the original DNA target fragment is determined.

2. *The Sanger chain-termination method* uses chemically altered bases to stop the growth of a complementary DNA chain at specific locations. As you've seen, the chain consists of linked 2′-deoxyribonucleoside monophosphate units (dNMP, where N represents A, T, G, or C). The link is a phosphodiester bond from the 3′-OH of one unit to the 5′-OH of the next. The free monomers used to construct the chain are 2′-deoxyribonucleoside triphosphates (dNTP). The Sanger method uses a modified monomer, called a dideoxyribonucleoside triphosphate (ddNTP), in which the 3′-OH group is also missing from the ribose unit (Figure B15.7). As soon as the ddNTP is incorporated into the growing chain,

Figure B15.6 DNA, the genetic material. In the cell nucleus, each chromosome consists of a DNA molecule wrapped around globular proteins called histones. Segments of the DNA chains are genes.

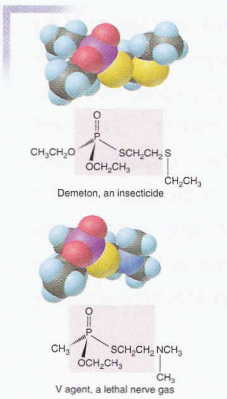
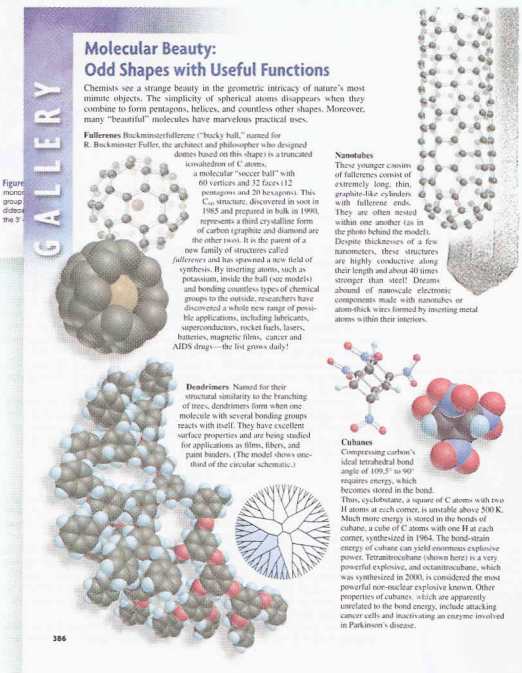
NEW and Unique to this Text!
In Chapter 15, a Chemical Connections essay describes the chemistry behind the groundbreaking achievement of elucidating the sequence of the human genome.



Demeton, an insecticide

V agent, a lethal nerve gas

Phosphorus Nerve Poisons Because phosphorus is essential for all organisms, its compounds have many biological actions. In addition to their widespread use as fertilizers, phosphorus compounds are also used as pesticides *and* as military nerve gases. In fact, these two types of substances often have similar structures (see above) and modes of action. Both types affect the target organism by inactivating an enzyme involved in muscle contraction. They bind an amino acid critical to the enzyme's function, allowing the muscle to contract but not relax; the effect on the organism—insect or human—is often fatal. Chemists have synthesized a nerve-gas antidote whose shape mimics the binding site of the enzyme. The drug binds the poison, removing it from the enzyme, and is excreted.



GALLERY

Molecular Beauty: Odd Shapes with Useful Functions

Chemists see a strange beauty in the geometric intricacy of nature's most minute objects. The simplicity of spherical atoms disappears when they combine to form pentagons, helices, and countless other shapes. Moreover, many "beautiful" molecules have marvelous practical uses.

Fullerenes Buckminsterfullerene ("bucky ball," named for R. Buckminster Fuller, the architect and philosopher who designed domes based on this shape) is a truncated icosahedron of C atoms, a molecular "soccer ball" with 60 vertices and 32 faces (12 pentagons and 20 hexagons). This C_{60} structure, discovered in soot in 1985 and prepared in bulk in 1990, represents a third crystalline form of carbon (graphite and diamond are the other two). It is the parent of a new family of structures called *fullerenes* and has spawned a new field of synthesis. By inserting atoms, such as potassium, inside the ball (see models) and bonding countless types of chemical groups to the outside, researchers have discovered a whole new range of possible applications, including lubricants, superconductors, rocket fuels, lasers, batteries, magnetic films, cancer and AIDS drugs—the list grows daily!

Nanotubes These younger cousins of fullerenes consist of extremely long, thin, graphite-like cylinders with fullerene ends. They are often nested within one another (as in the photo behind the models). Despite thicknesses of a few nanometers, these structures are highly conductive along their length and about 40 times stronger than steel! Dreams abound of nanoscale electronic components made with nanotubes or atom-thick wires formed by inserting metal atoms within their interiors.

Dendrimers Named for their structural similarity to the branching of trees, dendrimers form when one molecule with several bonding groups reacts with itself. They have excellent surface properties and are being studied for applications as films, fibers, and paint binders. (The model shows one-third of the circular schematic.)

Cubanes Compressing carbon's ideal tetrahedral bond angle of 109.5° to 90° requires energy, which becomes stored in the bond. Thus, cyclobutane, a square of C atoms with two H atoms at each corner, is unstable above 500 K. Much more energy is stored in the bonds of cubane, a cube of C atoms with one H at each corner, synthesized in 1964. The bond-strain energy of cubane can yield enormous explosive power. Tetranitrocubane (shown here) is a very powerful explosive, and octanitrocubane, which was synthesized in 2000, is considered the most powerful non-nuclear explosive known. Other properties of cubanes, which are apparently unrelated to the bond energy, include attacking cancer cells and inactivating an enzyme involved in Parkinson's disease.

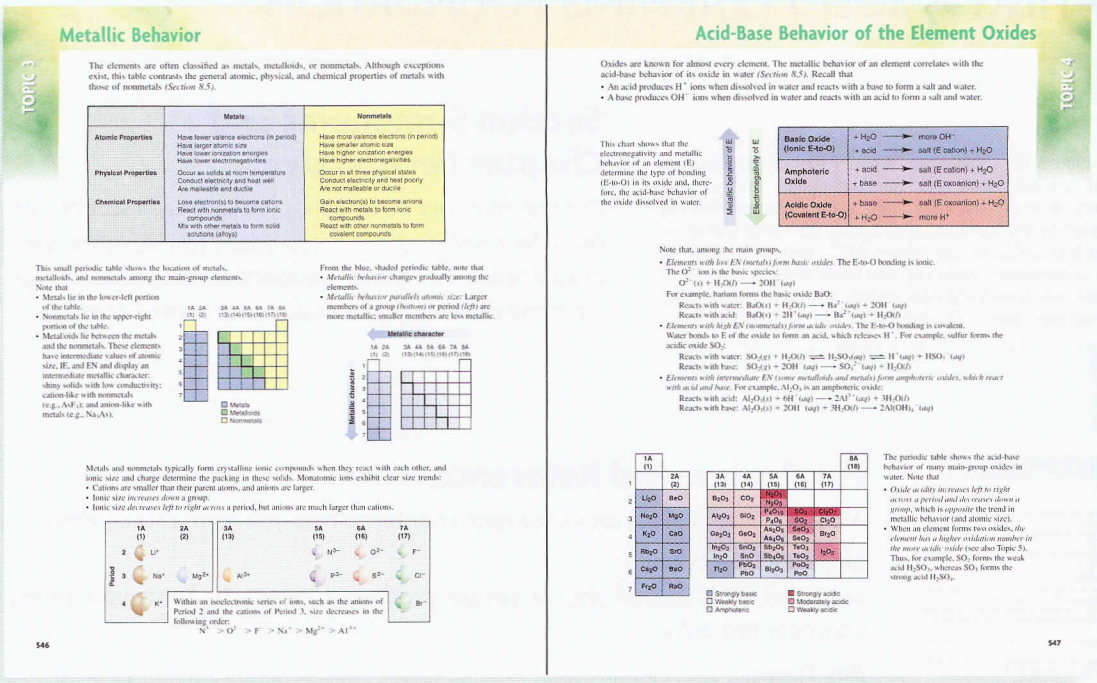
386

Margin Notes

More than 135 short, lively explanations apply ideas presented in the text. You'll learn how water controls the temperatures of your body and our planet, how crime labs track illegal drugs, how gas behavior affects lung function, how fat-free chips and decaf coffee are made, and what the risks of nuclear radiation are, in addition to handy tips for memorizing relationships, and much more.

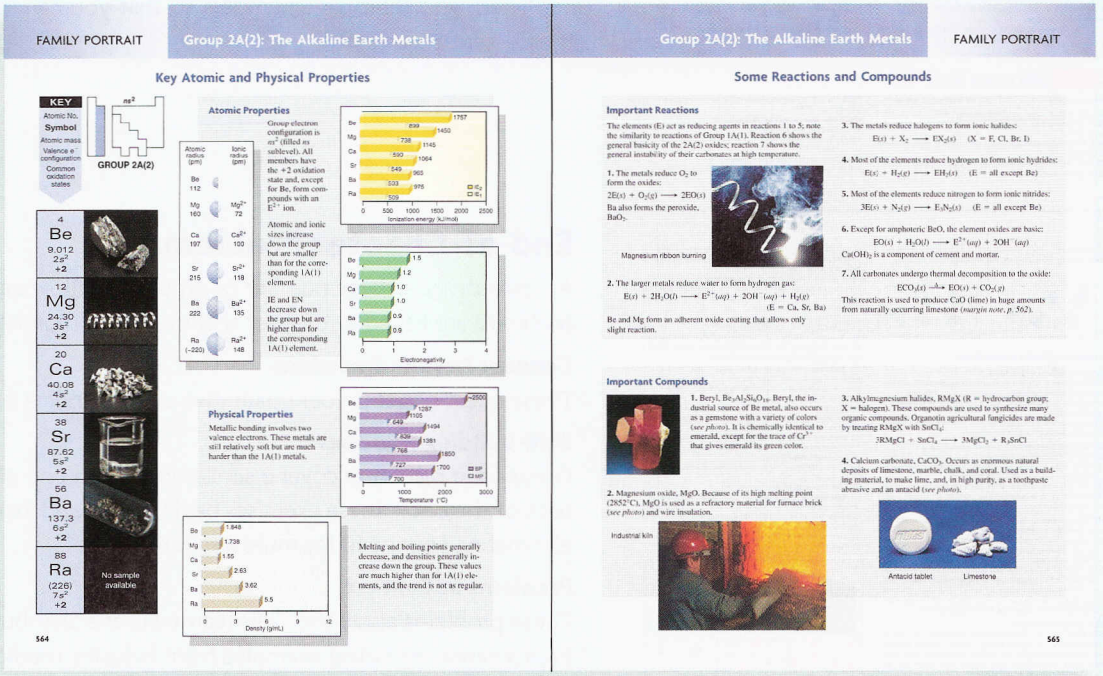
Galleries

These illustrated summaries of applications show how common and unusual substances and processes relate to chemical principles. You'll learn how a ballpoint pen works, why bubbles in a drink are round, why contact-lens rinse must have a certain concentration, why the strongest non-nuclear explosive is so powerful, and many other intriguing applications.



Interchapter

This multipage, illustrated Perspective on the Properties of the Elements reviews the major concepts from Chapters 7–13 that deal with atomic properties and their resulting effects on element behavior.



Family Portraits

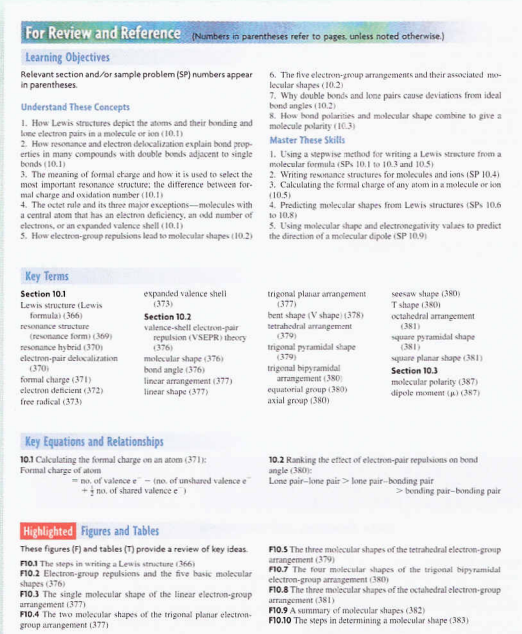
These illustrated summaries in Chapter 14 detail the atomic, physical, and chemical properties of each main group of elements and describe some of their most important compounds.

SECTION SUMMARY

Standard states are chosen conditions for substances. When 1 mol of a compound forms from its elements with all substances in their standard states, the enthalpy change is ΔH_f^0. Hess's law allows us to picture a reaction as the decomposition of reactants to their elements, followed by the formation of products from their elements. We use tabulated ΔH_f^0 values to find ΔH^0_{rxn} or use known ΔH^0_{rxn} and ΔH_f^0 values to find an unknown ΔH_f^0. Because of dwindling resources and environmental concerns, such as global warming, chemists are developing new energy alternatives, including coal and biomass conversion, hydrogen fuel, and noncombustible energy sources.

Section Summaries and Chapter Perspective

Concise summary paragraphs conclude each section, immediately restating the major ideas just covered. Each chapter ends with a brief perspective that places its topics in the context of previous and upcoming ones.



For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. How Lewis structures depict the atoms and their bonding and lone electron pairs in a molecule or ion (10.1)
2. How resonance and electron delocalization explain bond properties in many compounds with double bonds adjacent to single bonds (10.1)
3. The meaning of formal charge and how it is used to select the most important resonance structure; the difference between formal charge and oxidation number (10.1)
4. The octet rule and its three major exceptions—molecules with a central atom that has an electron deficiency, an odd number of electrons, or an expanded valence shell (10.1)
5. How electron-group repulsions lead to molecular shapes (10.2)
6. The five electron-group arrangements and their associated molecular shapes (10.2)
7. Why double bonds and lone pairs cause deviations from ideal bond angles (10.2)
8. How bond polarities and molecular shape combine to give a molecule polarity (10.3)

Master These Skills

1. Using a stepwise method for writing a Lewis structure from a molecular formula (SPs 10.1 to 10.3 and 10.5)
2. Writing resonance structures for molecules and ions (SP 10.4)
3. Calculating the formal charge of any atom in a molecule or ion (10.5)
4. Predicting molecular shapes from Lewis structures (SPs 10.6 to 10.8)
5. Using molecular shape and electronegativity values to predict the direction of a molecular dipole (SP 10.9)

Key Terms

Section 10.1
Lewis structure (Lewis formula) (366)
resonance structure (resonance form) (369)
resonance hybrid (370)
electron-pair delocalization (370)
formal charge (371)
electron deficient (372)
free radical (373)
expanded valence shell (373)

Section 10.2
valence-shell electron-pair repulsion (VSEPR) theory (376)
molecular shape (376)
bond angle (376)
linear arrangement (377)
linear shape (377)
trigonal planar arrangement (377)
bent shape (V shape) (378)
tetrahedral arrangement (379)
trigonal pyramidal shape (379)
trigonal bipyramidal arrangement (380)
equatorial group (380)
axial group (380)
seesaw shape (380)
T shape (380)
octahedral arrangement (381)
square pyramidal shape (381)
square planar shape (381)

Section 10.3
molecular polarity (387)
dipole moment (μ) (387)

Key Equations and Relationships

10.1 Calculating the formal charge on an atom (371):
Formal charge of atom = no. of valence e$^-$ − (no. of unshared valence e$^-$ + ½ no. of shared valence e$^-$)

10.2 Ranking the effect of electron-pair repulsions on bond angle (380):
Lone pair–lone pair > lone pair–bonding pair > bonding pair–bonding pair

Highlighted Figures and Tables

These figures (F) and tables (T) provide a review of key ideas.

F10.1 The steps in writing a Lewis structure (366)
F10.2 Electron-group repulsions and the five basic molecular shapes (376)
F10.3 The single molecular shape of the linear electron-group arrangement (377)
F10.4 The two molecular shapes of the trigonal planar electron-group arrangement (377)
F10.5 The three molecular shapes of the tetrahedral electron-group arrangement (379)
F10.7 The four molecular shapes of the trigonal bipyramidal electron-group arrangement (380)
F10.8 The three molecular shapes of the octahedral electron-group arrangement (381)
F10.9 A summary of molecular shapes (382)
F10.10 The steps in determining a molecular shape (383)

For Review and Reference

A rich catalog of study aids ends each chapter to help you review its content:

Learning Objectives

are listed, with section and/or sample problem numbers, to focus you on key concepts and skills.

Key Terms

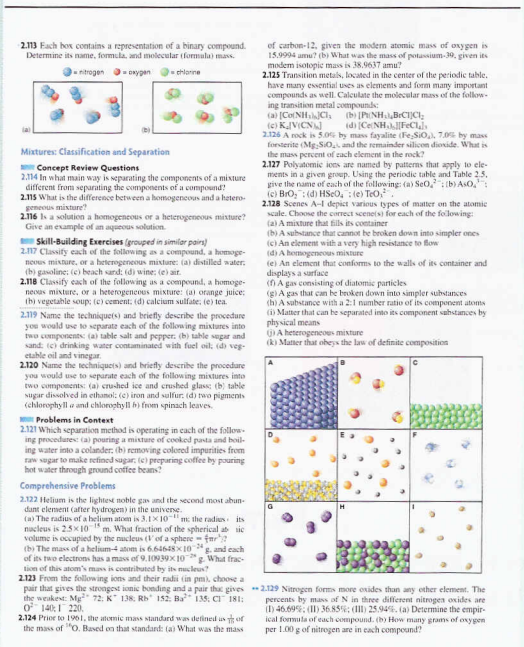
are boldfaced within the chapter and listed here by section (with page numbers); they are defined again in the Glossary.

Key Equations and Relationships

are screened and numbered within the chapter and listed here with page numbers.

Highlighted Figures and Tables

are listed with their page numbers so that you can find them easily and review their essential content.



2.113 Each box contains a representation of a binary compound. Determine its name, formula, and molecular (formula) mass.

= nitrogen = oxygen = chlorine

(a) (b)

Mixtures: Classification and Separation

Concept Review Questions

2.114 In what main way is separating the components of a mixture different from separating the components of a compound?
2.115 What is the difference between a homogeneous and a heterogeneous mixture?
2.116 Is a solution a homogeneous or a heterogeneous mixture? Give an example of an aqueous solution.

Skill-Building Exercises (grouped in similar pairs)

2.117 Classify each of the following as a compound, a homogeneous mixture, or a heterogeneous mixture: (a) distilled water; (b) gasoline; (c) beach sand; (d) wine; (e) air.
2.118 Classify each of the following as a compound, a homogeneous mixture, or a heterogeneous mixture: (a) orange juice; (b) vegetable soup; (c) cement; (d) calcium sulfate; (e) tea.
2.119 Name the technique(s) and briefly describe the procedure you would use to separate each of the following mixtures into two components: (a) table salt and pepper; (b) table sugar and sand; (c) drinking water contaminated with fuel oil; (d) vegetable oil and vinegar.
2.120 Name the technique(s) and briefly describe the procedure you would use to separate each of the following mixtures into two components: (a) crushed ice and crushed glass; (b) table sugar dissolved in ethanol; (c) iron and sulfur; (d) two pigments (chlorophyll *a* and chlorophyll *b*) from spinach leaves.

Problems in Context

2.121 Which separation method is operating in each of the following procedures: (a) pouring a mixture of cooked pasta and boiling water into a colander; (b) removing colored impurities from raw sugar to make refined sugar; (c) preparing coffee by pouring hot water through ground coffee beans?

Comprehensive Problems

2.122 Helium is the lightest noble gas and the second most abundant element (after hydrogen) in the universe.
(a) The radius of a helium atom is 3.1×10^{-11} m; the radius of its nucleus is 2.5×10^{-15} m. What fraction of the spherical atomic volume is occupied by the nucleus (V of a sphere = $\frac{4}{3}\pi r^3$)?
(b) The mass of a helium-4 atom is 6.64648×10^{-24} g, and each of its two electrons has a mass of 9.10939×10^{-28} g. What fraction of this atom's mass is contributed by its nucleus?
2.123 From the following ions and their radii (in pm), choose a pair that gives the strongest ionic bonding and a pair that gives the weakest: Mg^{2+} 72; K^+ 138; Rb^+ 152; Ba^{2+} 135; Cl^- 181; O^{2-} 140; I^- 220.
2.124 Prior to 1961, the atomic mass standard was defined as $\frac{1}{16}$ of the mass of ^{16}O. Based on that standard: (a) What was the mass of carbon-12, given the modern atomic mass of oxygen is 15.9994 amu? (b) What was the mass of potassium-39, given its modern isotopic mass is 38.9637 amu?
2.125 Transition metals, located in the center of the periodic table, have many essential uses as elements and form many important compounds as well. Calculate the molecular mass of the following transition metal compounds:
(a) $[Co(NH_3)_6]Cl_3$ (b) $[Pt(NH_3)_2BrCl]Cl_2$
(c) $K_4[V(CN)_8]$ (d) $[Ce(NH_3)_3][FeCl_4]$
2.126 A rock is 5.0% by mass fayalite (Fe_2SiO_4), 7.0% by mass forsterite (Mg_2SiO_4), and the remainder silicon dioxide. What is the mass percent of each element in the rock?
2.127 Polyatomic ions are named by patterns that apply to elements in a given group. Using the periodic table and Table 2.5, give the name of each of the following: (a) SeO_4^{2-}; (b) AsO_4^{3-}; (c) BrO_2^-; (d) $HSeO_4^-$; (e) TeO_3^{2-}.
2.128 Scenes A–I depict various types of matter on the atomic scale. Choose the correct scene(s) for each of the following:
(a) A mixture that fills its container
(b) A substance that cannot be broken down into simpler ones
(c) An element with a very high resistance to flow
(d) A homogeneous mixture
(e) An element that conforms to the walls of its container and displays a surface
(f) A gas consisting of diatomic particles
(g) A gas that can be broken down into simpler substances
(h) A substance with a 2:1 number ratio of its component atoms
(i) Matter that can be separated into its component substances by physical means
(j) A heterogeneous mixture
(k) Matter that obeys the law of definite composition

A B C D E F G H I

•• 2.129 Nitrogen forms more oxides than any other element. The percents by mass of N in three different nitrogen oxides are (I) 46.69%; (II) 36.85%; (III) 25.94%. (a) Determine the empirical formula of each compound. (b) How many grams of oxygen per 1.00 g of nitrogen are in each compound?

End-of-Chapter Problems

An exceptionally large number of problems follow each chapter. Three types of problems are keyed by chapter section, and comprehensive problems follow:

Concept Review Questions

These questions test your qualitative understanding of key ideas.

Skill-Building Exercises

Grouped in pairs that cover a similar idea, with one of each pair answered in the back of the book, these exercises begin simply and increase in difficulty, gradually eliminating your need for multistep directions.

Problems in Context

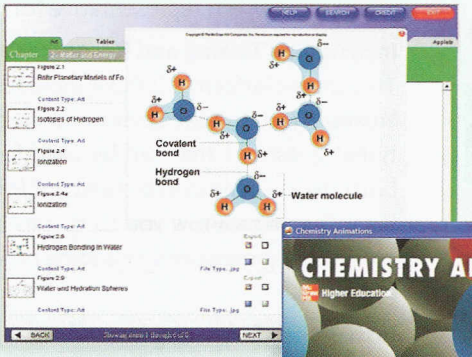
These problems apply the skills learned in the Skill-Building Exercises to interesting scenarios, including examples from industry, medicine, and the environment.

Comprehensive Problems

Following the section-based problems is a large group of more challenging problems. These are based on concepts and skills from any section and/or earlier chapter and are filled with applications from related sciences.

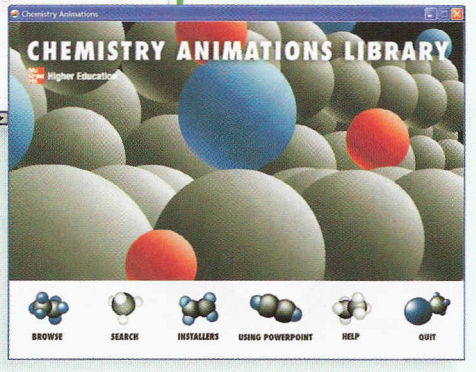
Multimedia Supplements

Digital Content Manager



Electronic art at your fingertips! This cross-platform CD-ROM provides you with artwork from the text in multiple formats. You can easily create customized classroom presentations, visually based tests and quizzes, dynamic content for a course website, or attractive printed support materials. Available on this DVD are the following resources:

- **Active Art Library** These key art pieces—formatted as PowerPoint slides—illustrate difficult concepts in a step-by-step manner. The artwork is broken into small, incremental frames, allowing you to incorporate the pieces into your lecture in whatever sequence or format you desire.
- **PowerPoint Lecture Outlines** Ready-made presentations—that combine art and lecture notes—cover all of the chapters in the text. These lectures can be used as is or customized by you to meet your specific needs.
- **Art and Photo Library** Full-color digital files of all of the illustrations and many of the photos in the text can be readily incorporated into lecture presentations, exams, or custom-made classroom materials.
- **Worked Example Library** and **Table Library** Access the worked examples and visual tables from the text in electronic format for inclusion in your classroom resources.

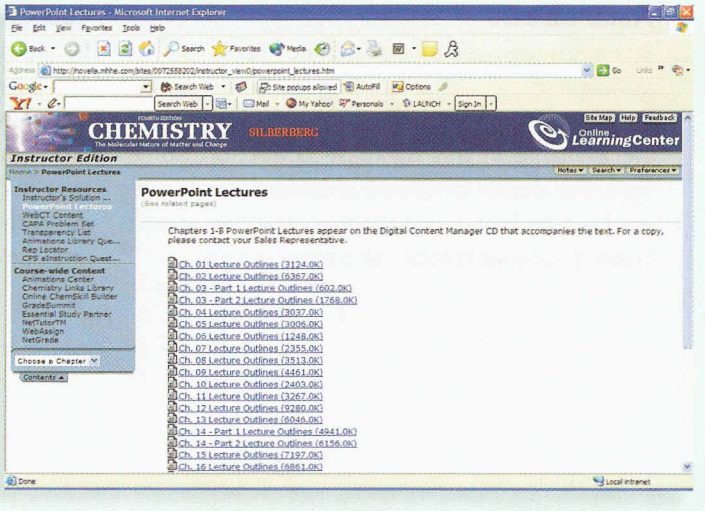


Chemistry Animations DVD

This CD-ROM contains more than 300 animations, several authored by Martin Silberberg. This easy-to-use CD allows you to view the animations quickly and import them into PowerPoint to create multimedia presentations.

Chemistry Online Learning Center

www.mhhe.com/silberberg



McGraw-Hill's *Chemistry* **Online Learning Center** contains many useful tools for empowering both students and instructors.

- **All assignments and questions are directly tied to text-specific materials** in *Chemistry*, Fourth Edition, but you can edit questions and algorithms, import your own content, and create announcements and due dates for assignments.
- A **secured Instructor Center** stores your course materials, saving you preparation time.
- ***Chemistry* Online Learning Center** provides you with access to these essential resources: PowerPoint Images, a PowerPoint lecture outline, *Instructor's Manual* and *Instructions Solutions Manual,* and animations.
- **ChemSkill Builder** online, McGraw-Hill's powerful electronic homework system, gives students the tutorial practice they need to master concepts covered in your general chemistry course. *ChemSkill Builder* contains more than 1,500 algorithmically generated questions as well as interactive exercises, quizzes, animations, and study tools that correlate directly with each chapter of the text. A record of student work is maintained in an online gradebook so that homework can be easily assigned and factored into the course syllabus.

Course Management Software

With help from **WebCT**, **Blackboard,** or **WebAssign**, you can take complete control over your course content. These course cartridges also provide online testing and powerful student tracking features. The *Chemisty* Online Learning Center is available within all of these platforms. Contact your McGraw-Hill representative for more details.

Instructor's Testing and Resource CD-ROM

This cross-platform CD-ROM includes the *Instructor's Solutions Manual,* which is comprised of all answers from the textbook's end-of-chapter problems, as well as the *Test Bank,* which offers additional questions that can be used for homework assignments and/or the preparation of exams; both are available in Word and pdf formats. The user-friendly computerized text bank utilizes testing software to allow you to quickly create customized exams by sorting questions by format, editing existing questions or adding new ones, and scrambling questions for multiple versions of the same test.

Instructor's Solutions Manual

By Rich Langley of Stephen F. Austin State University

This supplement contains complete, worked-out solutions for all the end-of-chapter problems in the text. It can be found within the secure Instructor's Center, within the Online Learning Center.

Printed Supplements

Transparencies

This boxed set of 300 full-color transparency acetates features images from the text that are modified to ensure maximum readability in both small and large classroom settings.

Primis LabBase

By Joseph Lagowski of University of Texas at Austin

More than 40 general chemistry lab experiments are available in this database collection, some from the *Journal of Chemical Education* and others used by Professor Lagowski, enabling you to create your own custom laboratory manual.

General Chemistry Laboratory Manual

By Petra A. M. van Koppen of University of California, Santa Barbara

This definitive lab manual for the two-semester general chemistry course contains 21 experiments that cover the most commonly assigned experiments for the introductory level.

Cooperative Chemistry Laboratory Manual

By Melanie Cooper of Clemson University

This innovative guide features open-ended problems designed to simulate experience in a research lab. Working in groups, students investigate one problem over a period of several weeks, thus completing three or four projects during the semester, rather than one preprogrammed experiment per class. The emphasis here is on experimental design, analysis, problem solving, and communication.

LEARNING AIDS FOR STUDENTS

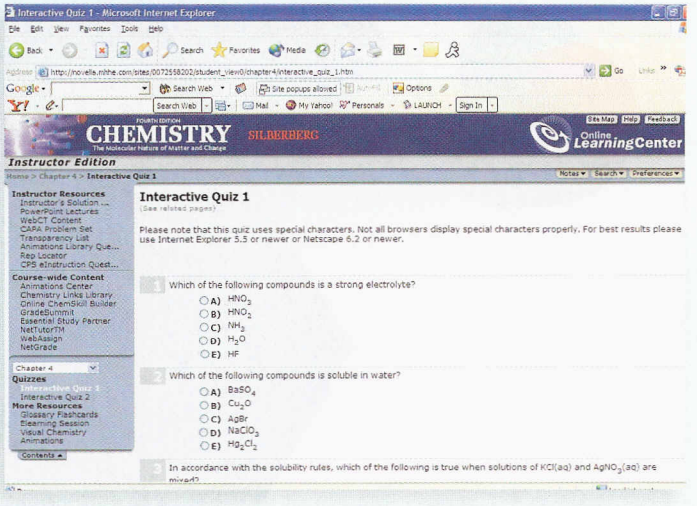
Multimedia Supplements

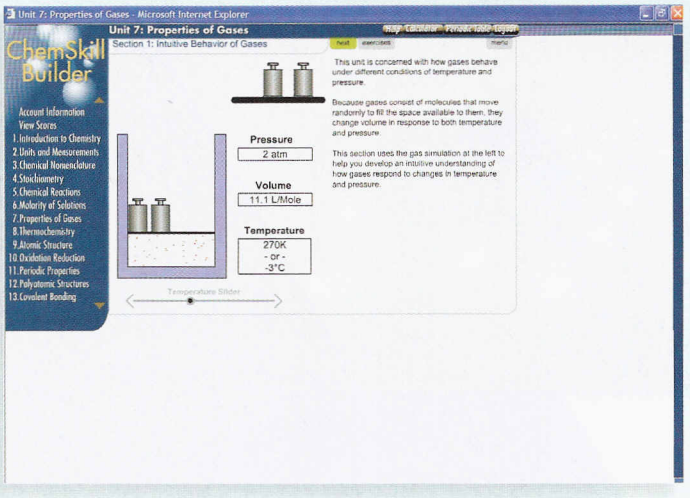
Online Learning Center ***www.mhhe.com/silberberg***

McGraw-Hill's *Online Learning Center* is your online home page for help.

Text-specific features to complement and solidify lecture concepts include:

- Online homework and quizzes (which are automatically graded and recorded for your instructor)
- Study tools that relate directly to each chapter of the text





- **ChemSkill Builder** online, McGraw-Hill's powerful electronic homework system, gives you the tutorial practice you need to master concepts covered in your general chemistry course. *ChemSkill Builder* contains more than 1,500 algorithmically generated questions as well as interactive exercises, quizzes, animations, and study tools matched to each chapter of the text. A record of your work is maintained in an online gradebook so that your homework scores can be easily viewed.

Printed Supplements

Student Solutions Manual

By Rich Langley of Stephen F. Austin University

This supplement contains detailed solutions and explanations for all even-numbered problems in the main text.

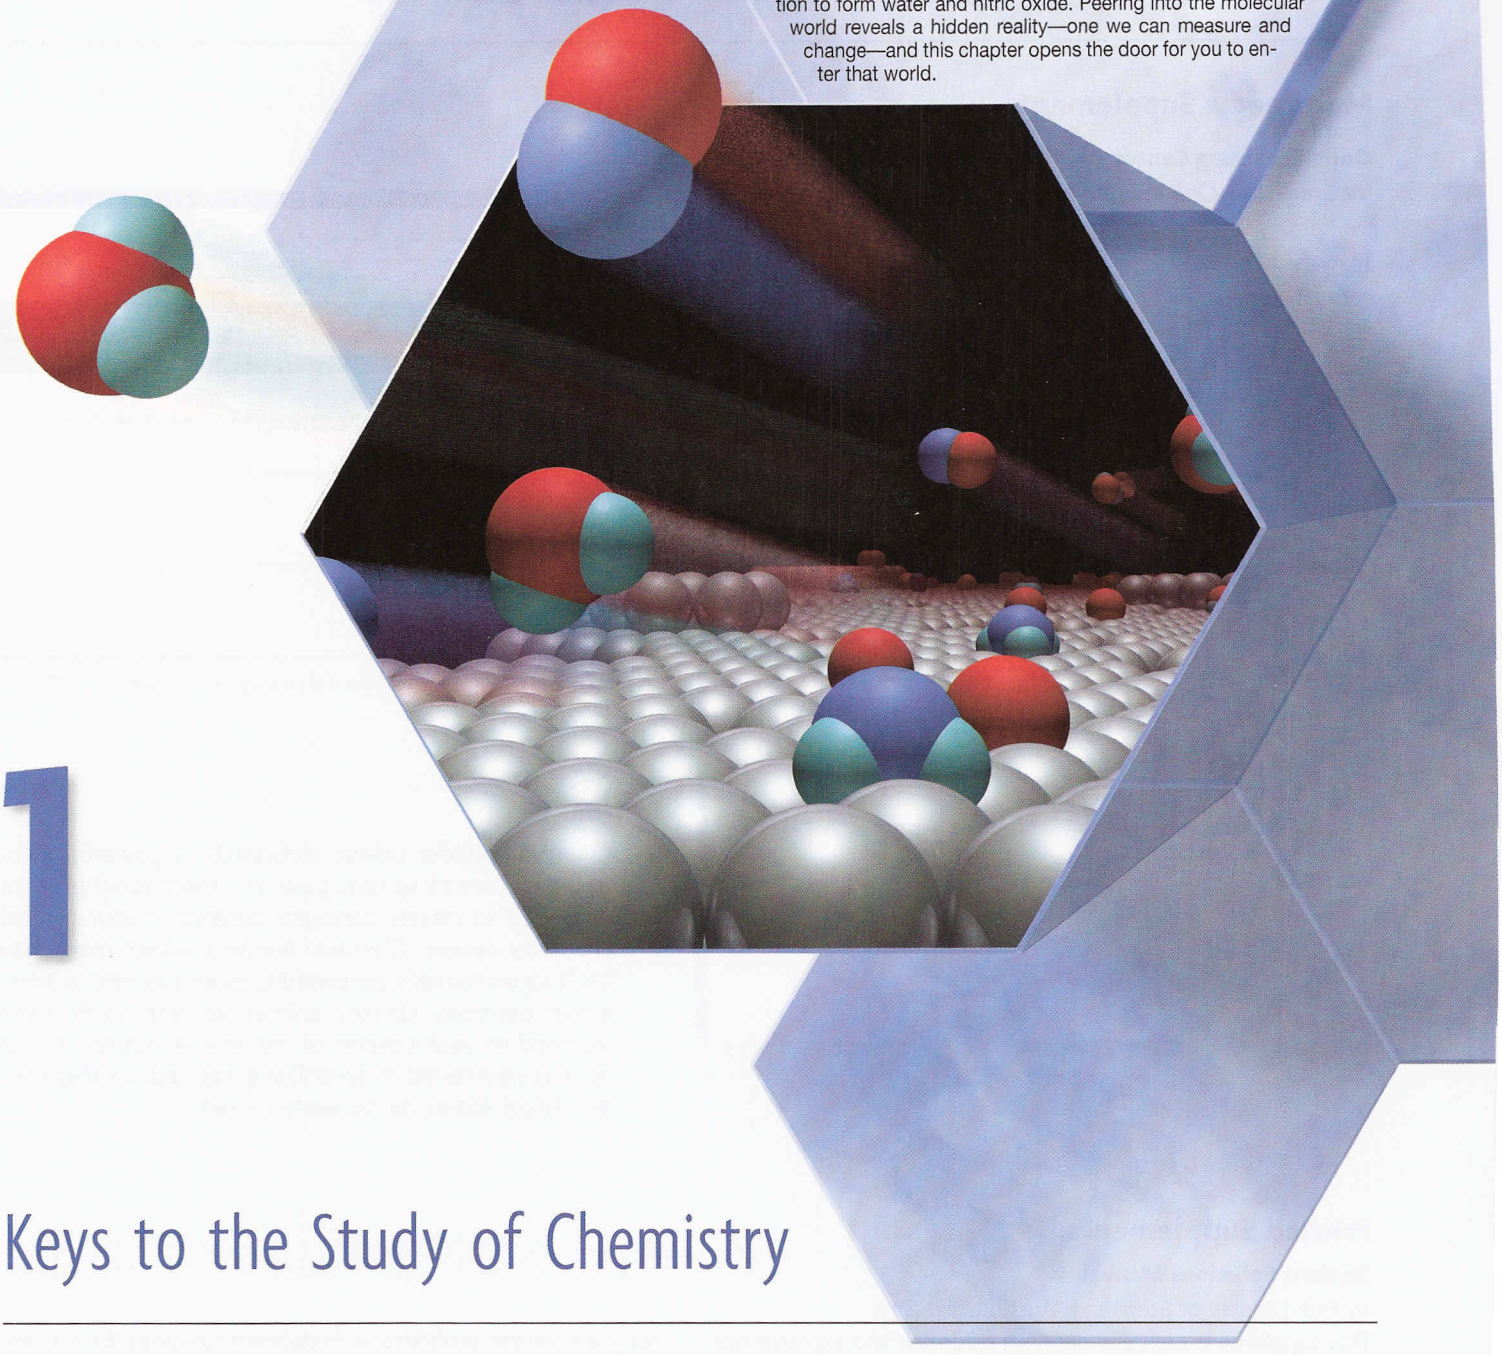
Student Study Guide

By Libby Weberg

This valuable ancillary is designed to help you recognize your learning style; understand how to read, classify, and create a problem-solving list; and practice problem-solving skills. For each section of a chapter, the author provides study objectives and a summary of the corresponding text. Following the summary are sample problems with detailed solutions. Each chapter has true-false questions and a self-test, with all answers provided at the end of the chapter.

Chemistry Resource Card

The resource card is a quick and easy source of information on general chemistry. Without having to consult the text, you have right at hand the periodic table and list of elements, tables for conversion factors, equilibrium and thermodynamic data, nomenclature, and key equations.



Reality Up Close The first step in nitric acid synthesis would surround you with a blur of ammonia and oxygen particles, as you watched from the surface of the platinum catalyst that speeds their reaction to form water and nitric oxide. Peering into the molecular world reveals a hidden reality—one we can measure and change—and this chapter opens the door for you to enter that world.

Precision and Accuracy

The science of chemistry stands at the forefront of change in the 21st century, creating "greener" energy sources to power society *and* sustain the environment, using breakthrough knowledge of the human genetic makeup to understand diseases and design medicines, and even researching the origin of life as we investigate our and nearby solar systems for signs of it. Addressing these and countless other challenges and opportunities depends on an understanding of the concepts you will learn in this course.

At this point, your interest in chemistry may be little more than satisfying a requirement for your major. You know that chemistry is a basic science with connections to many careers, but once this course is out of the way, who cares? You may wonder whether chemistry is important at all to you personally. Soon, you'll be wondering how any educated person can function today without knowing some chemistry!

In fact, the impact of chemistry on your daily life is mind-boggling. Consider the beginning of a typical day—perhaps this one—from a chemical point of view. Molecules align in the liquid crystal display of your clock, electrons flow through its circuitry to create a noise, and you throw off a thermal insulator of manufactured polymer. You jump in the shower to emulsify fatty substances on your skin and hair with treated water and formulated detergents. You adorn yourself in an array of processed chemicals—pleasant-smelling pigmented materials suspended in cosmetic gels, dyed polymeric fibers, synthetic footwear, and metal-alloyed jewelry. Today, breakfast is a bowl of nutrient-enriched, spoilage-retarded cereal and milk, a piece of fertilizer-grown, pesticide-treated fruit, and a cup of a hot aqueous solution of neurally stimulating alkaloid. After brushing your teeth with artificially flavored, dental-hardening agents dispersed in a colloidal abrasive, you're ready to leave, so you grab your laptop, an electronic device based on ultrathin, microetched semiconductor layers powered by a series of voltaic cells, collect some books—processed cellulose and plastic, electronically printed with light- and oxygen-resistant inks—hop in your hydrocarbon-fueled, metal-vinyl-ceramic vehicle, electrically ignite a synchronized series of controlled gaseous explosions, and you're off to class!

The influence of chemistry extends to the natural environment as well. The air, water, and land and the organisms that thrive there form a remarkably complex system of chemical interactions. While modern chemical products have enhanced the quality of our lives, their manufacture and use also pose increasing dangers, such as toxic wastes, acid rain, global warming, and ozone depletion. If our careless application of chemical principles has led to some of these problems, our careful application of the same principles is helping to solve them.

Perhaps the significance of chemistry is most profound when you contemplate the chemical nature of biology. Molecular events taking place within you right now allow your eyes to scan this page and your brain cells to translate fluxes of electric charge into thoughts. The most vital biological questions—How did life arise and evolve? How does an organism reproduce, grow, and age? What is the essence of health and disease?—ultimately have chemical answers.

This course comes with a bonus—the development of two mental skills you can apply to any science-related field. The first skill, common to all science courses, is the ability to solve problems systematically. The second is specific to chemistry, for as you comprehend its ideas, your mind's eye will learn to see a hidden level of the universe, one filled with incredibly minute particles hurtling at fantastic speeds, colliding billions of times a second, and interacting in ways that determine everything inside and outside of you. This first chapter holds the keys to help you enter this new world.

Concepts & Skills to Review

before you study this chapter

- exponential (scientific) notation (Appendix A)

IN THIS CHAPTER . . . We begin with fundamental definitions and concepts of matter and energy and their changes. Then, a brief discussion of chemistry's historical origins leads to an overview of how scientists build models to study nature. We consider chemical problem solving, including unit conversion, modern systems of measurement—focusing on mass, length, volume, density, and temperature—and numerical manipulations in calculations. A final essay examines how modern chemists work with other scientists for society's benefit.

1.1 SOME FUNDAMENTAL DEFINITIONS

The science of chemistry deals with the makeup of the entire physical universe. A good place to begin our discussion is with the definition of a few central ideas, some of which may already be familiar to you. **Chemistry** is *the study of matter and its properties, the changes that matter undergoes, and the energy associated with those changes.*

The Properties of Matter

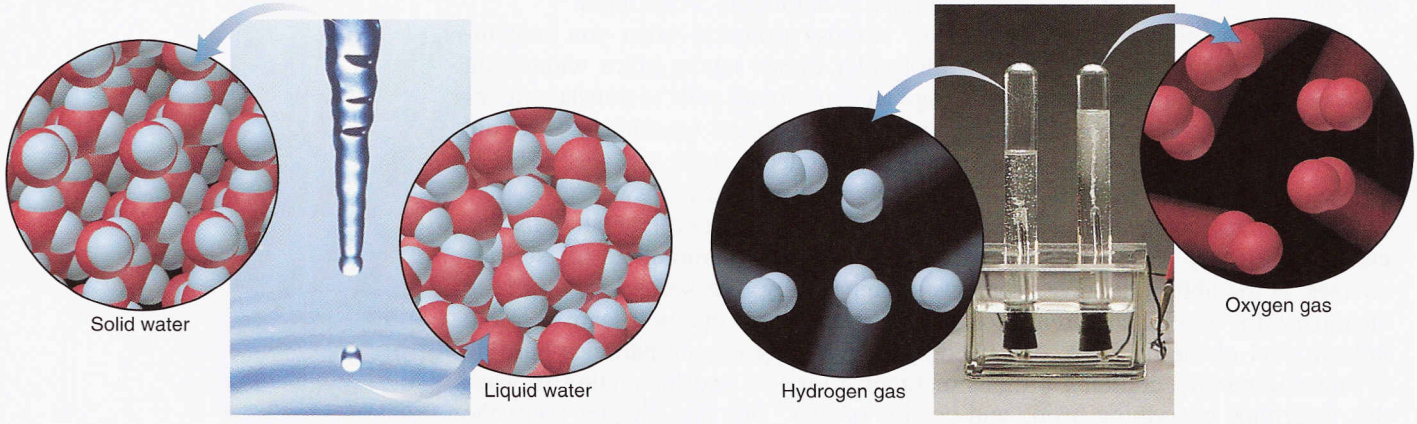
Matter is the "stuff" of the universe: air, glass, planets, students—*anything that has mass and volume*. (In Section 1.5, we discuss the meanings of mass and volume in terms of how they are measured.) Chemists are particularly interested in the **composition** of matter, *the types and amounts of simpler substances that make it up*. A *substance* is a type of matter that has a defined, fixed composition.

We learn about matter by observing its **properties,** *the characteristics that give each substance its unique identity.* To identify a person, we observe such properties as height, weight, eye color, race, fingerprints, and, now, even DNA fingerprint, until we arrive at a unique identification. To identify a substance, chemists observe two types of properties, physical and chemical, which are closely related to two types of change that matter undergoes. **Physical properties** are those that a substance shows *by itself, without changing into or interacting with another substance*. Some physical properties are color, melting point, electrical conductivity, and density.

Animation: The Three States of Matter
Online Learning Center

A **physical change** occurs when a substance *alters its physical form,* ***not*** *its composition*. Thus, a physical change results in different physical properties. For example, when ice melts, several physical properties have changed, such as hardness, density, and ability to flow. But the sample has *not* changed its composition: it is still water. The photo in Figure 1.1A shows this change the way you

Figure 1.1 The distinction between physical and chemical change.



A Physical change:
Solid form of water becomes liquid form; composition does not change because particles are the same.

B Chemical change:
Electric current decomposes water into different substances (hydrogen and oxygen); composition does change because particles are different.

would see it in everyday life. In your imagination, try to see the magnified view that appears in the "blow-up" circles. Here we see the particles that make up the sample; note that the same particles appear in solid and liquid water.
Physical change (same substance before and after):

$$\text{Water (solid form)} \longrightarrow \text{water (liquid form)}$$

On the other hand, **chemical properties** are those that a substance shows *as it changes into or interacts with another substance (or substances).* Some examples of chemical properties are flammability, corrosiveness, and reactivity with acids. A **chemical change,** also called a **chemical reaction,** occurs when *a substance (or substances) is converted into a different substance (or substances).*

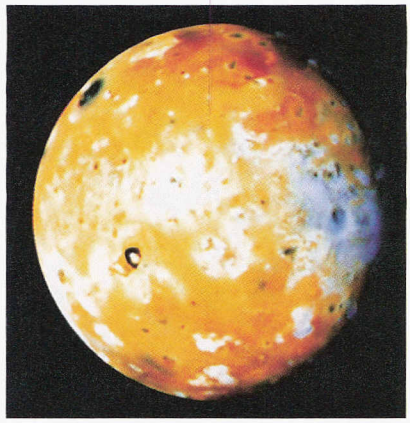
Figure 1.1B shows the chemical change (reaction) that occurs when you pass an electric current through water: the water decomposes (breaks down) into two other substances, hydrogen and oxygen, each with physical and chemical properties different from each other *and* from water. The sample *has* changed its composition: it is no longer water, as you can see from the different particles in the magnified view.
Chemical change (different substances before and after):

$$\text{Water} \xrightarrow{\text{electric current}} \text{hydrogen gas} + \text{oxygen gas}$$

A substance is identified by its own set of physical and chemical properties. Some properties of copper appear in Table 1.1.

Table 1.1 Some Characteristic Properties of Copper

Physical Properties	Chemical Properties
Reddish brown, metallic luster	Slowly forms a basic, blue-green sulfate in moist air
Easily shaped into sheets (malleable) and wires (ductile)	Reacts with nitric acid (photo) and sulfuric acid
Good conductor of heat and electricity	
Can be melted and mixed with zinc to form brass	Slowly forms a deep-blue solution in aqueous ammonia
Density = 8.95 g/cm^3	
Melting point = 1083°C	
Boiling point = 2570°C	



The Incredible Range of Physical Change Scientists often study physical change in remarkable settings, using instruments that allow observation far beyond the confines of the laboratory. Instruments aboard the *Voyager* and *Galileo* spacecrafts and the Hubble Space Telescope have measured temperatures on Jupiter's moon Io (shown here) that are hot enough to maintain lakes of molten sulfur and cold enough to create vast snowfields of sulfur dioxide and polar caps swathed in hydrogen sulfide frost. (On Earth, sulfur dioxide is one of the gases released from volcanoes and coal-fired power plants, and hydrogen sulfide occurs in swamp gas.)

The Three States of Matter

Matter occurs commonly in three physical forms called **states:** solid, liquid, and gas. As shown in Figure 1.2 for a general substance, each state is defined by the way it fills a container. A **solid** *has a fixed shape that does not conform to the container shape.* Solids are *not* defined by rigidity or hardness: solid iron is rigid, but solid lead is flexible and solid wax is soft. A **liquid** *conforms to the container shape but fills the container only to the extent of the liquid's volume;* thus, a liquid forms a *surface.* A **gas** *conforms to the container shape also, but it fills the entire container,* and thus, does *not* form a surface. Now, look at the views within the blow-up circles of the figure. The particles in the solid lie next to each other in a regular, three-dimensional array with a definite shape. Particles in the liquid also lie together but move randomly around one another. Particles in the gas usually have great distances between them, as they move randomly throughout the container.

Depending on the temperature and pressure of the surroundings, many substances can exist in each of the three physical states and undergo changes in state as well. As the temperature increases, solid water melts to liquid water, which boils to gaseous water (also called *water vapor*). Similarly, with decreasing temperature, water vapor condenses to liquid water, and with further cooling, the liquid freezes to ice. Many other substances behave in the same way: solid iron melts to liquid (molten) iron and then boils to iron gas at a higher temperature. Cooling the iron gas changes it to liquid and then to solid iron.

Thus, a physical change caused by heating can generally be reversed by cooling, and vice versa. This is *not* generally true for a chemical change. For example, heating iron in moist air causes a chemical reaction that yields the brown, crumbly substance known as rust. Cooling does not reverse this change; rather, another chemical change (or series of them) is required.

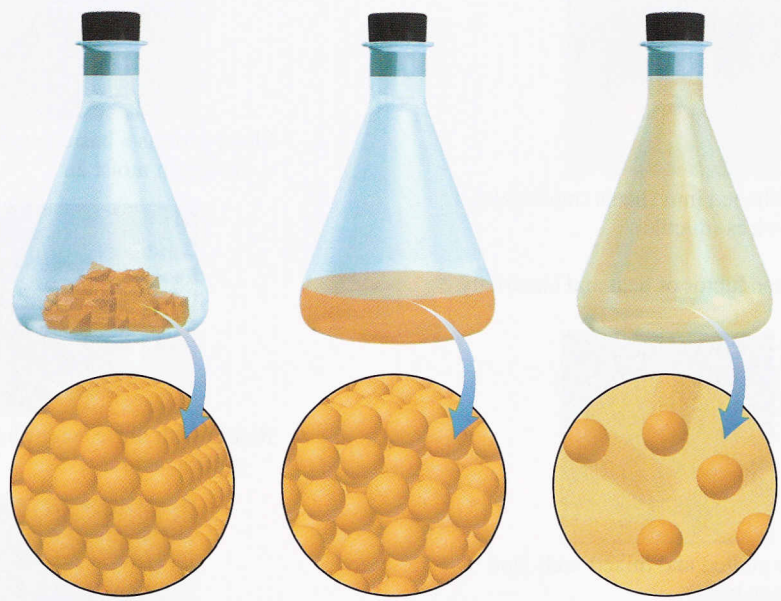


Figure 1.2 The physical states of matter. The magnified (blow-up) views show the atomic-scale arrangement of the particles in the three states of matter.

To summarize the key distinctions:

- A physical change leads to a different form of the same substance (same composition), whereas a chemical change leads to a different substance (different composition).
- A physical change caused by a temperature change can generally be reversed by the opposite temperature change, but this is not generally true of a chemical change.

The following sample problem provides more examples of these types of changes.

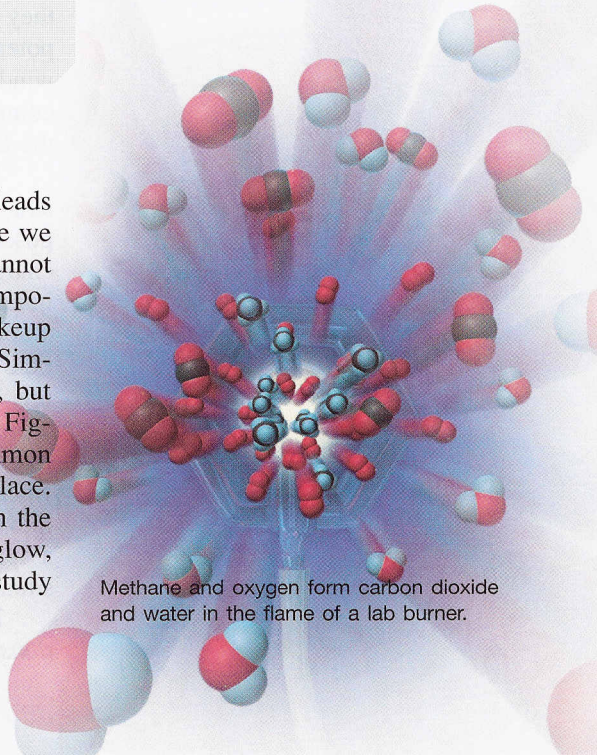
SAMPLE PROBLEM 1.1 Distinguishing Between Physical and Chemical Change

Problem Decide whether each of the following processes is primarily a physical or a chemical change, and explain briefly:
(a) Frost forms as the temperature drops on a humid winter night.
(b) A cornstalk grows from a seed that is watered and fertilized.
(c) Dynamite explodes to form a mixture of gases.
(d) Perspiration evaporates when you relax after jogging.
(e) A silver fork tarnishes slowly in air.
Plan The basic question we ask to decide whether a change is chemical or physical is, "Does the substance change composition or just change form?"
Solution **(a)** Frost forming is a physical change: the drop in temperature changes water vapor (gaseous water) in humid air to ice crystals (solid water).
(b) A seed growing involves chemical change: the seed uses substances from air, fertilizer, soil, and water and energy from sunlight to make complex changes in composition.
(c) Dynamite exploding is a chemical change: the dynamite is converted into other substances.
(d) Perspiration evaporating is a physical change: the water in sweat changes its form, from liquid to gas, but not its composition.
(e) Tarnishing is a chemical change: silver changes to silver sulfide by reacting with sulfur-containing substances in the air.

FOLLOW-UP PROBLEM 1.1 Decide whether each of the following processes is primarily a physical or a chemical change, and explain briefly:
(a) Purple iodine vapor appears when solid iodine is warmed.
(b) Gasoline fumes are ignited by a spark in an automobile engine cylinder.
(c) A scab forms over an open cut.

The Central Theme in Chemistry

Understanding the properties of a substance and the changes it undergoes leads to the central theme in chemistry: *macroscopic* properties and behavior, those we can see, are the results of *submicroscopic* properties and behavior that we cannot see. The distinction between chemical and physical change is defined by composition, which we study macroscopically. But it ultimately depends on the makeup of substances at the atomic scale, as the magnified views of Figure 1.1 show. Similarly, the defining properties of the three states of matter are macroscopic, but they arise from the submicroscopic behavior shown in the magnified views of Figure 1.2. Picturing a chemical scene on the molecular scale, even one as common as the flame of a laboratory burner (see margin), clarifies what is taking place. What is happening when water boils or copper melts? What events occur in the invisible world of minute particles that cause a seed to grow, a neon light to glow, or a nail to rust? Throughout the text, we return to this central idea: we study *observable* changes in matter to understand their *unobservable* causes.



Methane and oxygen form carbon dioxide and water in the flame of a lab burner.

The Importance of Energy in the Study of Matter

In general, physical and chemical changes are accompanied by energy changes. **Energy** is often defined as *the ability to do work*. Essentially, all work involves moving something. Work is done when your arm lifts a book, when an engine moves a car's wheels, or when a falling rock moves the ground as it lands. The object doing the work (arm, engine, rock) transfers some of the energy it possesses to the object on which the work is done (book, wheels, ground).

The total energy an object possesses is the sum of its potential energy and its kinetic energy. **Potential energy** is the *energy due to the* ***position*** *of the object.* **Kinetic energy** is the *energy due to the* ***motion*** *of the object.* Let's examine four systems that illustrate the relationship between these two forms of energy: (1) a weight raised above the ground, (2) two balls attached by a spring, (3) two electrically charged particles, and (4) a fuel and its waste products. A key concept illustrated by all four cases is that *energy is conserved: it may be converted from one form to the other, but it is not destroyed.*

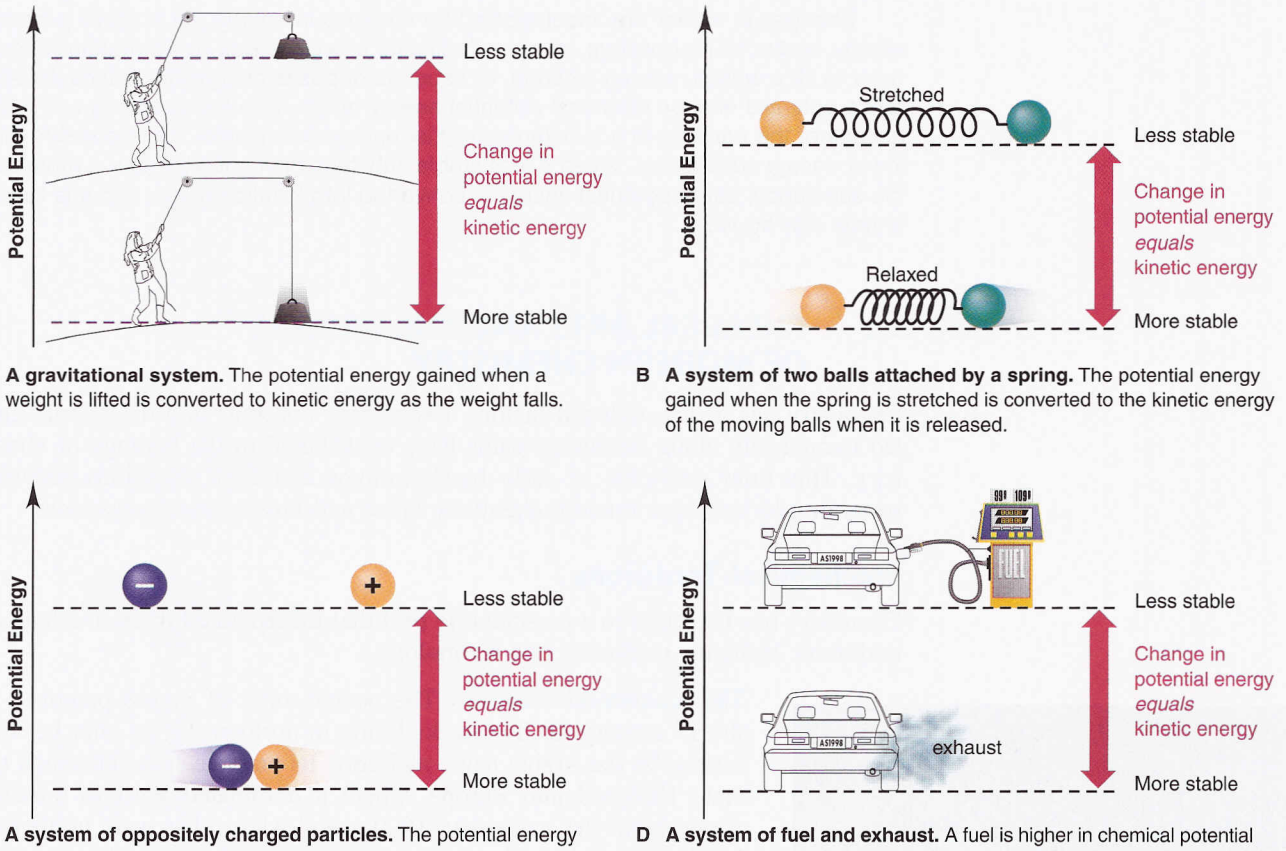
Look at Figure 1.3A and consider a weight you lift above the ground. The energy you use to move the weight against the gravitational attraction of the Earth increases the weight's potential energy (energy due to its position). When the weight is dropped, this additional potential energy is converted to kinetic energy (energy due to motion). Some of this kinetic energy is transferred to the ground as the weight does work, such as driving a stake or simply moving dirt and pebbles. As you can see, the added potential energy does not disappear: it is converted to kinetic energy.

In nature, situations of lower energy are typically favored over those of higher energy: because the weight has less potential energy (and thus less total energy) at rest on the ground than held in the air, it will fall when released. We speak of the situation with the weight elevated and higher in potential energy as being *less stable,* and the situation after the weight has fallen and is lower in potential energy as being *more stable.*

To bring the concept somewhat closer to chemistry, consider the two balls attached by a relaxed spring in Figure 1.3B. When you pull the balls apart, the energy you exert to stretch the spring increases its potential energy. This change in potential energy is converted to kinetic energy when you release the balls and they move closer together. The system of balls and spring is less stable (has more potential energy) when the spring is stretched than when it is relaxed. When you wind a clock, the potential energy in the mainspring increases as the spring is compressed. As the spring relaxes, its potential energy is slowly converted into the kinetic energy of the moving gears and hands.

There are no springs in a chemical substance, of course, but the following situation is similar in terms of energy. Much of the matter in the universe is composed of positively and negatively charged particles. A well-known behavior of charged particles (similar to the behavior of the poles of magnets) results from interactions known as *electrostatic forces: opposite charges attract each other, and like charges repel each other.* When work is done to separate a positive particle from a negative one, the potential energy of the particles increases. As Figure 1.3C shows, that increase in potential energy is converted to kinetic energy when the particles move together again. Also, when two positive (or two negative) particles are pushed toward each other, their potential energy increases, and when they are allowed to move apart, that increase in potential energy is changed into kinetic energy. Like the weight above the ground and the balls connected by a spring, charged particles move naturally toward a position of lower energy, a situation that is more stable.

The chemical potential energy of a substance results from the relative positions and the attractions and repulsions among all its particles. Some substances



A **A gravitational system.** The potential energy gained when a weight is lifted is converted to kinetic energy as the weight falls.

B **A system of two balls attached by a spring.** The potential energy gained when the spring is stretched is converted to the kinetic energy of the moving balls when it is released.

C **A system of oppositely charged particles.** The potential energy gained when the charges are separated is converted to kinetic energy as the attraction pulls them together.

D **A system of fuel and exhaust.** A fuel is higher in chemical potential energy than the exhaust. As the fuel burns, some of its potential energy is converted to the kinetic energy of the moving car.

Figure 1.3 **Potential energy is converted to kinetic energy.** In all four parts of the figure, the dashed horizontal lines indicate the potential energy of the system in each situation.

are richer in this chemical potential energy than others. Fuels and foods, for example, contain more potential energy than the waste products they form. Figure 1.3D shows that when gasoline burns in a car engine, substances with higher chemical potential energy (gasoline and air) form substances with lower potential energy (exhaust gases). This difference in potential energy is converted into the kinetic energy that moves the car, heats the passenger compartment, makes the lights shine, and so forth. Similarly, the difference in potential energy between the food and air we take in and the waste products we excrete is used to move, grow, keep warm, study chemistry, and so on. Note again the essential point: *energy is neither created nor destroyed—it is always conserved as it is converted from one form to the other.*

SECTION SUMMARY

Chemists study the composition and properties of matter and how they change. Each substance has a unique set of physical properties (attributes of the substance itself) and chemical properties (attributes of the substance as it interacts with or changes to other substances). Changes in matter can be physical (different form of the same substance) or chemical (different substance). Matter exists in three physical states—solid, liquid, and gas. The observable features that distinguish these states reflect the arrangement of their particles. A change in physical state brought about by heating may be reversed by cooling. A chemical change can be reversed only by other chemical changes. Macroscopic changes result from submicroscopic changes.

Changes in matter are accompanied by changes in energy. An object's potential energy is due to its position; an object's kinetic energy is due to its motion. Energy used to lift a weight, stretch a spring, or separate opposite charges increases the system's potential energy. Chemical potential energy arises from the positions and interactions of the particles in a substance. Higher energy substances are less stable than lower energy substances. When a less stable substance is converted into a more stable substance, some potential energy is converted into kinetic energy, and this kinetic energy can do work.

1.2 CHEMICAL ARTS AND THE ORIGINS OF MODERN CHEMISTRY

Chemistry has a rich, colorful history. Even some concepts and discoveries that led temporarily along confusing paths have contributed to the heritage of chemistry. This brief overview of early breakthroughs and false directions provides some insight into how modern chemistry arose and how science progresses.

Prechemical Traditions

Chemistry has its origin in a prescientific past that incorporated three overlapping traditions: alchemy, medicine, and technology.

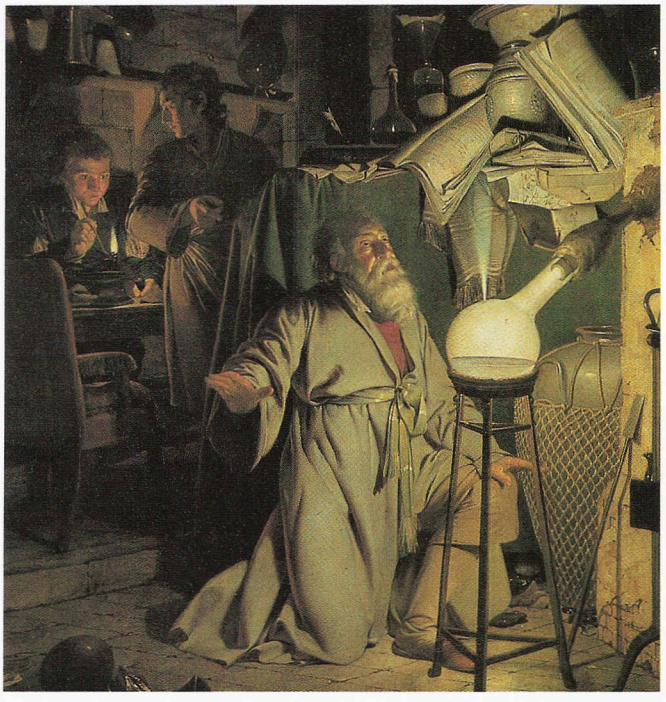


Figure 1.4 An alchemist at work.
The apparatus shown here is engaged in distillation, a process still commonly used to separate substances.
This is a portion of a painting by the Englishman Joseph Wright entitled "The Alchymist, in search of the Philosopher's Stone, Discovers Phosphorus, and prays for the successful Conclusion of his Operation as was the custom of the Ancient Chymical Astrologers." Some suggest it portrays the German alchemist Hennig Brand in his laboratory, lit by the glow of phosphorus, which he discovered in 1669.

The Alchemical Tradition The occult study of nature practiced in the 1st century AD by Greeks living in northern Egypt later became known by the Arabic name **alchemy.** Its practice spread through the Near East and into Europe, where it dominated Western thinking about matter for more than 1500 years! Alchemists were influenced by the Greek idea that matter naturally strives toward perfection, and they searched for ways to change less valued substances into precious ones. What started as a search for spiritual properties in matter evolved over a thousand years into an obsession with potions to bestow eternal youth and elixirs to transmute "baser" metals, such as lead, into "purer" ones, such as gold. Greed prompted some later European alchemists to paint lead objects with a thin coating of gold to fool wealthy patrons.

Alchemy's legacy to chemistry is mixed at best. The confusion arising from alchemists' use of different names for the same substance and from their belief that matter could be altered magically was very difficult to eliminate. Nevertheless, through centuries of laboratory inquiry, alchemists invented the chemical methods of distillation, percolation, and extraction, and they devised apparatus that today's chemists still use routinely (Figure 1.4). Most important, alchemists encouraged the widespread acceptance of observation and experimentation, which replaced the Greek approach of studying nature solely through reason.

The Medical Tradition Alchemists greatly influenced medical practice in medieval Europe. Since the 13th century, distillates of roots, herbs, and other plant matter have been used as sources of medicines. Paracelsus (1493–1541), an active alchemist and important physician of the time, considered the body to be a chemical system whose balance of substances could be restored by medical treatment. His followers introduced mineral drugs into 17th-century pharmacy. Although many of these drugs were useless and some harmful, later practitioners employed other mineral prescriptions with increasing success. Thus began the indispensable alliance between medicine and chemistry that thrives today.

The Technological Tradition For thousands of years, people have developed technological skills to carry out changes in matter. Pottery making, dyeing, and especially metallurgy (begun about 7000 years ago) contributed greatly to experience with the properties of materials. During the Middle Ages and the Renaissance, such technology flourished. Books describing how to purify, assay, and coin silver and gold and how to use balances, furnaces, and crucibles were published and regularly updated. Other writings discussed making glass, gunpowder, and other materials. Some even introduced quantitative measurement, which had been lacking in alchemical writings.

Many creations of these early artisans are still unsurpassed today, and people marvel at them in the great centers of world art. Nevertheless, while the artisans' working knowledge of substances was expert, their approach to understanding matter shows little interest in exploring *why* a substance changes or *how to predict* its behavior.

The Phlogiston Fiasco and the Impact of Lavoisier

Chemical investigation in the modern sense—inquiry into the causes of changes in matter—began in the late 17th century but was hampered by an incorrect theory of **combustion,** the process of burning.

At the time, most scientists embraced the **phlogiston theory,** which held sway for nearly 100 years. The theory proposed that combustible materials contain varying amounts of an undetectable substance called *phlogiston,* which is released when the material burns. Highly combustible materials like charcoal contain a lot of phlogiston, and thus release a lot when they burn; similarly, slightly combustible materials like metals contain very little and thus release very little.

However, the theory could not answer some key questions from its critics: "Why is air needed for combustion, and why does charcoal stop burning in a closed vessel?" The theory's supporters responded that air "attracted" the phlogiston out of the charcoal, and that burning in a vessel stops when the air is "saturated" with phlogiston. When a metal burns, it forms its *calx,* which weighs more than the metal, so critics asked, "How can the *loss* of phlogiston cause a *gain* in mass?" Supporters proposed that phlogiston had negative mass! These responses seem ridiculous now, but they point out that the pursuit of science, like any other endeavor, is subject to human failings; even today, it is easier to dismiss conflicting evidence than to give up an established idea.

Into this chaos of "explanations" entered the young French chemist Antoine Lavoisier (1743–1794), who demonstrated the true nature of combustion. In a series of careful measurements, Lavoisier heated mercury calx, decomposing it into mercury and a gas, whose combined masses equaled the starting mass of calx. The reverse experiment—heating mercury with the gas—re-formed the mercury calx, and again, *the total mass remained constant.* Lavoisier proposed that when a metal forms its calx, it does not lose phlogiston but rather combines with this gas, which must be a component of air. To test this idea, Lavoisier heated mercury in a measured volume of air to form mercury calx and noted that only four-fifths of the air volume remained. He placed a burning candle in the remaining air, and it went out, showing that the gas that had combined with the mercury was necessary for combustion. Lavoisier named the gas *oxygen* and called metal calxes *metal oxides.*

Lavoisier's new theory of combustion made sense of the earlier confusion. A combustible substance such as charcoal stops burning in a closed vessel once it combines with all the available oxygen, and a metal oxide weighs more than the metal because it contains the added mass of oxygen. This theory triumphed because it relied on *quantitative, reproducible measurements,* not on the strange

Scientific Thinker Extraordinaire Lavoisier's fame would be widespread, even if he had never performed a chemical experiment. A short list of his other contributions: He improved the production of French gunpowder, which became a key factor in the success of the American Revolution. He established on his farm a scientific balance between cattle, pasture, and cultivated acreage to optimize crop yield. He developed public assistance programs for widows and orphans. He quantified the relation of fiscal policy to agricultural production. He proposed a system of free public education and of societies to foster science, politics, and the arts. He sat on the committee that unified weights and measures in the new metric system. His research into combustion clarified the essence of respiration and metabolism. To support these pursuits, he joined a firm that collected taxes for the king, and only this role was remembered during the French Revolution. Despite his devotion to French society, the father of modern chemistry was guillotined at the age of 50.

A Great Chemist Yet Strict Phlogistonist Despite the phlogiston theory, chemists made key discoveries during the years it held sway. Many were made by the English clergyman Joseph Priestley (1733–1804), who systematically studied the physical and chemical properties of many gases (inventing "soda water," carbon dioxide dissolved in water, along the way). The gas obtained by heating mercury calx was of special interest to him. In 1775, he wrote to his friend Benjamin Franklin: "Hitherto only two mice and myself have had the privilege of breathing it." Priestley also demonstrated that the gas supports combustion, but he drew the wrong conclusion about it. He called the gas "dephlogisticated air," air devoid of phlogiston, and thus ready to attract it from a burning substance. Priestley's contributions make him one of the great chemists of all time. He was a liberal thinker, favoring freedom of conscience and supporting both the French and American Revolutions, positions that caused severe personal problems throughout his later life. But, scientifically, he remained a conservative, believing strictly in phlogiston and refusing to accept the new theory of combustion.

properties of undetectable substances. Because this approach is at the heart of science, many propose that the *science* of chemistry began with Lavoisier.

SECTION SUMMARY

Alchemy, medicine, and technology established processes that have been important to chemists since the 17th century. These prescientific traditions placed little emphasis on objective experimentation, focusing instead on practical experience or mystical explanations. The phlogiston theory dominated thinking about combustion for almost 100 years, but in the mid-1770s, Lavoisier showed that oxygen, a component of air, is required for combustion and combines with a substance as it burns.

1.3 THE SCIENTIFIC APPROACH: DEVELOPING A MODEL

The principles of chemistry have been modified through time and are still evolving. Imagine how differently people learned about the material world tens of thousands of years ago. At the dawn of human experience, our ancestors survived through knowledge acquired by *trial and error:* which types of stone were hard enough to shape others, which types of wood were rigid and which were flexible, which hides could be treated to make clothing, which plants were edible and which were poisonous. Today, the science of chemistry, with its powerful *quantitative theories,* helps us understand the essential nature of materials to make better use of them and create new ones: specialized drugs, advanced composites, synthetic polymers, and countless other new materials (Figure 1.5).

Is there something special about the way scientists think? If we could break down a "typical" modern scientist's thought processes, we could organize them into an approach called the **scientific method.** This approach is not a stepwise checklist, but rather a flexible process of creative thinking and testing aimed at objective, verifiable discoveries about how nature works. It is very important to realize that there is no typical scientist and no single method, and that luck can

Figure 1.5 Modern materials in a variety of applications. A, Specialized steels in bicycles; synthetic polymers in clothing and helmets. **B,** High-tension polymers in synthetic hip joints. **C,** Medicinal agents in pills. **D,** Liquid crystal displays in electronic devices.

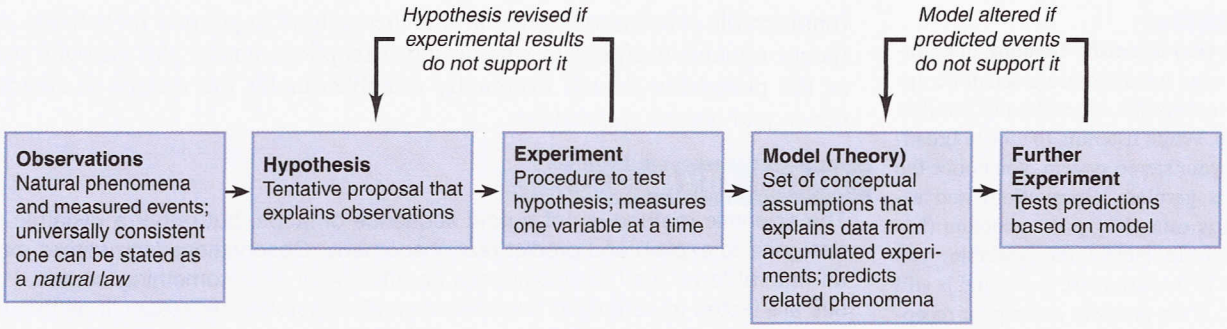

Figure 1.6 The scientific approach to understanding nature. Note that hypotheses and models are mental pictures that are changed to match observations and experimental results, *not* the other way around.

and often has played a key role in scientific discovery. In general terms, the scientific approach includes the following parts (Figure 1.6):

1. ***Observations.*** These are the facts that our ideas must explain. Observation is basic to scientific thinking. The most useful observations are quantitative because they can be compared and allow trends to be seen. Pieces of quantitative information are **data.** When the same observation is made by many investigators in many situations with no clear exceptions, it is summarized, often in mathematical terms, and called a **natural law.** The observation that mass remains constant during chemical change—made by Lavoisier and numerous experimenters since—is known as the law of mass conservation (discussed in Chapter 2).

2. ***Hypothesis.*** Whether derived from actual observation or from a "spark of intuition," a hypothesis is a proposal made to explain an observation. A valid hypothesis need not be correct, but it must be testable. Thus, a hypothesis is often the reason for performing an experiment. If the hypothesis is inconsistent with the experimental results, it must be revised or discarded.

3. ***Experiment.*** An experiment is a clear set of procedural steps that tests a hypothesis. Experimentation is the connection between our hypotheses about nature and nature itself. Often, hypothesis leads to experiment, which leads to revised hypothesis, and so forth. Hypotheses can be altered, but the results of an experiment cannot.

An experiment typically contains at least two **variables,** quantities that can have more than a single value. A well-designed experiment is **controlled** in that it measures the effect of one variable on another while keeping all others constant. For experimental results to be accepted, they must be *reproducible,* not only by the person who designed the experiment, but also by others. Both skill and creativity play a part in great experimental design.

4. ***Model.*** Formulating conceptual models, or **theories,** *based on experiments* is what distinguishes scientific thinking from speculation. As hypotheses are revised according to experimental results, a model gradually emerges that describes how the observed phenomenon occurs. A model is not an exact representation of nature, but rather a simplified version of nature that can be used to make *predictions* about related phenomena. Further investigation refines a model by testing its predictions and altering it to account for new facts.

Lavoisier's overthrow of the phlogiston theory demonstrates the scientific approach. *Observations* of burning and smelting led some to *hypothesize* that combustion involved the loss of phlogiston. *Experiments* by others showing that air is required for burning and that a metal gains mass during combustion led Lavoisier to propose a new *hypothesis,* which he tested repeatedly with quantitative *experiments.* Accumulating evidence supported his developing *model (theory)* that combustion involves combination with a component of air (oxygen).

Everyday Scientific Thinking In an informal way, we often use a scientific approach in daily life. Consider this familiar scenario. While listening to an FM broadcast on your stereo system, you notice the sound is garbled (observation) and assume it is caused by poor reception (hypothesis). To isolate this variable, you play a CD (experiment): the sound is still garbled. If the problem is not poor reception, perhaps the speakers are at fault (new hypothesis). To isolate this variable, you play the CD and listen with headphones (experiment): the sound is clear. You conclude that the speakers need to be repaired (model). The repair shop says the speakers check out fine (new observation), but the power amplifier may be at fault (new hypothesis). Replacing a transistor in the amplifier corrects the garbled sound (new experiment), so the power amplifier was the problem (revised model). Approaching a problem scientifically is a common practice, even if you're not aware of it.

Innumerable *predictions* based on this theory have supported its validity. A sound theory remains useful even when minor exceptions appear. An unsound one, such as the phlogiston theory, eventually crumbles under the weight of contrary evidence and absurd refinements.

SECTION SUMMARY

The scientific method is not a rigid sequence of steps, but rather a dynamic process designed to explain and predict real phenomena. Observations (sometimes expressed as natural laws) lead to hypotheses about how or why something occurs. Hypotheses are tested in controlled experiments and adjusted if necessary. If all the data collected support a hypothesis, a model (theory) can be developed to explain the observations. A good model is useful in predicting related phenomena but must be refined if conflicting data appear.

1.4 CHEMICAL PROBLEM SOLVING

In many ways, learning chemistry is learning how to solve chemistry problems, not only those in exams or homework, but also more complex ones in professional life and society. (The Chemical Connections essay at the end of this chapter provides an example.) This textbook was designed to help strengthen your problem-solving skills. Almost every chapter contains sample problems that apply newly introduced ideas and skills and are worked out in detail. In this section, we discuss the problem-solving approach. Because most problems include calculations, let's first go over some important ideas about measured quantities.

Units and Conversion Factors in Calculations

All measured quantities consist of a number *and* a unit; a person's height is "6 feet," not "6." Ratios of quantities have ratios of units, such as miles/hour. (We discuss the most important units in chemistry in the next section.) To minimize errors, try to make a habit of including units in all calculations.

The arithmetic operations used with measured quantities are the same as those used with pure numbers; in other words, units can be multiplied, divided, and canceled:

- A carpet measuring 3 feet (ft) by 4 ft has an area of

$$\text{Area} = 3\ \text{ft} \times 4\ \text{ft} = (3 \times 4)\ (\text{ft} \times \text{ft}) = 12\ \text{ft}^2$$

- A car traveling 350 miles (mi) in 7 hours (h) has a speed of

$$\text{Speed} = \frac{350\ \text{mi}}{7\ \text{h}} = \frac{50\ \text{mi}}{1\ \text{h}}\ (\text{often written } 50\ \text{mi}\cdot\text{h}^{-1})$$

- In 3 hours, the car travels a distance of

$$\text{Distance} = 3\ \cancel{\text{h}} \times \frac{50\ \text{mi}}{1\ \cancel{\text{h}}} = 150\ \text{mi}$$

Conversion factors are ratios used to express a measured quantity in different units. Suppose we want to know the distance of that 150-mile car trip in feet. To convert the distance between miles and feet, we use equivalent quantities to construct the desired conversion factor. The equivalent quantities in this case are 1 mile and the number of feet in 1 mile:

$$1\ \text{mi} = 5280\ \text{ft}$$

We can construct two conversion factors from this equivalency. Dividing both sides by 5280 ft gives one conversion factor (shown in blue):

$$\frac{1\ \text{mi}}{5280\ \text{ft}} = \frac{5280\ \cancel{\text{ft}}}{5280\ \cancel{\text{ft}}} = 1$$

And, dividing both sides by 1 mi gives the other conversion factor (the inverse):

$$\frac{1\ \cancel{\text{mi}}}{1\ \cancel{\text{mi}}} = \frac{5280\ \text{ft}}{1\ \text{mi}} = 1$$

It's very important to see that, since the numerator and denominator of a conversion factor are equal, multiplying by a conversion factor is the same as multiplying by 1. Therefore, *even though the number and unit of the quantity change, the size of the quantity remains the same.*

In our example, we want to convert the distance in miles to the equivalent distance in feet. Therefore, we choose the conversion factor with units of feet in the numerator, because it cancels units of miles and gives units of feet:

$$\text{Distance (ft)} = 150\ \cancel{\text{mi}} \times \frac{5280\ \text{ft}}{1\ \cancel{\text{mi}}} = 792{,}000\ \text{ft}$$

$$\text{mi} \quad \Longrightarrow \quad \text{ft}$$

Choosing the correct conversion factor is made much easier if you think through the calculation to decide whether the answer expressed in the new units should have a larger or smaller number. In the previous case, we know that a foot is *smaller* than a mile, so the distance in feet should have a *larger* number (792,000) than the distance in miles (150). The conversion factor has the larger number (5280) in the numerator, so it gave a larger number in the answer. The main goal is that *the chosen conversion factor cancels all units except those required for the answer.* Set up the calculation so that the unit you are converting *from* (beginning unit) is in the *opposite position in the conversion factor* (numerator or denominator). It will then cancel and leave the unit you are converting *to* (final unit):

$$\cancel{\text{beginning unit}} \times \frac{\text{final unit}}{\cancel{\text{beginning unit}}} = \text{final unit} \qquad \text{as in} \qquad \cancel{\text{mi}} \times \frac{\text{ft}}{\cancel{\text{mi}}} = \text{ft}$$

Or, in cases that involve units raised to a power,

$$(\cancel{\text{beginning unit}} \times \cancel{\text{beginning unit}}) \times \frac{\text{final unit}^2}{\cancel{\text{beginning unit}^2}} = \text{final unit}^2$$

$$\text{as in} \qquad (\cancel{\text{ft}} \times \cancel{\text{ft}}) \times \frac{\text{mi}^2}{\cancel{\text{ft}^2}} = \text{mi}^2$$

Or, in cases that involve a ratio of units,

$$\frac{\cancel{\text{beginning unit}}}{\text{final unit}_1} \times \frac{\text{final unit}_2}{\cancel{\text{beginning unit}}} = \frac{\text{final unit}_2}{\text{final unit}_1} \qquad \text{as in} \qquad \frac{\cancel{\text{mi}}}{\text{h}} \times \frac{\text{ft}}{\cancel{\text{mi}}} = \frac{\text{ft}}{\text{h}}$$

We use the same procedure to convert between systems of units, for example, between the English (or American) unit system and the International System (a revised metric system discussed fully in the next section). Suppose we know the height of Angel Falls in Venezuela (Figure 1.7) to be 3212 ft, and we find its height in miles as

$$\text{Height (mi)} = 3212\ \cancel{\text{ft}} \times \frac{1\ \text{mi}}{5280\ \cancel{\text{ft}}} = 0.6083\ \text{mi}$$

$$\text{ft} \quad \Longrightarrow \quad \text{mi}$$

Now, we want its height in kilometers (km). The equivalent quantities are

$$1.609\ \text{km} = 1\ \text{mi}$$

Since we are converting from miles to kilometers, we use the conversion factor with kilometers in the numerator in order to cancel miles:

$$\text{Height (km)} = 0.6083\ \cancel{\text{mi}} \times \frac{1.609\ \text{km}}{1\ \cancel{\text{mi}}} = 0.9788\ \text{km}$$

$$\text{mi} \quad \Longrightarrow \quad \text{km}$$

Notice that, since kilometers are *smaller* than miles, this conversion factor gave us a *larger* number (0.9788 is larger than 0.6083).

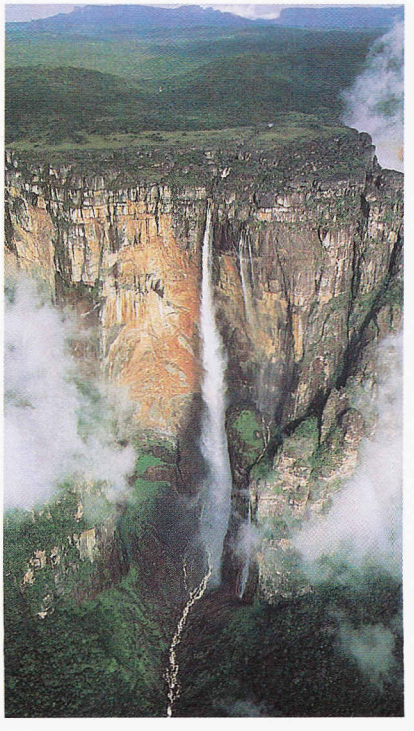

Figure 1.7 Angel Falls. The world's tallest waterfall is 3212 ft high.

If we want the height of Angel Falls in meters (m), we use the equivalent quantities 1 km = 1000 m to construct the conversion factor:

$$\text{Height (m)} = 0.9788 \cancel{\text{km}} \times \frac{1000 \text{ m}}{1 \cancel{\text{km}}} = 978.8 \text{ m}$$

km ⟹ m

In longer calculations, we often string together several conversion steps:

$$\text{Height (m)} = 3212 \cancel{\text{ft}} \times \frac{1 \cancel{\text{mi}}}{5280 \cancel{\text{ft}}} \times \frac{1.609 \cancel{\text{km}}}{1 \cancel{\text{mi}}} \times \frac{1000 \text{ m}}{1 \cancel{\text{km}}} = 978.8 \text{ m}$$

ft ⟹ mi ⟹ km ⟹ m

The use of conversion factors in calculations is known by various names, such as the factor-label method or **dimensional analysis** (because units represent physical dimensions). We use this method in quantitative problems throughout the text.

A Systematic Approach to Solving Chemistry Problems

The approach we use in this text provides a systematic way to work through a problem. It emphasizes reasoning, not memorizing, and is based on a very simple idea: plan how to solve the problem *before* you go on to solve it, and then check your answer. Try to develop a similar approach on homework and exams. In general, the sample problems consist of several parts:

1. **Problem.** This part states all the information you need to solve the problem (usually framed in some interesting context).
2. **Plan.** The overall solution is broken up into two parts, *plan* and *solution,* to make a point: *think* about how to solve the problem *before* juggling numbers. There is often more than one way to solve a problem, so the plan shown in a given text problem is just one possibility. The plan will
   - Clarify the known and unknown. (What information do you have, and what are you trying to find?)
   - Suggest the steps from known to unknown. (What ideas, conversions, or equations are needed to solve the problem?)
   - Present a "roadmap" of the solution for many problems in early chapters (and in some later ones). The roadmap is a visual summary of the planned steps. Each step is shown by an arrow labeled with information about the conversion factor or operation needed.
3. **Solution.** In this part, the steps appear in the same order as they were planned.
4. **Check.** In most cases, a quick check is provided to see if the results make sense: Are the units correct? Does the answer seem to be the right size? Did the change occur in the expected direction? Is it reasonable chemically? We often do a rough calculation to see if the answer is "in the same ballpark" as the calculated result, just to make sure we didn't make a large error. *Always* check your answers, especially in a multipart problem, where an error in an early step can affect all later steps. Here's a typical "ballpark" calculation. You are at the music store and buy three CD's at $14.97 each. With a 5% sales tax, the bill comes to $47.16. In your mind, you quickly check that 3 times approximately $15 is $45, and, given the sales tax, the cost should be a bit more. So, the amount of the bill is in the right ballpark.
5. **Comment.** This part is included occasionally to provide additional information, such as an application, an alternative approach, a common mistake to avoid, or an overview.
6. **Follow-up Problem.** This part consists of a problem statement only and provides practice by applying the same ideas as the sample problem. Try to solve it *before* you look at the brief worked-out solution at the end of the chapter.

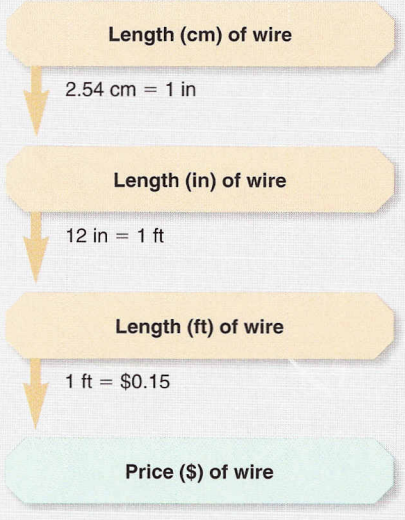
Of course, you can't learn to solve chemistry problems, any more than you can learn to swim, by reading about an approach. Practice is the key to mastery. Here are a few suggestions that can help:

- Follow along in the sample problem with pencil, paper, and calculator.
- Do the follow-up problem as soon as you finish studying the sample problem. Check your answer against the solution at the end of the chapter.
- Read the sample problem and text explanations again if you have trouble.
- Work on as many of the problems at the end of the chapter as you can. They review and extend the concepts and skills in the text. Answers are given in the back of the book for problems with a colored number, but try to solve them yourself first. Let's apply this approach in a unit-conversion problem.

SAMPLE PROBLEM 1.2 Converting Units of Length

Problem To wire your stereo equipment, you need 325 centimeters (cm) of speaker wire that sells for \$0.15/ft. What is the price of the wire?

Plan We know the length of wire in centimeters and the cost in dollars per foot (\$/ft). We can find the unknown price of the wire by converting the length from centimeters to inches (in) and from inches to feet. Then the cost (1 ft = \$0.15) gives us the equivalent quantities to construct the factor that converts feet of wire to price in dollars. The roadmap starts with the known and moves through the calculation steps to the unknown.



Solution Converting the known length from centimeters to inches: The equivalent quantities alongside the roadmap arrow are the ones needed to construct the conversion factor. We choose 1 in/2.54 cm, rather than the inverse, because it gives an answer in inches:

$$\text{Length (in)} = \text{length (cm)} \times \text{conversion factor} = 325 \text{ cm} \times \frac{1 \text{ in}}{2.54 \text{ cm}} = 128 \text{ in}$$

Converting the length from inches to feet:

$$\text{Length (ft)} = \text{length (in)} \times \text{conversion factor} = 128 \text{ in} \times \frac{1 \text{ ft}}{12 \text{ in}} = 10.7 \text{ ft}$$

Converting the length in feet to price in dollars:

$$\text{Price (\$)} = \text{length (ft)} \times \text{conversion factor} = 10.7 \text{ ft} \times \frac{\$0.15}{1 \text{ ft}} = \$1.60$$

Check The units are correct for each step. The conversion factors make sense in terms of the relative unit sizes: the number of inches is *smaller* than the number of centimeters (an inch is *larger* than a centimeter), and the number of feet is *smaller* than the number of inches. The total price seems reasonable: a little more than 10 ft of wire at \$0.15/ft should cost a little more than \$1.50.

Comment 1. We could also have strung the three steps together:

$$\text{Price (\$)} = 325 \text{ cm} \times \frac{1 \text{ in}}{2.54 \text{ cm}} \times \frac{1 \text{ ft}}{12 \text{ in}} \times \frac{\$0.15}{1 \text{ ft}} = \$1.60$$

2. There are usually alternative sequences in unit-conversion problems. Here, for example, we would get the same answer if we first converted the cost of wire from \$/ft to \$/cm and kept the wire length in cm. Try it yourself.

FOLLOW-UP PROBLEM 1.2 A furniture factory needs 31.5 ft^2 of fabric to upholster one chair. Its Dutch supplier sends the fabric in bolts of exactly 200 m^2. What is the maximum number of chairs that can be upholstered by 3 bolts of fabric (1 m = 3.281 ft)?

SECTION SUMMARY

A measured quantity consists of a number and a unit. Conversion factors are used to express a quantity in different units and are constructed as a ratio of equivalent quantities. The problem-solving approach used in this text usually has four parts: (1) devise a plan for the solution, (2) put the plan into effect in the calculations, (3) check to see if the answer makes sense, and (4) practice with similar problems.

How Many Barleycorns from His Majesty's Nose to His Thumb? Systems of measurement began thousands of years ago as trade, building, and land surveying spread throughout the civilized world. For most of that time, however, measurement was based on inexact physical standards. For example, an inch was the length of three barleycorns (seeds) placed end to end; a yard was the distance from the tip of King Edgar's nose to the tip of his thumb with his arm outstretched; and an acre was the area tilled by one man working with a pair of oxen in a day.

1.5 MEASUREMENT IN SCIENTIFIC STUDY

Almost everything we own—clothes, house, food, vehicle—is manufactured with measured parts, sold in measured amounts, and paid for with measured currency. Measurement is so commonplace that it's easy to take for granted, but it has a history characterized by the search for *exact, invariable standards.*

Our current system of measurement began in 1790, when the newly formed National Assembly of France, of which Lavoisier was a member, set up a committee to establish consistent unit standards. This effort led to the development of the *metric system.* In 1960, another international committee met in France to establish the International System of Units, a revised metric system now accepted by scientists throughout the world. The units of this system are called **SI units,** from the French **S**ystème **I**nternational d'Unités.

General Features of SI Units

As Table 1.2 shows, the SI system is based on a set of seven **fundamental units,** or **base units,** each of which is identified with a physical quantity. All other units, called **derived units,** are combinations of these seven base units. For example, the derived unit for speed, meters per second (m/s), is the base unit for length (m) divided by the base unit for time (s). (Derived units that occur as a ratio of two or more base units can be used as conversion factors.) For quantities that are much smaller or much larger than the base unit, we use decimal prefixes and exponential (scientific) notation. Table 1.3 shows the most important prefixes. (If

Table 1.2 SI Base Units

Physical Quantity (Dimension)	Unit Name	Unit Abbreviation
Mass	kilogram	kg
Length	meter	m
Time	second	s
Temperature	kelvin	K
Electric current	ampere	A
Amount of substance	mole	mol
Luminous intensity	candela	cd

Table 1.3 Common Decimal Prefixes Used with SI Units

Prefix*	Prefix Symbol	Word	Conventional Notation	Exponential Notation
tera	T	trillion	1,000,000,000,000	1×10^{12}
giga	G	billion	1,000,000,000	1×10^{9}
mega	M	million	1,000,000	1×10^{6}
kilo	k	thousand	1,000	1×10^{3}
hecto	h	hundred	100	1×10^{2}
deka	da	ten	10	1×10^{1}
—	—	one	1	1×10^{0}
deci	d	tenth	0.1	1×10^{-1}
centi	c	hundredth	0.01	1×10^{-2}
milli	m	thousandth	0.001	1×10^{-3}
micro	μ	millionth	0.000001	1×10^{-6}
nano	n	billionth	0.000000001	1×10^{-9}
pico	p	trillionth	0.000000000001	1×10^{-12}
femto	f	quadrillionth	0.000000000000001	1×10^{-15}

*The prefixes most frequently used by chemists appear in bold type.

you need a review of exponential notation, read Appendix A.) Because these prefixes are based on powers of 10, SI units are easier to use in calculations than are English units such as pounds and inches.

Some Important SI Units in Chemistry

Let's discuss some of the SI units for quantities that we use early in the text: length, volume, mass, density, temperature, and time. (Units for other quantities are presented in later chapters, as they are used.) Table 1.4 shows some useful SI quantities for length, volume, and mass, along with their equivalents in the English system.

Table 1.4 Common SI-English Equivalent Quantities

Quantity	SI	SI Equivalents	English Equivalents	English to SI Equivalent
Length	1 kilometer (km)	1000 (10^3) meters	0.6214 mile (mi)	1 mile = 1.609 km
	1 meter (m)	100 (10^2) centimeters	1.094 yards (yd)	1 yard = 0.9144 m
		1000 millimeters (mm)	39.37 inches (in)	1 foot (ft) = 0.3048 m
	1 centimeter (cm)	0.01 (10^{-2}) meter	0.3937 inch	1 inch = 2.54 cm (exactly)
Volume	1 cubic meter (m^3)	1,000,000 (10^6) cubic centimeters	35.31 cubic feet (ft^3)	1 cubic foot = 0.02832 m^3
	1 cubic decimeter (dm^3)	1000 cubic centimeters	0.2642 gallon (gal)	1 gallon = 3.785 dm^3
			1.057 quarts (qt)	1 quart = 0.9464 dm^3
				1 quart = 946.4 cm^3
	1 cubic centimeter (cm^3)	0.001 dm^3	0.03381 fluid ounce	1 fluid ounce = 29.57 cm^3
Mass	1 kilogram (kg)	1000 grams	2.205 pounds (lb)	1 pound = 0.4536 kg
	1 gram (g)	1000 milligrams (mg)	0.03527 ounce (oz)	1 ounce = 28.35 g

Length The SI base unit of length is the **meter (m).** The standard meter is now based on two quantities, the speed of light in a vacuum and the second. A meter is a little longer than a yard (1 m = 1.094 yd); a centimeter (10^{-2} m) is about two-fifths of an inch (1 cm = 0.3937 in; 1 in = 2.54 cm). Biological cells are often measured in micrometers (1 μm = 10^{-6} m). On the atomic-size scale, nanometers and picometers are used (1 nm = 10^{-9} m; 1 pm = 10^{-12} m). Many proteins have diameters of around 2 nm; atomic diameters are around 200 pm (0.2 nm). An older unit still in use is the angstrom (1 Å = 10^{-10} m = 0.1 nm = 100 pm).

Volume Any sample of matter has a certain **volume (*V*),** the amount of space that the sample occupies. The SI unit of volume is the **cubic meter (m^3).** In chemistry, the most important volume units are non-SI units, the **liter (L)** and the **milliliter (mL)** (note the uppercase L). Physicians and other medical practitioners measure body fluids in cubic decimeters (dm^3), which is equivalent to liters:

$$1\ L = 1\ dm^3 = 10^{-3}\ m^3$$

As the prefix *milli-* indicates, 1 mL is $\frac{1}{1000}$ of a liter, and it is equal to exactly 1 cubic centimeter (cm^3):

$$1\ mL = 1\ cm^3 = 10^{-3}\ dm^3 = 10^{-3}\ L = 10^{-6}\ m^3$$

A liter is slightly larger than a quart (qt) (1 L = 1.057 qt; 1 qt = 946.4 mL); 1 fluid ounce ($\frac{1}{32}$ of a quart) equals 29.57 mL (29.57 cm^3).

How Long Is a Meter? The history of the meter exemplifies the ongoing drive to define units based on unchanging standards. The French scientists who set up the metric system defined the meter as 1/10,000,000 the distance from the equator (through Paris!) to the North Pole. The meter was later redefined as the distance between two fine lines engraved on a corrosion-resistant metal bar kept at the International Bureau of Weights and Measures in France. Fear that the bar would be damaged by war led to the adoption of an exact, unchanging, universally available atomic standard: 1,650,763.73 wavelengths of orange-red light from electrically excited krypton atoms. The current standard is even more reliable: 1 meter is the distance light travels in a vacuum in 1/299,792,458 second.

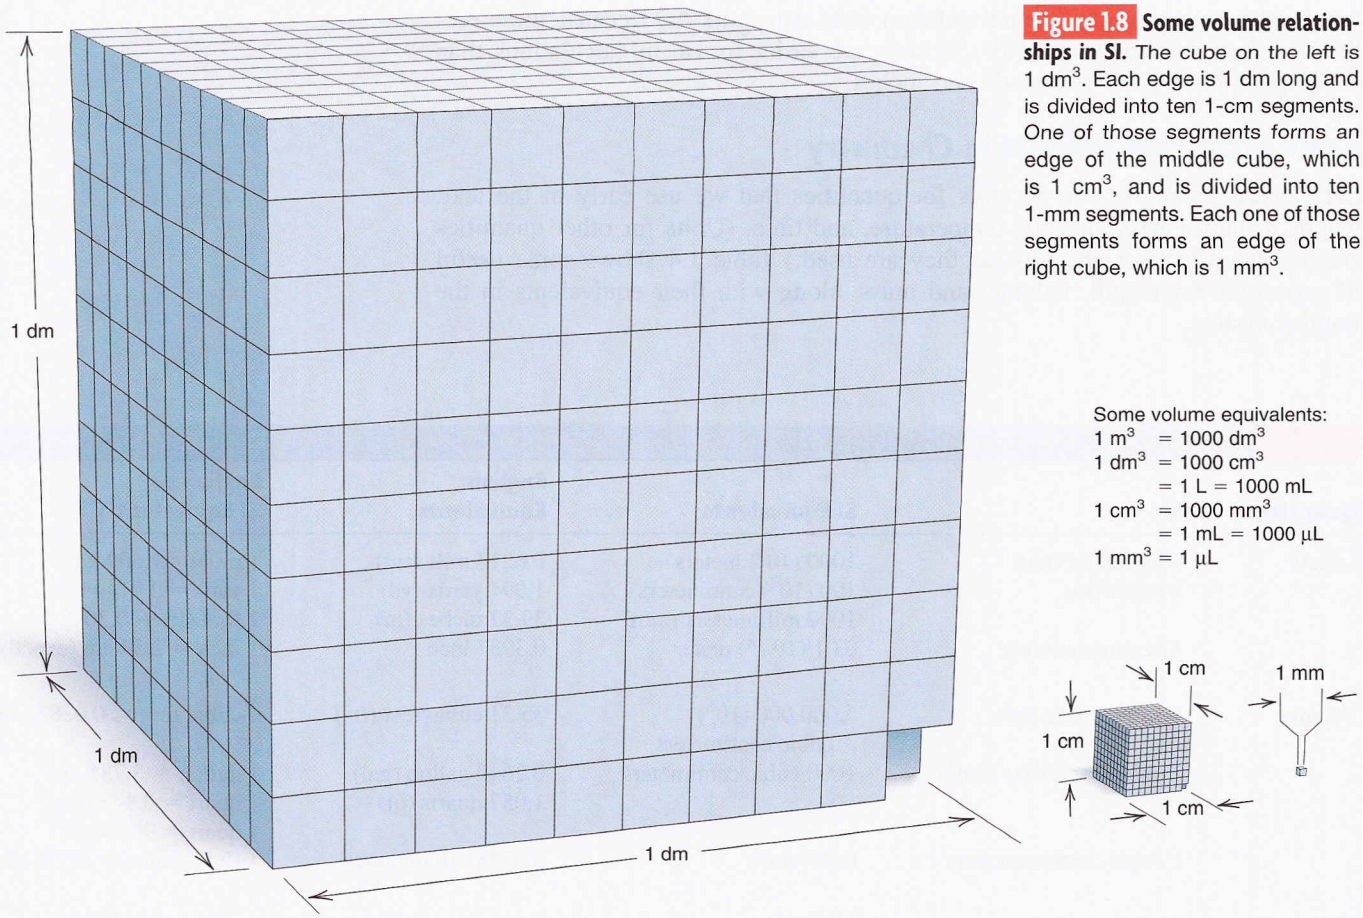


Figure 1.8 Some volume relationships in SI. The cube on the left is 1 dm^3. Each edge is 1 dm long and is divided into ten 1-cm segments. One of those segments forms an edge of the middle cube, which is 1 cm^3, and is divided into ten 1-mm segments. Each one of those segments forms an edge of the right cube, which is 1 mm^3.

Figure 1.8 is a life-size depiction of the 1000-fold decreases in volume from the cubic decimeter to the cubic millimeter. The edge of a cubic meter would be about 2.5 times the width of this textbook when open.

Figure 1.9 shows some of the types of laboratory glassware designed to contain liquids or measure their volumes. Many come in sizes from a few milliliters to a few liters. Erlenmeyer flasks and beakers are used to contain liquids. Graduated cylinders, pipets, and burets are used to measure and transfer liquids. Volumetric flasks and many pipets have a fixed volume indicated by a mark on the neck. In quantitative work, liquid solutions are prepared in volumetric flasks,

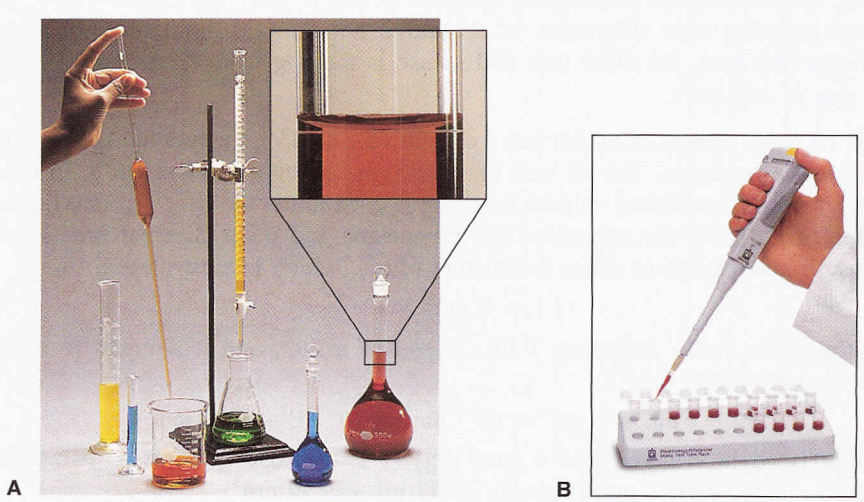

Figure 1.9 Common laboratory volumetric glassware. A, From left to right are two graduated cylinders, a pipet being emptied into a beaker, a buret delivering liquid to an Erlenmeyer flask, and two volumetric flasks. **Inset,** In contact with glass, this liquid forms a concave meniscus (curved surface). **B,** Automatic pipets deliver a given volume of liquid.

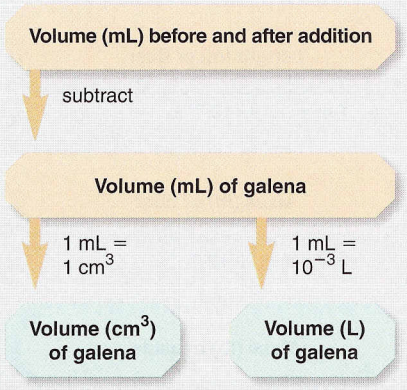
measured in cylinders, pipets, and burets, and then transferred to beakers or flasks for further chemical operations. Automatic pipets transfer a given volume of liquid accurately and quickly.

SAMPLE PROBLEM 1.3 Converting Units of Volume

Problem The volume of an irregularly shaped solid can be determined from the volume of water it displaces. A graduated cylinder contains 19.9 mL of water. When a small piece of galena, an ore of lead, is added, it sinks and the volume increases to 24.5 mL. What is the volume of the piece of galena in cm^3 and in L?

Plan We have to find the volume of the galena from the change in volume of the cylinder contents. The volume of galena in mL is the difference in the known volumes before and after adding it. The units mL and cm^3 represent identical volumes, so the volume of the galena in mL equals the volume in cm^3. We construct a conversion factor to convert the volume from mL to L. The calculation steps are shown in the roadmap.



Solution Finding the volume of galena:

$$\text{Volume (mL)} = \text{volume after} - \text{volume before} = 24.5\ \text{mL} - 19.9\ \text{mL} = 4.6\ \text{mL}$$

Converting the volume from mL to cm^3:

$$\text{Volume } (cm^3) = 4.6\ \cancel{\text{mL}} \times \frac{1\ cm^3}{1\ \cancel{\text{mL}}} = 4.6\ cm^3$$

Converting the volume from mL to L:

$$\text{Volume (L)} = 4.6\ \cancel{\text{mL}} \times \frac{10^{-3}\ \text{L}}{1\ \cancel{\text{mL}}} = 4.6\times10^{-3}\ \text{L}$$

Check The units and magnitudes of the answers seem correct. It makes sense that the volume expressed in mL would have a number 1000 times larger than the volume expressed in L, because a milliliter is $\frac{1}{1000}$ of a liter.

FOLLOW-UP PROBLEM 1.3 Within a cell, proteins are synthesized on particles called ribosomes. Assuming ribosomes are generally spherical, what is the volume (in dm^3 and μL) of a ribosome whose average diameter is 21.4 nm (V of a sphere $= \frac{4}{3}\pi r^3$)?

Mass The **mass** of an object refers to the quantity of matter it contains. The SI unit of mass is the **kilogram (kg),** the only base unit whose standard is a physical object—a platinum-iridium cylinder kept in France. It is also the only base unit whose name has a prefix. (In contrast to the practice with other base units, however, we attach prefixes to the word "gram," as in "microgram," rather than to the word "kilogram"; thus, we never say "microkilogram.")

The terms *mass* and *weight* have distinct meanings. Since a given object's quantity of matter cannot change, its *mass is constant.* Its **weight,** on the other hand, depends on its mass *and* the strength of the local gravitational field pulling on it. Because the strength of this field varies with height above the Earth's surface, the object's weight also varies. For instance, you actually weigh slightly less on a high mountaintop than at sea level.

Does this mean that if you weighed an object on a laboratory balance in Miami (sea level) and in Denver (about 1.7 km above sea level), you would obtain different results? Fortunately not. Such balances are designed to measure mass rather than weight, so this chaotic situation does not occur. (We are actually "massing" an object when we weigh it on a balance, but we rarely use that term.) Mechanical balances compare the object's unknown mass with known masses built into the balance, so the local gravitational field pulls equally on them. Electronic (analytical) balances determine mass by generating an electric field that counteracts the local gravitational field. The magnitude of the current needed to restore the pan to its zero position is then displayed as the object's mass. Therefore, an electronic balance must be readjusted with standard masses when it is moved to a different location.

SAMPLE PROBLEM 1.4 Converting Units of Mass

Problem International computer communications are often carried by optical fibers in cables laid along the ocean floor. If one strand of optical fiber weighs 1.19×10^{-3} lb/m, what is the mass (in kg) of a cable made of six strands of optical fiber, each long enough to link New York and Paris (8.84×10^{3} km)?

Plan We have to find the mass of cable (in kg) from the given mass/length of fiber, number of fibers/cable, and the length (distance from New York to Paris). One way to do this (as shown in the roadmap) is to first find the mass of one fiber and then find the mass of cable. We convert the length of one fiber from km to m and then find its mass (in lb) by using the lb/m factor. The cable mass is six times the fiber mass, and finally we convert lb to kg.

Length (km) of fiber
↓ 1 km = 10^3 m
Length (m) of fiber
↓ 1 m = 1.19×10^{-3} lb
Mass (lb) of fiber
↓ 6 fibers = 1 cable
Mass (lb) of cable
↓ 2.205 lb = 1 kg
Mass (kg) of cable

Solution Converting the fiber length from km to m:

$$\text{Length (m) of fiber} = 8.84\times10^{3}\ \cancel{\text{km}} \times \frac{10^{3}\ \text{m}}{1\ \cancel{\text{km}}} = 8.84\times10^{6}\ \text{m}$$

Converting the length of one fiber to mass (lb):

$$\text{Mass (lb) of fiber} = 8.84\times10^{6}\ \cancel{\text{m}} \times \frac{1.19\times10^{-3}\ \text{lb}}{1\ \cancel{\text{m}}} = 1.05\times10^{4}\ \text{lb}$$

Finding the mass of the cable (lb):

$$\text{Mass (lb) of cable} = \frac{1.05\times10^{4}\ \text{lb}}{1\ \cancel{\text{fiber}}} \times \frac{6\ \cancel{\text{fibers}}}{1\ \text{cable}} = 6.30\times10^{4}\ \text{lb/cable}$$

Converting the mass of cable from lb to kg:

$$\text{Mass (kg) of cable} = \frac{6.30\times10^{4}\ \cancel{\text{lb}}}{1\ \text{cable}} \times \frac{1\ \text{kg}}{2.205\ \cancel{\text{lb}}} = 2.86\times10^{4}\ \text{kg/cable}$$

Check The units are correct. Let's think through the relative sizes of the answers to see if they make sense: The number of m should be 10^3 larger than the number of km. If 1 m of fiber weighs about 10^{-3} lb, about 10^7 m should weigh about 10^4 lb. The cable mass should be six times as much, or about 6×10^4 lb. Since 1 lb is about $\frac{1}{2}$ kg, the number of kg should be about half the number of lb.

Comment Actually, the pound (lb) is the English unit of *weight*, not *mass*. The English unit of mass, called the *slug*, is rarely used.

FOLLOW-UP PROBLEM 1.4 An intravenous bag delivers a nutrient solution to a hospital patient at a rate of 1.5 drops per second. If a drop weighs 65 mg on average, how many kilograms of solution are delivered in 8.0 h?

Figure 1.10 shows the ranges of some common lengths, volumes, and masses.

Density The **density** (*d*) of an object is its mass divided by its volume:

$$\text{Density} = \frac{\text{mass}}{\text{volume}} \tag{1.1}$$

Whenever needed, you can isolate mathematically each of the component variables by treating density as a conversion factor:

$$\text{Mass} = \text{volume} \times \text{density} = \cancel{\text{volume}} \times \frac{\text{mass}}{\cancel{\text{volume}}}$$

Or,

$$\text{Volume} = \text{mass} \times \frac{1}{\text{density}} = \cancel{\text{mass}} \times \frac{\text{volume}}{\cancel{\text{mass}}}$$

Under given conditions of temperature and pressure, *density is a characteristic physical property of a substance* and has a specific value, even though the separate values of mass and volume vary. Mass and volume are examples of **extensive properties,** those dependent on the amount of substance present. Density, on the other hand, is an **intensive property,** one that is independent of the amount of substance present. For example, the mass of a gallon of water is four times the mass of a quart of water, but its volume is also four times greater; therefore, the

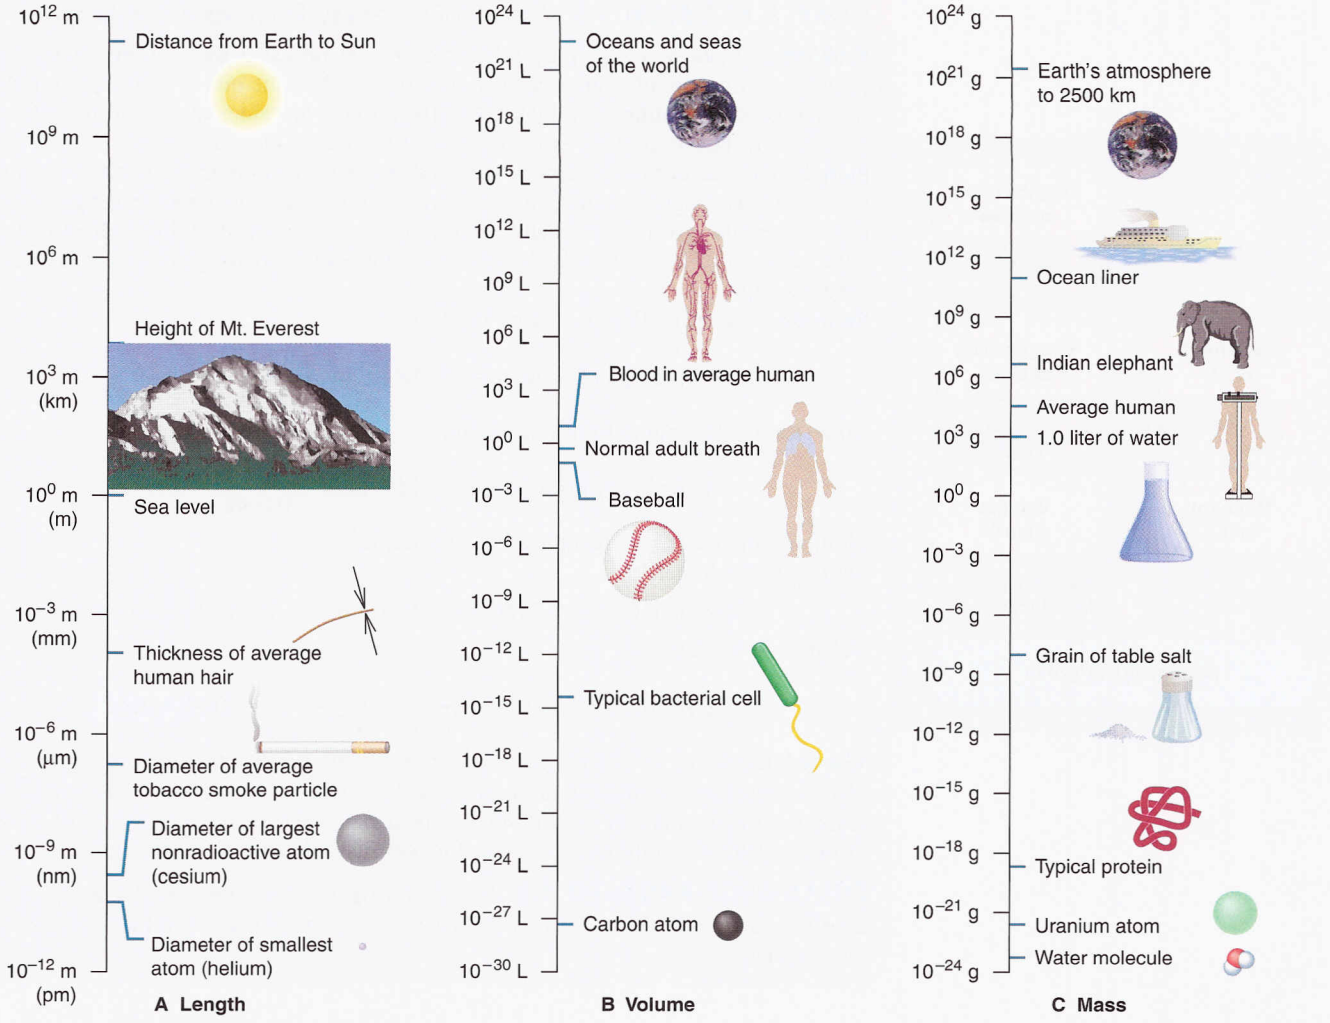


Figure 1.10 Some interesting quantities of length (A), volume (B), and mass (C). Note that the scales are exponential.

density of the water, the *ratio* of its mass to its volume, is constant at a particular temperature and pressure, regardless of the sample size.

The SI unit of density is the kilogram per cubic meter (kg/m^3), but in chemistry, density is typically given in units of g/L (g/dm^3) or g/mL (g/cm^3). For example, the density of liquid water at ordinary pressure and room temperature (20°C) is 1.0 g/mL. The densities of some common substances are given in Table 1.5. As you might expect from the magnified views of the physical states (see Figure 1.2), the densities of gases are much lower than those of liquids or solids.

Table 1.5 Densities of Some Common Substances*

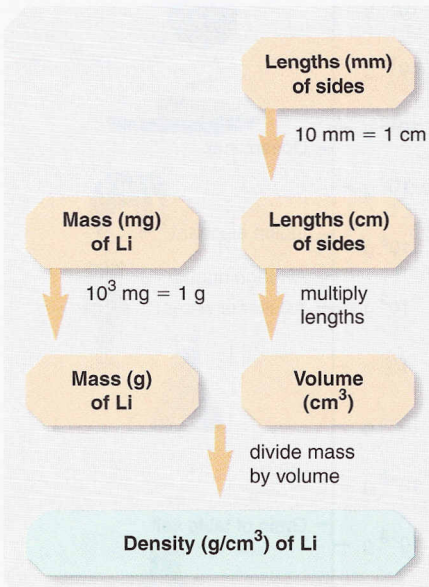
Substance	Physical State	Density (g/cm^3)
Hydrogen	gas	0.0000899
Oxygen	gas	0.00133
Grain alcohol	liquid	0.789
Water	liquid	0.998
Table salt	solid	2.16
Aluminum	solid	2.70
Lead	solid	11.3
Gold	solid	19.3

*At room temperature (20°C) and normal atmospheric pressure (1 atm).

SAMPLE PROBLEM 1.5 Calculating Density from Mass and Length

Problem Lithium is a soft, gray solid that has the lowest density of any metal. It is an essential component of some advanced batteries, such as the one in your laptop. If a small rectangular slab of lithium weighs 1.49×10^3 mg and has sides that measure 20.9 mm by 11.1 mm by 11.9 mm, what is the density of lithium in g/cm^3?

Plan To find the density in g/cm^3, we need the mass of lithium in g and the volume in cm^3. The mass is given in mg, so we convert mg to g. Volume data are not given, but we can convert the given side lengths from mm to cm, and then multiply them to find the volume in cm^3. Finally, we divide mass by volume to get density. The steps are shown in the roadmap.



Solution Converting the mass from mg to g:

$$\text{Mass (g) of lithium} = 1.49\times10^3\ \cancel{\text{mg}}\left(\frac{10^{-3}\ \text{g}}{1\ \cancel{\text{mg}}}\right) = 1.49\ \text{g}$$

Converting side lengths from mm to cm:

$$\text{Length (cm) of one side} = 20.9\ \cancel{\text{mm}}\times\frac{1\ \text{cm}}{10\ \cancel{\text{mm}}} = 2.09\ \text{cm}$$

Similarly, the other side lengths are 1.11 cm and 1.19 cm.

Finding the volume:

$$\text{Volume (cm}^3\text{)} = 2.09\ \text{cm}\times1.11\ \text{cm}\times1.19\ \text{cm} = 2.76\ \text{cm}^3$$

Calculating the density:

$$\text{Density of lithium} = \frac{\text{mass}}{\text{volume}} = \frac{1.49\ \text{g}}{2.76\ \text{cm}^3} = 0.540\ \text{g/cm}^3$$

Check Since 1 cm = 10 mm, the number of cm in each length should be $\frac{1}{10}$ the number of mm. The units for density are correct, and the size of the answer (~0.5 g/cm^3) seems correct since the number of g (1.49) is about half the number of cm^3 (2.76). Since the problem states that lithium has a very low density, this answer makes sense.

FOLLOW-UP PROBLEM 1.5 The piece of galena in Sample Problem 1.3 has a volume of 4.6 cm^3. If the density of galena is 7.5 g/cm^3, what is the mass (in kg) of that piece of galena?

Temperature There is a common misunderstanding about heat and temperature. **Temperature** (***T***) is a measure of how hot or cold a substance is *relative to another substance*. **Heat** is the energy that flows between objects that are at different temperatures. Temperature is related to the *direction* of that energy flow: when two objects at different temperatures touch, energy flows from the one with the higher temperature to the one with the lower temperature until their temperatures are equal. When you hold an ice cube, its "cold" seems to flow *into* your hand; actually, heat flows *from* your hand into the ice. (In Chapter 6, we will see how heat is measured and how it is related to chemical and physical change.) Energy is an *extensive* property (as is volume), but temperature is an *intensive* property (as is density): a vat of boiling water has more energy than a cup of boiling water, but the temperatures of the two water samples are the same.

In the laboratory, the most common means for measuring temperature is the **thermometer,** a device that contains a fluid that expands when it is heated. When the thermometer's fluid-filled bulb is immersed in a substance hotter than itself, heat flows from the substance through the glass and into the fluid, which expands and rises in the thermometer tube. If a substance is colder than the thermometer, heat flows outward from the fluid, which contracts and falls within the tube.

The three temperature scales most important for us to consider are the Celsius (°C, formerly called centigrade), the Kelvin (K), and the Fahrenheit (°F)

scales. The SI base unit of temperature is the **Kelvin (K);** note that the kelvin has no degree sign (°). Figure 1.11 shows some interesting temperatures in this scale. The Kelvin scale, also known as the *absolute scale,* is preferred in all scientific work, although the Celsius scale is used frequently. In the United States, the Fahrenheit scale is still used for weather reporting, body temperature, and other everyday purposes. *The three scales differ in the size of the unit and/or the temperature of the zero point.* Figure 1.12 shows the freezing and boiling points of water in the three scales.

The **Celsius scale,** devised in the 18th century by the Swedish astronomer Anders Celsius, is based on changes in the physical state of water: 0°C is set at water's freezing point, and 100°C is set at its boiling point (at normal atmospheric pressure). The **Kelvin (absolute) scale** was devised by the English physicist William Thomson, known as Lord Kelvin, in 1854 during his experiments on the expansion and contraction of gases. *The Kelvin scale uses the same size degree unit as the Celsius scale*—$\frac{1}{100}$ of the difference between the freezing and boiling points of water—*but it differs in zero point.* The zero point in the Kelvin scale, 0 K, is called *absolute zero* and equals −273.15°C. In the Kelvin scale, *all temperatures have positive values.* Water freezes at +273.15 K (0°C) and boils at +373.15 K (100°C).

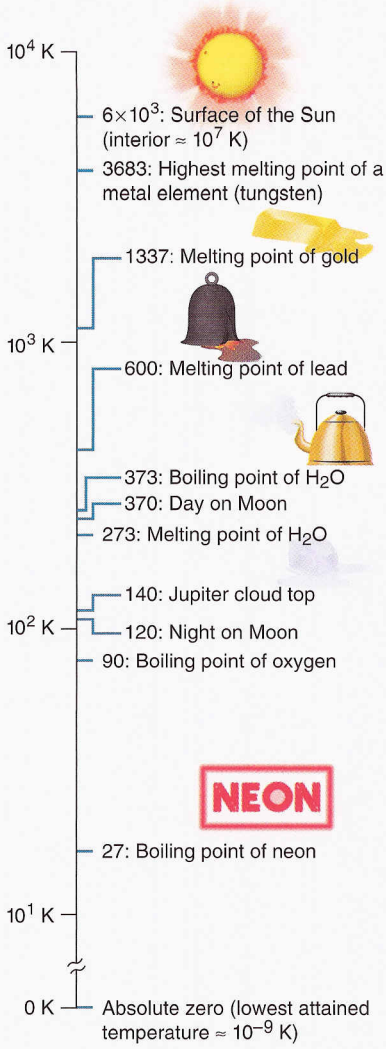


Figure 1.11 Some interesting temperatures.

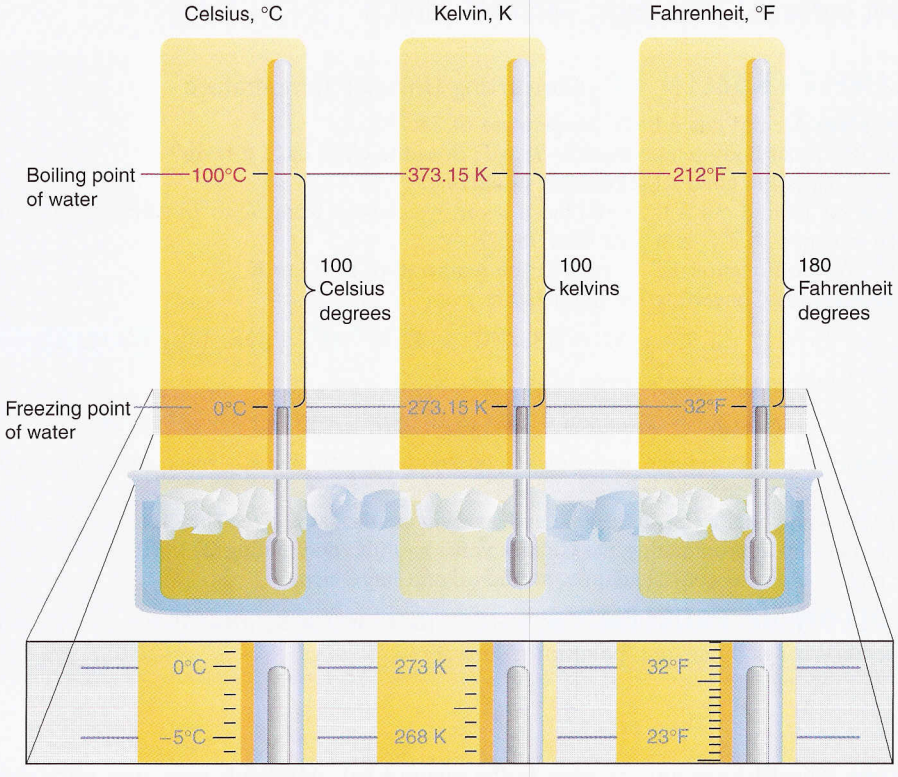

Figure 1.12 The freezing point and the boiling point of water in the Celsius, Kelvin (absolute), and Fahrenheit temperature scales. As you can see, this range consists of 100 degrees on the Celsius and Kelvin scales, but 180 degrees on the Fahrenheit scale. At the bottom of the figure, a portion of each of the three thermometer scales is expanded to show the sizes of the units. A Celsius degree (°C; *left*) and a kelvin (K; *center*) are the same size, and each is $\frac{9}{5}$ the size of a Fahrenheit degree (°F; *right*).

We can convert between the Celsius and Kelvin scales by remembering the difference in zero points: since 0°C = 273.15 K,

$$T \text{ (in K)} = T \text{ (in °C)} + 273.15 \quad (1.2)$$

Solving Equation 1.2 for T (in °C) gives

$$T \text{ (in °C)} = T \text{ (in K)} - 273.15 \quad (1.3)$$

The Fahrenheit scale differs from the other scales in its zero point *and* in the size of its unit. Water freezes at 32°F and boils at 212°F. Therefore, 180 Fahrenheit degrees (212°F − 32°F) represents the same temperature change as 100 Celsius degrees (or 100 kelvins). Because 100 Celsius degrees equal 180 Fahrenheit degrees,

$$1 \text{ Celsius degree} = \tfrac{180}{100} \text{ Fahrenheit degrees} = \tfrac{9}{5} \text{ Fahrenheit degrees}$$

To convert a temperature in °C to °F, first change the degree size and then adjust the zero point:

$$T \text{ (in °F)} = \tfrac{9}{5}T \text{ (in °C)} + 32 \quad (1.4)$$

To convert a temperature in °F to °C, do the two steps in the opposite order; that is, first adjust the zero point and then change the degree size. In other words, solve Equation 1.4 for T (in °C):

$$T \text{ (in °C)} = [T \text{ (in °F)} - 32]\tfrac{5}{9} \quad (1.5)$$

(The only temperature with the same numerical value in the Celsius and Fahrenheit scales is −40°; that is, −40°F = −40°C.)

SAMPLE PROBLEM 1.6 Converting Units of Temperature

Problem A child has a body temperature of 38.7°C.
(a) If normal body temperature is 98.6°F, does the child have a fever?
(b) What is the child's temperature in kelvins?

Plan **(a)** To find out if the child has a fever, we convert from °C to °F (Equation 1.4) and see whether 38.7°C is higher than 98.6°F.
(b) We use Equation 1.2 to convert the temperature in °C to K.

Solution **(a)** Converting the temperature from °C to °F:

$$T \text{ (in °F)} = \tfrac{9}{5}T \text{ (in °C)} + 32 = \tfrac{9}{5}(38.7\text{°C}) + 32 = 101.7\text{°F; yes, the child has a fever.}$$

(b) Converting the temperature from °C to K:

$$T \text{ (in K)} = T \text{ (in °C)} + 273.15 = 38.7\text{°C} + 273.15 = 311.8 \text{ K}$$

Check **(a)** From everyday experience, you know that 101.7°F is a reasonable temperature for someone with a fever.
(b) We know that a Celsius degree and a kelvin are the same size. Therefore, we can check the math by approximating the Celsius value as 40°C and adding 273: 40 + 273 = 313, which is close to our calculation, so there is no large errror.

FOLLOW-UP PROBLEM 1.6 Mercury melts at 234 K, lower than any other pure metal. What is its melting point in °C and °F?

Time The SI base unit of time is the **second (s).** Although time was once measured by the day and year, it is now based on an atomic standard: microwave radiation absorbed by cesium atoms (Figure 1.13). In the laboratory, we study the speed of a reaction by measuring the time it takes a fixed amount of substance to undergo a chemical change. The range of reaction speed is enormous: a fast reaction may be over in less than a nanosecond (10^{-9} s), whereas slow ones, such as rusting or aging, take years. Chemists now use lasers to study changes that occur in a few picoseconds (10^{-12} s) or femtoseconds (10^{-15} s).

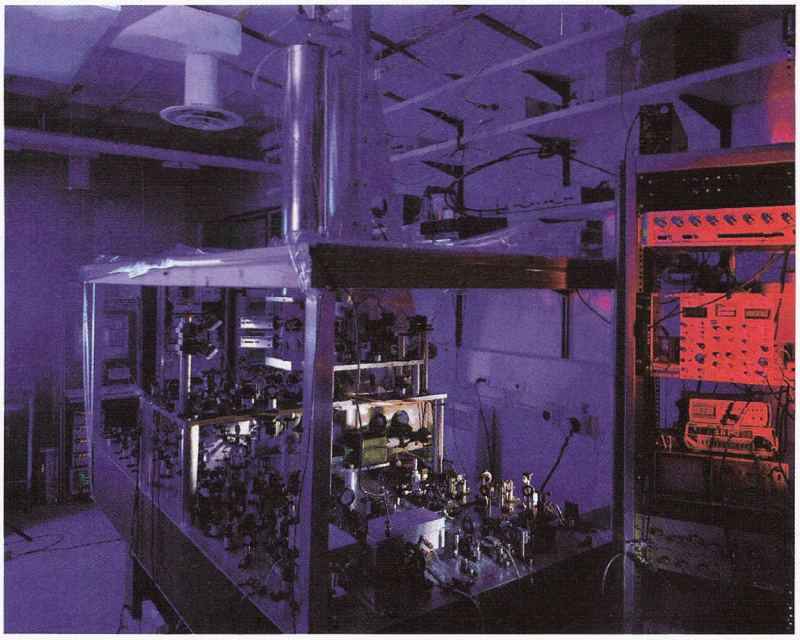

Figure 1.13 The cesium atomic clock. The accuracy of the best pendulum clock is to within 3 seconds per year and that of the best quartz clock is 1000 times greater. The most recent version of the atomic clock, NIST-F1, developed by the Physics Laboratory of the National Institute of Standards and Technology, is over 6000 times more accurate still, to within 1 second in 20 million years! Rather than using the oscillations of a pendulum, the atomic clock measures the oscillations of microwave radiation absorbed by gaseous cesium atoms: 1 second is defined as 9,192,631,770 of these oscillations. This new clock cools the cesium atoms with infrared lasers to around 10^{-6} K, which allows much longer observation times of the atoms, and thus much greater accuracy.

SECTION SUMMARY

SI units consist of seven base units and numerous derived units. Exponential notation and prefixes based on powers of 10 are used to express very small and very large numbers. The SI base unit of length is the meter (m). Length units on the atomic scale are the nanometer (nm) and picometer (pm). Volume units are derived from length units; the most important volume units in chemistry are the cubic meter (m^3) and the liter (L). The mass of an object, a measure of the quantity of matter present in it, is constant. The SI unit of mass is the kilogram (kg). The weight of an object varies with the gravitational field influencing it. Density (d) is the ratio of mass to volume of a substance and is one of its characteristic physical properties. Temperature (T) is a measure of the relative hotness of an object. Heat is energy that flows from an object at higher temperature to one at lower temperature. Temperature scales differ in the size of the degree unit and/or the zero point. In chemistry, temperature is measured in kelvins (K) or degrees Celsius (°C). Extensive properties, such as mass, volume, and energy, depend on the amount of a substance. Intensive properties, such as density and temperature, are independent of amount.

The Central Importance of Measurement in Science It's important to keep in mind *why* scientists measure things: "When you can measure what you are speaking about, and express it in numbers, you know something about it; but when you cannot measure it, . . . your knowledge is of a meager and unsatisfactory kind; it may be the beginning of knowledge, but you have scarcely, in your thoughts, advanced to the stage of science" (William Thomson, Lord Kelvin, 1824–1907).

1.6 UNCERTAINTY IN MEASUREMENT: SIGNIFICANT FIGURES

We can never measure a quantity exactly, because measuring devices are made to limited specifications and we use our imperfect senses and skills to read them. Therefore, every measurement we make includes some **uncertainty.**

The measuring device we choose in a given situation depends on how much uncertainty we are willing to accept. When you buy potatoes, a supermarket scale that measures in 0.1-kg increments is perfectly acceptable; it tells you that the mass is, for example, 2.0 ± 0.1 kg. The term "± 0.1 kg" expresses the uncertainty in the measurement: the potatoes weigh between 1.9 and 2.1 kg. For a large-scale reaction, a chemist uses a lab balance that measures in 0.001-kg increments in order to obtain 2.036 ± 0.001 kg of a chemical, that is, between 2.035 and 2.037 kg. The greater number of digits in the mass of the chemical indicates that we know its mass with *more certainty* than we know the mass of the potatoes.

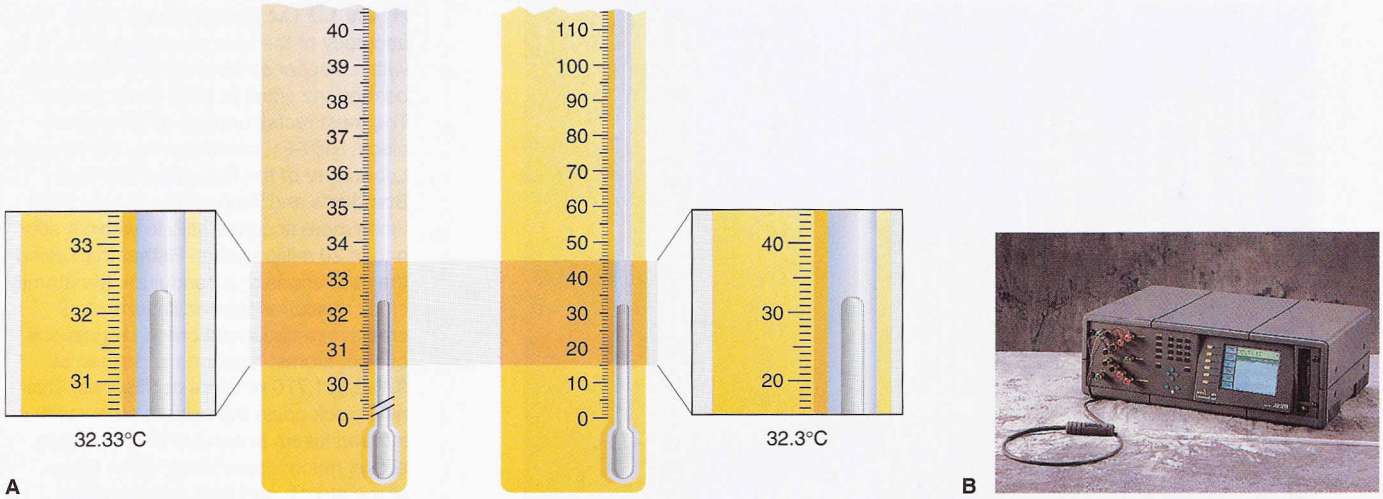

Figure 1.14 The number of significant figures in a measurement depends on the measuring device. A, Two thermometers measuring the same temperature are shown with expanded views. The thermometer on the left is graduated in 0.1°C and reads 32.33°C; the one on the right is graduated in 1°C and reads 32.3°C. Therefore, a reading with more significant figures (more certainty) can be made with the thermometer on the left. **B,** This modern electronic thermometer measures the resistance through a fine platinum wire in the probe to determine temperatures to the nearest microkelvin (10^{-6} K).

We *always estimate the rightmost digit* when reading a measuring device. The uncertainty can be expressed with the ± sign, but generally we drop the sign and *assume an uncertainty of one unit in the rightmost digit.* The digits we record in a measurement, both the certain and the uncertain ones, are called **significant figures.** There are four significant figures in 2.036 kg and two in 2.0 kg. *The greater the number of significant figures in a measurement, the greater is the certainty.* Figure 1.14 shows this point for two thermometers.

Determining Which Digits Are Significant

When you take measurements or use them in calculations, you must know the number of digits that are significant. In general, *all digits are significant, except zeros that are not measured but are used only to position the decimal point.* Here is a simple procedure that applies this general point:

1. Make sure that the measured quantity has a decimal point.
2. Start at the left of the number and move right until you reach the first nonzero digit.
3. Count that digit and every digit to its right as significant.

Sometimes, there may be a slight complication with zeros that *end* a number. Zeros that end a number and lie either after or before the decimal point *are* significant; thus, 1.030 mL has four significant figures, and 5300. L has four significant figures also. The problem arises if there is no decimal point, as in 5300 L. In such cases, we would assume that the zeros are *not* significant; exponential notation is needed to show which of the zeros, if any, were measured and therefore are significant. Thus, 5.300×10^3 L has four significant figures, 5.30×10^3 L has three, and 5.3×10^3 L has only two. In this and other modern texts (and research articles), a terminal decimal point is used when necessary to clarify the number of significant figures; thus, 500 mL has one significant figure, but 5.00×10^2 mL, 500. mL, and 0.500 L have three.

SAMPLE PROBLEM 1.7 Determining the Number of Significant Figures

Problem For each of the following quantities, underline the zeros that are significant figures (sf), and determine the number of significant figures in each quantity. For **(d)** to **(f)**, express each in exponential notation first.

(a) 0.0030 L **(b)** 0.1044 g **(c)** 53,069 mL
(d) 0.00004715 m **(e)** 57,600. s **(f)** 0.0000007160 cm^3

Plan We determine the number of significant figures by counting digits, as just presented, paying particular attention to the position of zeros in relation to the decimal point.

Solution **(a)** 0.00<u>3</u>0 L has 2 sf

(b) 0.1<u>0</u>44 g has 4 sf

(c) 53,<u>0</u>69 mL has 5 sf

(d) 0.00004715 m, or 4.715×10^{-5} m, has 4 sf

(e) 57,6<u>00</u>. s, or $5.76\underline{00}\times10^{4}$ s, has 5 sf

(f) 0.000000716<u>0</u> cm^3, or $7.16\underline{0}\times10^{-7}$ cm^3, has 4 sf

Check Be sure that every zero counted as significant comes after nonzero digit(s) in the number.

FOLLOW-UP PROBLEM 1.7 For each of the following quantities, underline the zeros that are significant figures and determine the number of significant figures (sf) in each quantity. For **(d)** to **(f)**, express each in exponential notation first.

(a) 31.070 mg **(b)** 0.06060 g **(c)** 850.°C
(d) 200.0 mL **(e)** 0.0000039 m **(f)** 0.000401 L

Significant Figures in Calculations

Measurements often contain differing numbers of significant figures. In a calculation, we keep track of the number of significant figures in each quantity so that we don't claim more significant figures (more certainty) in the answer than in the original data. If we have too many significant figures, we **round off** the answer to obtain the proper number of them.

The general rule for rounding is that *the least certain measurement sets the limit on certainty for the entire calculation and determines the number of significant figures in the final answer.* Suppose you want to find the density of a new ceramic. You measure the mass of a piece on an analytical balance and obtain 3.8056 g; you measure its volume as 2.5 mL by displacement of water in a graduated cylinder. The mass has five significant figures, but the volume has only two. Should you report the density as 3.8056 g/2.5 mL = 1.5222 g/mL or as 1.5 g/mL? The answer with five significant figures implies more certainty than the answer with two. But you didn't measure the volume to five significant figures, so you can't possibly know the density with that much certainty. Therefore, you report the answer as 1.5 g/mL.

Significant Figures and Arithmetic Operations The following two rules tell how many significant figures to show based on the arithmetic operation:

1. *For multiplication and division.* The answer contains the same number of *significant figures* as in the measurement with the fewest significant figures. Suppose you want to find the volume of a sheet of a new graphite composite. The length (9.2 cm) and width (6.8 cm) are obtained with a meterstick and the thickness (0.3744 cm) with a set of fine calipers. The volume calculation is

$$\text{Volume } (cm^3) = 9.2 \text{ cm} \times 6.8 \text{ cm} \times 0.3744 \text{ cm} = 23 \text{ } cm^3$$

The calculator shows 23.4225 cm^3, but you should report the answer as 23 cm^3, with two significant figures, because the length and width measurements determine the overall certainty, and they contain only two significant figures.

2. *For addition and subtraction.* The answer has the same number of *decimal places* as there are in the measurement with the fewest decimal places. Suppose you measure 83.5 mL of water in a graduated cylinder and add 23.28 mL of protein solution from a buret. The total volume is

$$\text{Volume (mL)} = 83.5 \text{ mL} + 23.28 \text{ mL} = 106.8 \text{ mL}$$

Here the calculator shows 106.78 mL, but you report the volume as 106.8 mL, with one decimal place, because the measurement with fewer decimal places (83.5 mL) has one decimal place.

Rules for Rounding Off In most calculations, you need to round off the answer to obtain the proper number of significant figures or decimal places. Notice that in calculating the volume of the graphite composite above, we removed the extra digits, but in calculating the total protein solution volume, we removed the extra digit and increased the last digit by one. Here are rules for rounding off:

1. If the digit removed is *more than 5,* the preceding number is increased by 1: 5.379 rounds to 5.38 if three significant figures are retained and to 5.4 if two significant figures are retained.

2. If the digit removed is *less than 5,* the preceding number is unchanged: 0.2413 rounds to 0.241 if three significant figures are retained and to 0.24 if two significant figures are retained.

3. If the digit removed *is 5,* the preceding number is increased by 1 if it is odd and remains unchanged if it is even: 17.75 rounds to 17.8, but 17.65 rounds to 17.6. If the 5 is followed only by zeros, rule 3 is followed; if the 5 is followed by nonzeros, rule 1 is followed: 17.6500 rounds to 17.6, but 17.6513 rounds to 17.7.

4. *Always carry one or two additional significant figures through a multistep calculation and round off the final answer* ***only.*** Don't be concerned if you string together a calculation to check a sample or follow-up problem and find that your answer differs in the last decimal place from the one in the book. To show you the correct number of significant figures in text calculations, we round off intermediate steps, and this process may sometimes change the last digit.

Significant Figures and Electronic Calculators A calculator usually gives answers with too many significant figures. For example, if your calculator displays ten digits and you divide 15.6 by 9.1, it will show 1.714285714. Obviously, most of these digits are not significant; the answer should be rounded off to 1.7 so that it has two significant figures, the same as in 9.1. A good way to prove to yourself that the additional digits are not significant is to perform two calculations, including the uncertainty in the last digits, to obtain the highest and lowest possible answers. For $(15.6 \pm 0.1)/(9.1 \pm 0.1)$,

The highest answer is $\frac{15.7}{9.0} = 1.744444\ldots$ The lowest answer is $\frac{15.5}{9.2} = 1.684782\ldots$

No matter how many digits the calculator displays, the values differ in the first decimal place, so the answer has two significant figures and should be reported as 1.7. Many calculators have a FIX button that allows you to set the number of digits displayed.

Significant Figures and Choice of Measuring Device The measuring device you choose determines the number of significant figures you can obtain. Suppose you are doing an experiment that requires mixing a liquid with a solid. You weigh the solid on the analytical balance and obtain a value with five significant figures. It would make sense to measure the liquid with a buret or pipet, which measures volumes to more significant figures than a graduated cylinder. If you chose the cylinder, you would have to round off more digits in the calculations, so the certainty in the mass value would be wasted (Figure 1.15). With experience, you'll choose a measuring device based on the number of significant figures you need in the final answer.

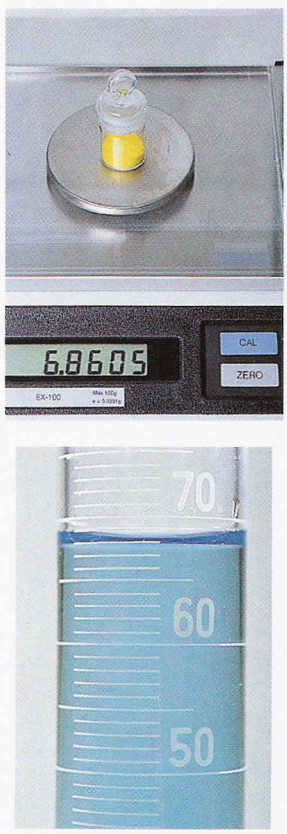

Figure 1.15 Significant figures and measuring devices. The mass (6.8605 g) measured with an analytical balance *(top)* has more significant figures than the volume (68.2 mL) measured with a graduated cylinder *(bottom).*

Exact Numbers Some numbers are called **exact numbers** because they have no uncertainty associated with them. Some exact numbers are part of a unit definition: there are 60 minutes in 1 hour, 1000 micrograms in 1 milligram, and 2.54 centimeters in 1 inch. Other exact numbers result from actually counting individual items: there are exactly 3 quarters in my hand, 26 letters in the English alphabet, and so forth. Since they have no uncertainty, *exact numbers do not limit the number of significant figures in the answer.* Put another way, exact numbers have as many significant figures as a calculation requires.

SAMPLE PROBLEM 1.8 Significant Figures and Rounding

Problem Perform the following calculations and round the answer to the correct number of significant figures:

(a) $\dfrac{16.3521\ \text{cm}^2 - 1.448\ \text{cm}^2}{7.085\ \text{cm}}$ **(b)** $\dfrac{(4.80\times10^4\ \text{mg})\left(\dfrac{1\ \text{g}}{1000\ \text{mg}}\right)}{11.55\ \text{cm}^3}$

Plan We use the rules just presented in the text. In **(a),** we subtract before we divide. In **(b),** we note that the unit conversion involves an exact number.

Solution **(a)** $\dfrac{16.3521\ \text{cm}^2 - 1.448\ \text{cm}^2}{7.085\ \text{cm}} = \dfrac{14.904\ \text{cm}^2}{7.085\ \text{cm}} = 2.104\ \text{cm}$

(b) $\dfrac{(4.80\times10^4\ \text{mg})\left(\dfrac{1\ \text{g}}{1000\ \text{mg}}\right)}{11.55\ \text{cm}^3} = \dfrac{48.0\ \text{g}}{11.55\ \text{cm}^3} = 4.16\ \text{g/cm}^3$

Check Note that in (a) we lose a decimal place in the numerator, and in (b) we retain 3 sf in the answer because there are 3 sf in 4.80. Rounding to the nearest whole number is always a good way to check: **(a)** $(16 - 1)/7 \approx 2$; **(b)** $(5\times10^4/1\times10^3)/12 \approx 4$.

FOLLOW-UP PROBLEM 1.8 Perform the following calculation and round the answer to the correct number of significant figures: $\dfrac{25.65\ \text{mL} + 37.4\ \text{mL}}{73.55\ \text{s}\left(\dfrac{1\ \text{min}}{60\ \text{s}}\right)}$

Precision, Accuracy, and Instrument Calibration

Precision and accuracy are two aspects of certainty. We often use these terms interchangeably in everyday speech, but in scientific measurements they have distinct meanings. **Precision,** or *reproducibility,* refers to how close the measurements in a series are to each other. **Accuracy** refers to how close a measurement is to the actual value.

Precision and accuracy are linked with two common types of error:

1. **Systematic error** produces values that are *either* all higher or all lower than the actual value. Such error is part of the experimental system, often caused by a faulty measuring device or by a consistent mistake in taking a reading.
2. **Random error,** in the absence of systematic error, produces values that are higher *and* lower than the actual value. Random error *always* occurs, but its size depends on the measurer's skill and the instrument's precision.

Precise measurements have low random error, that is, small deviations from the average. *Accurate measurements have low systematic error and, generally, low random error as well.* In some cases, when many measurements are taken that have a high random error, the *average* may still be accurate.

Suppose each of four students measures 25.0 mL of water in a pre-weighed graduated cylinder and then weighs the water *plus* cylinder on a balance. If the density of water is 1.00 g/mL at the temperature of the experiment, the actual mass of 25.0 mL of water is 25.0 g. Each student performs the operation four times, subtracts the mass of the empty cylinder, and obtains one of the four graphs

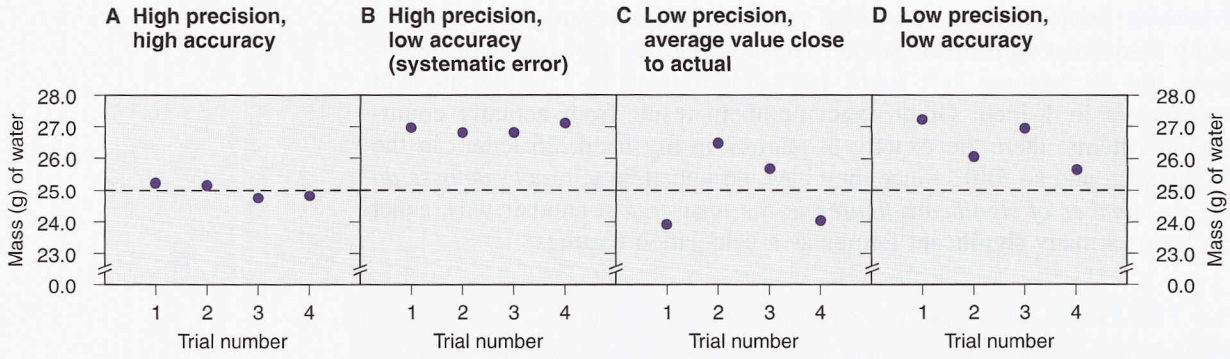

Figure 1.16 Precision and accuracy in a laboratory calibration. Each graph represents four measurements made with a graduated cylinder that is being calibrated (see text for details).

shown in Figure 1.16. In graphs A and B, the random error is small; that is, the precision is high (the weighings are reproducible). In A, however, the accuracy is high as well (all the values are close to 25.0 g), whereas in B the accuracy is low (there is a systematic error). In graphs C and D, there is a large random error; that is, the precision is low. Large random error is often called large *scatter*. Note, however, that in D there is also a systematic error (all the values are high), whereas in C the average of the values is close to the actual value.

Systematic error can be avoided, or at least taken into account, through **calibration** of the measuring device, that is, by comparing it with a known standard. The systematic error in graph B, for example, might be caused by a poorly manufactured cylinder that reads "25.0" when it actually contains about 27 mL. If you detect such an error by means of a calibration procedure, you could adjust all volumes measured with that cylinder. Instrument calibration is an essential part of careful measurement.

SECTION SUMMARY

Because the final digit of a measurement is estimated, all measurements have a limit to their certainty, which is expressed by the number of significant figures. The certainty of a calculated result depends on the certainty of the data, so the answer has as many significant figures as in the least certain measurement. Excess digits are rounded off in the final answer. The choice of laboratory device depends on the certainty needed. Exact numbers have as many significant figures as the calculation requires.

Precision (how close values are to each other) and accuracy (how close values are to the actual value) are two aspects of certainty. Systematic errors result in values that are either all higher or all lower than the actual value. Random errors result in some values that are higher and some values that are lower than the actual value. Precise measurements have low random error; accurate measurements have low systematic error and often low random error. The size of random errors depends on the skill of the measurer and the precision of the instrument. A systematic error, however, is often caused by faulty equipment and can be compensated for by calibration.

Chapter Perspective

This chapter has provided several keys for you to use repeatedly in your study of chemistry: descriptions of some essential concepts; insight into how scientists think; the units of modern measurement and the mathematical skills to apply them; and a systematic approach to solving problems. You can begin using these keys in the next chapter, where we discuss the components of matter and their classification and trace the winding path of scientific discovery that led to our current model of atomic structure.

Chemistry Problem Solving in the Real World

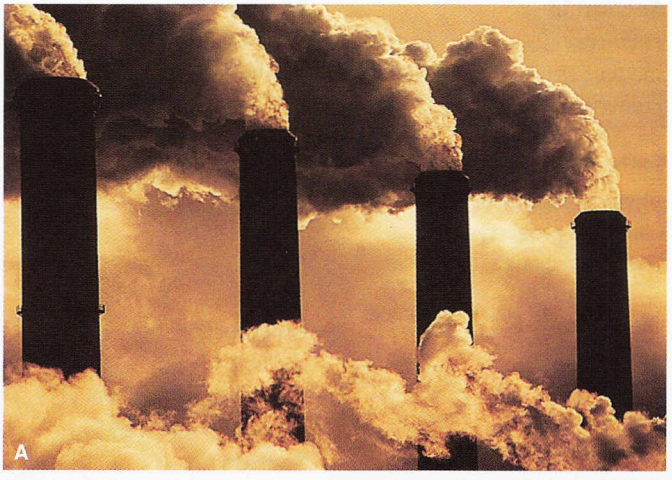
Learning chemistry is essential to many fields, including medicine, engineering, and environmental science. It is also essential to an understanding of complex science-related issues, such as the recycling of plastics, the reduction of urban smog, and the application of genetic cloning—to mention just three of many.

Any major scientific discipline such as chemistry consists of several subdisciplines that form connections with other sciences to spawn new fields. Traditionally, chemistry has five main branches—organic, inorganic, analytical, physical, and biological chemistry—but these long ago formed interconnections, such as physical organic and bioinorganic chemistry. Solving the problems of today requires further connections, such as ecological chemistry, materials science, atmospheric chemistry, and molecular genetics. The more complex the system under study is, the greater the need for interdisciplinary scientific thinking.

Environmental issues are especially complex, and one of the most intractable is the acid rain problem. Let's see how it is being approached by chemists interacting with scientists in related fields. Acid rain results in large part from burning high-sulfur coal, a major fuel used throughout much of North America and Europe. As the coal burns, the gaseous products, including an oxide of its sulfur impurities, are carried away by prevailing winds. In contact with oxygen and rain, this sulfur oxide undergoes chemical changes, yielding acid rain. (We discuss the chemical details in later chapters.) In the northeastern United States and adjacent parts of Canada, acid rain has killed fish, decimated forests, injured crops, and released harmful substances into the soil. Acid rain has severely damaged many forests and lakes in Germany, Sweden, Norway, and several countries in central and eastern Europe. And acidic precipitation has now been confirmed at both Poles!

Chemists and other scientists are currently working together to solve this problem (Figure B1.1). As geochemists search for low-sulfur coal deposits, their engineering colleagues design better ways of removing sulfur oxides from smokestack gases. Atmospheric chemists and meteorologists track changes through the affected regions, develop computer models to predict the changes, and coordinate their findings with environmental chemists at ground stations. Ecological chemists, microbiologists, and aquatic biologists monitor the effects of acid rain on microbes, insects, birds, and fish. Agricultural chemists and agronomists study ways to protect crop yields. Biochemists and genetic engineers develop new, more acid-resistant crop species. Soil chemists measure changes in mineral content, sharing their data with forestry scientists to save valuable timber and recreational woodlands. Organic chemists and chemical engineers convert coal to cleaner fuels. Working in tandem with this intense experimental activity are scientifically trained economic and policy experts who provide business and government leaders with the information to make decisions and foster "greener" approaches to energy use. With all this input, interdisciplinary understanding of the acid rain problem has increased enormously and certainly will continue to do so.

These professions are just a few of those involved in studying a single chemistry-related issue. Chemical principles apply to many other specialties, from medicine and pharmacology to art restoration and criminology, from genetics and space research to archaeology and oceanography. Chemistry problem solving has far-reaching relevance to many aspects of your daily life and your future career as well.



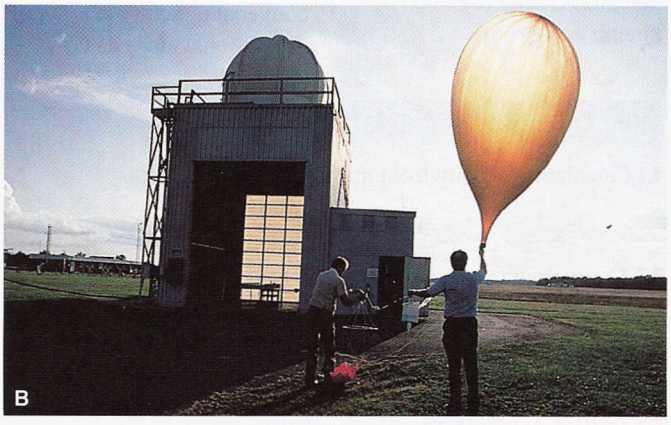


Figure B1.1 The central role of chemistry in solving real-world problems. Researchers in many chemical specialties join with those in other sciences to investigate complex modern issues such as acid rain. **A,** The sulfur oxide in power plant emissions will be reduced by devices that remove it from smokestack gases. **B,** Atmospheric chemists study the location and concentration of air pollutants with balloons that carry monitoring equipment aloft. **C,** Ecologists sample lake, pond, and river water and observe wildlife to learn the effects of acidic precipitation on aquatic environments.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The distinction between physical and chemical properties and changes (1.1; SP 1.1)
2. The defining features of the states of matter (1.1)
3. The nature of potential and kinetic energy and their interconversion (1.1)
4. The process of approaching a phenomenon scientifically, and the distinctions between observation, hypothesis, experiment, and model (1.3)
5. The common units of length, volume, mass, and temperature and their numerical prefixes (1.5)
6. The distinctions between mass and weight, heat and temperature, and intensive and extensive properties (1.5)
7. The meaning of uncertainty in measurements and the use of significant figures and rounding (1.6)
8. The distinctions between accuracy and precision and between systematic and random error (1.6)

Master These Skills

1. Using conversion factors in calculations (1.4; SPs 1.2–1.4)
2. Finding density from mass and volume (SP 1.5)
3. Converting among the Kelvin, Celsius, and Fahrenheit scales (SP 1.6)
4. Determining the number of significant figures (SP 1.7) and rounding to the correct number of digits (SP 1.8)

Key Equations and Relationships

1.1 Calculating density from mass and volume (20):

$$\text{Density} = \frac{\text{mass}}{\text{volume}}$$

1.2 Converting temperature from °C to K (24):

$$T\,(\text{in K}) = T\,(\text{in °C}) + 273.15$$

1.3 Converting temperature from K to °C (24):

$$T\,(\text{in °C}) = T\,(\text{in K}) - 273.15$$

1.4 Converting temperature from °C to °F (24):

$$T\,(\text{in °F}) = \tfrac{9}{5}T\,(\text{in °C}) + 32$$

1.5 Converting temperature from °F to °C (24):

$$T\,(\text{in °C}) = [T\,(\text{in °F}) - 32]\tfrac{5}{9}$$

Highlighted Figures and Tables

These figures (F) and tables (T) provide a review of key ideas. Entries in **color** contain frequently used data.

Brief Solutions to Follow-up Problems

1.1 (a) Physical. Solid iodine changes to gaseous iodine.
(b) Chemical. Gasoline burns in air to form different substances.
(c) Chemical. In contact with air, torn skin and blood react to form different substances.

1.2 No. of chairs

$$= 3\ \text{bolts} \times \frac{200\ \text{m}^2}{1\ \text{bolt}} \times \frac{3.281\ \text{ft}}{1\ \text{m}} \times \frac{3.281\ \text{ft}}{1\ \text{m}} \times \frac{1\ \text{chair}}{31.5\ \text{ft}^2}$$

$$= 205\ \text{chairs}$$

1.3 $$\text{Radius of ribosome (dm)} = \frac{21.4\ \text{nm}}{2} \times \frac{1\ \text{dm}}{10^8\ \text{nm}}$$

$$= 1.07\times10^{-7}\ \text{dm}$$

$$\text{Volume of ribosome (dm}^3\text{)} = \tfrac{4}{3}\pi r^3 = \tfrac{4}{3}(3.14)(1.07\times10^{-7}\ \text{dm})^3$$

$$= 5.13\times10^{-21}\ \text{dm}^3$$

$$\text{Volume of ribosome (}\mu\text{L)} = (5.13\times10^{-21}\ \text{dm}^3)\left(\frac{1\ \text{L}}{1\ \text{dm}^3}\right)\left(\frac{10^6\ \mu\text{L}}{1\ \text{L}}\right)$$

$$= 5.13\times10^{-15}\ \mu\text{L}$$

1.4 $$\text{Mass (kg) of solution} = 8.0\ \text{h} \times \frac{60\ \text{min}}{1\ \text{h}} \times \frac{60\ \text{s}}{1\ \text{min}} \times \frac{1.5\ \text{drops}}{1\ \text{s}} \times \frac{65\ \text{mg}}{1\ \text{drop}} \times \frac{1\ \text{g}}{10^3\ \text{mg}} \times \frac{1\ \text{kg}}{10^3\ \text{g}}$$

$$= 2.8\ \text{kg}$$

1.5 $$\text{Mass (kg) of sample} = 4.6\ \text{cm}^3 \times \frac{7.5\ \text{g}}{1\ \text{cm}^3} \times \frac{1\ \text{kg}}{10^3\ \text{g}}$$

$$= 0.034\ \text{kg}$$

1.6 T (in °C) = 234 K − 273.15 = −39°C
T (in °F) = $\frac{9}{5}$(−39°C) + 32 = −38°F
Answer contains two significant figures (see Section 1.6).

1.7 (a) 31.070 mg, 5 sf (b) 0.06060 g, 4 sf
(c) 850.°C, 3 sf (d) 2.000×10^2 mL, 4 sf
(e) 3.9×10^{-6} m, 2 sf (f) 4.01×10^{-4} L, 3 sf

1.8 $$\frac{25.65\ \text{mL} + 37.4\ \text{mL}}{73.55\ \text{s}\left(\frac{1\ \text{min}}{60\ \text{s}}\right)} = 51.4\ \text{mL/min}$$

Problems

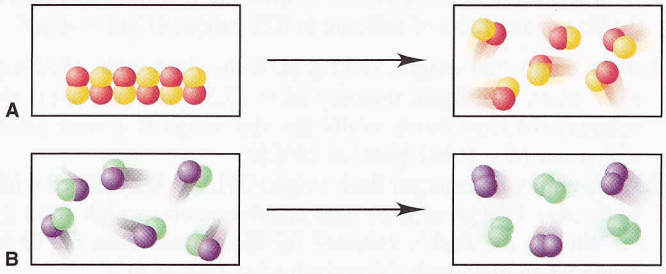
Problems with **colored** numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Some Fundamental Definitions

(Sample Problem 1.1)

Concept Review Question

1.1 Scenes A and B depict changes in matter at the atomic scale:



(a) Which show(s) a physical change?
(b) Which show(s) a chemical change?
(c) Which result(s) in different physical properties?
(d) Which result(s) in different chemical properties?
(e) Which result(s) in a change in state?

Skill-Building Exercises *(grouped in similar pairs)*

1.2 Describe solids, liquids, and gases in terms of how they fill a container. Use your descriptions to identify the physical state (at room temperature) of the following: (a) helium in a toy balloon; (b) mercury in a thermometer; (c) soup in a bowl.

1.3 Use your descriptions in the previous problem to identify the physical state (at room temperature) of the following: (a) air in your room; (b) vitamin tablets in a bottle; (c) sugar in a packet.

1.4 Define *physical property* and *chemical property*. Identify each type of property in the following statements:
(a) Yellow-green chlorine gas attacks silvery sodium metal to form white crystals of sodium chloride (table salt).
(b) A magnet separates a mixture of black iron shavings and white sand.

1.5 Define *physical change* and *chemical change*. State which type of change occurs in each of the following statements:
(a) Passing an electric current through molten magnesium chloride yields molten magnesium and gaseous chlorine.
(b) The iron in discarded automobiles slowly forms reddish brown, crumbly rust.

1.6 Which of the following is a chemical change? Explain your reasoning: (a) boiling canned soup; (b) toasting a slice of bread; (c) chopping a log; (d) burning a log.

1.7 Which of the following changes can be reversed by changing the temperature (that is, which are physical changes): (a) dew condensing on a leaf; (b) an egg turning hard when it is boiled; (c) ice cream melting; (d) a spoonful of batter cooking on a hot griddle?

1.8 For each pair, which has higher potential energy?
(a) The fuel in your car or the products in its exhaust
(b) Wood in a fireplace or the ashes in the fireplace after the wood burns

1.9 For each pair, which has higher kinetic energy?
(a) A sled resting at the top of a hill or a sled sliding down the hill
(b) Water above a dam or water falling over the dam

Chemical Arts and the Origins of Modern Chemistry

Concept Review Questions

1.10 The alchemical, medical, and technological traditions were precursors to chemistry. State a contribution that each made to the development of the science of chemistry.

1.11 How did the phlogiston theory explain combustion?

1.12 One important observation that supporters of the phlogiston theory had trouble explaining was that the calx of a metal weighs more than the metal itself. Why was that observation important? How did the phlogistonists respond?

1.13 Lavoisier developed a new theory of combustion that overturned the phlogiston theory. What measurements were central to his theory, and what key discovery did he make?

The Scientific Approach: Developing a Model

Concept Review Questions

1.14 How are the key elements of scientific thinking used in the following scenario? While making your breakfast toast, you notice it fails to pop out of the toaster. Thinking the spring mechanism is stuck, you notice that the bread is unchanged. Assuming you forgot to plug in the toaster, you check and find it is plugged in. When you take the toaster into the dining room and plug it into a different outlet, you find the toaster works. Returning to the kitchen, you turn on the switch for the overhead light and nothing happens.

1.15 Why is a quantitative observation more useful than a non-quantitative one? Which of the following are quantitative?
(a) The sun rises in the east.
(b) An astronaut weighs one-sixth as much on the Moon as on Earth.
(c) Ice floats on water.
(d) An old-fashioned hand pump cannot draw water from a well more than 34 ft deep.

1.16 Describe the essential features of a well-designed experiment.

1.17 Describe the essential features of a scientific model.

Chemical Problem Solving

(Sample Problem 1.2)

Concept Review Question

1.18 When you convert feet to inches, how do you decide which portion of the conversion factor should be in the numerator and which in the denominator?

Skill-Building Exercises *(grouped in similar pairs)*

1.19 Write the conversion factor(s) for (a) in^2 to cm^2; (b) km^2 to m^2; (c) mi/h to m/s; (d) lb/ft^2 to g/cm^3.

1.20 Write the conversion factor(s) for (a) cm/min to in/min; (b) m^3 to in^3; (c) m/s^2 to km/h^2; (d) gallons/h to L/s.

Measurement in Scientific Study

(Sample Problems 1.3 to 1.6)

Concept Review Questions

1.21 Describe the difference between intensive and extensive properties. Which of the following properties are intensive: (a) mass; (b) density; (c) volume; (d) melting point?

1.22 Explain the difference between mass and weight. Why is your weight on the Moon one-sixth that on Earth?

1.23 For each of the following cases, state whether the density of the object increases, decreases, or remains the same:
(a) A sample of chlorine gas is compressed.
(b) A lead weight is carried from sea level to the top of a high mountain.
(c) A sample of water is frozen.
(d) An iron bar is cooled.
(e) A diamond is submerged in water.

1.24 Explain the difference between heat and temperature. Does 1 L of water at 65°F have more, less, or the same quantity of energy as 1 L of water at 65°C?

1.25 A one-step conversion is sufficient to convert a temperature in the Celsius scale into the Kelvin scale, but not into the Fahrenheit scale. Explain.

Skill-Building Exercises *(grouped in similar pairs)*

1.26 The average radius of a molecule of lysozyme, an enzyme in tears, is 1430 pm. What is its radius in nanometers (nm)?

1.27 The radius of a barium atom is 2.22×10^{-10} m. What is its radius in angstroms (Å)?

1.28 What is the length in inches (in) of a 100.-m soccer field?

1.29 The center on your basketball team is 6 ft 10 in tall. How tall is the player in centimeters (cm)?

1.30 A small hole in the wing of a space shuttle requires a 17.7-cm^2 patch. (a) What is the patch's area in square kilometers (km^2)? (b) If the patching material costs NASA \$3.25/in^2, what is the cost of the patch?

1.31 The area of a telescope lens is 6322 mm^2. (a) What is the area of the lens in square feet (ft^2)? (b) If it takes a technician 45 s to polish 135 mm^2, how long does it take her to polish the entire lens?

1.32 Express your body weight in kilograms (kg).

1.33 There are 2.60×10^{15} short tons of oxygen in the atmosphere (1 short ton = 2000 lb). How many metric tons of oxygen are present (1 metric ton = 1000 kg)?

1.34 The average density of the Earth is 5.52 g/cm^3. What is its density in (a) kg/m^3; (b) lb/ft^3?

1.35 The speed of light in a vacuum is 2.998×10^8 m/s. What is its speed in (a) km/h; (b) mi/min?

1.36 The volume of a certain bacterial cell is 1.72 μm^3. (a) What is its volume in cubic millimeters (mm^3)? (b) What is the volume of 10^5 cells in liters (L)?

1.37 (a) How many cubic meters of milk are in 1 qt (946.4 mL)? (b) How many liters of milk are in 835 gallons (1 gal = 4 qt)?

1.38 An empty vial weighs 55.32 g. (a) If the vial weighs 185.56 g when filled with liquid mercury (d = 13.53 g/cm^3), what is its volume? (b) How much would the vial weigh if it were filled with water (d = 0.997 g/cm^3 at 25°C)?

1.39 An empty Erlenmeyer flask weighs 241.3 g. When filled with water (d = 1.00 g/cm^3), the flask and its contents weigh 489.1 g. (a) What is the flask's volume? (b) How much does the flask weigh when filled with chloroform (d = 1.48 g/cm^3)?

1.40 A small cube of aluminum measures 15.6 mm on a side and weighs 10.25 g. What is the density of aluminum in g/cm^3?

1.41 A steel ball-bearing with a circumference of 32.5 mm weighs 4.20 g. What is the density of the steel in g/cm^3 (V of a sphere = $\frac{4}{3}\pi r^3$; circumference of a circle = $2\pi r$)?

1.42 Perform the following conversions:
(a) 72°F (a pleasant spring day) to °C and K
(b) −164°C (the boiling point of methane, the main component of natural gas) to K and °F
(c) 0 K (absolute zero, theoretically the coldest possible temperature) to °C and °F

1.43 Perform the following conversions:
(a) 106°F (the body temperature of many birds) to K and °C

(b) 3410°C (the melting point of tungsten, the highest for any element) to K and °F

(c) 6.1×10^3 K (the surface temperature of the Sun) to °F and °C

Problems in Context

1.44 Anton van Leeuwenhoek, a 17th-century pioneer in the use of the microscope, described the microorganisms he saw as "animalcules" whose length was "25 thousandths of an inch." How long were the animalcules in meters?

1.45 The distance between two adjacent peaks on a wave is called the *wavelength*.

(a) The wavelength of a beam of ultraviolet light is 255 nanometers (nm). What is its wavelength in meters?

(b) The wavelength of a beam of red light is 683 nm. What is its wavelength in angstroms (Å)?

1.46 In the early 20th century, thin metal foils were used to study atomic structure. (a) How many in^2 of gold foil with a thickness of 1.6×10^{-5} in could have been made from 2.0 troy oz? (b) If gold cost \$20.00/troy oz at that time, how many cm^2 of gold foil could have been made from \$75.00 worth of gold (1 troy oz = 31.1 g; d of gold = 19.3 g/cm^3)?

1.47 A cylindrical tube 7.8 cm high and 0.85 cm in diameter is used to collect blood samples. How many cubic decimeters (dm^3) of blood can it hold (V of a cylinder = $\pi r^2 h$)?

1.48 Copper can be drawn into thin wires. How many meters of 34-gauge wire (diameter = 6.304×10^{-3} in) can be produced from the copper in 5.01 lb of covellite, an ore of copper that is 66% copper by mass? (*Hint:* Treat the wire as a cylinder: V of cylinder = $\pi r^2 h$; d of copper = 8.95 g/cm^3.)

Uncertainty in Measurement: Significant Figures

(Sample Problems 1.7 and 1.8)

Concept Review Questions

1.49 What is an exact number? How are exact numbers treated differently from other numbers in a calculation?

1.50 All nonzero digits are significant. State a rule that tells which zeros are significant.

1.51 A newspaper reported that the attendance at Slippery Rock's home football game was 5209. (a) How many significant figures does this number contain? (b) Was the actual number of people counted? (c) After Slippery Rock's next home game, the newspaper reported an attendance of 5000. If you assume that this number contains two significant figures, how many people could actually have been at the game?

Skill-Building Exercises *(grouped in similar pairs)*

1.52 Underline the significant zeros in the following numbers:

(a) 0.39 (b) 0.039 (c) 0.0390 (d) 3.0900×10^4

1.53 Underline the significant zeros in the following numbers:

(a) 5.08 (b) 508 (c) 5.080×10^3 (d) 0.05080

1.54 Round off each number to the indicated number of significant figures (sf): (a) 0.0003554 (to 2 sf); (b) 35.8348 (to 4 sf); (c) 22.4555 (to 3 sf).

1.55 Round off each number to the indicated number of significant figures (sf): (a) 231.554 (to 4 sf); (b) 0.00845 (to 2 sf); (c) 144,000 (to 1 sf).

1.56 Round off each number in the following calculation to one fewer significant figure, and find the answer:

$$\frac{19\times155\times8.3}{3.2\times2.9\times4.7}$$

1.57 Round off each number in the following calculation to one fewer significant figure, and find the answer:

$$\frac{9.8\times6.18\times2.381}{24.3\times1.8\times18.5}$$

1.58 Carry out the following calculations, making sure that your answer has the correct number of significant figures:

(a) $\dfrac{2.795\text{ m}\times3.10\text{ m}}{6.48\text{ m}}$

(b) $V=\frac{4}{3}\pi r^3$, where r = 9.282 cm

(c) 1.110 cm + 17.3 cm + 108.2 cm + 316 cm

1.59 Carry out the following calculations, making sure that your answer has the correct number of significant figures:

(a) $\dfrac{2.420\text{ g}+15.6\text{ g}}{4.8\text{ g}}$ (b) $\dfrac{7.87\text{ mL}}{16.1\text{ mL}-8.44\text{ mL}}$

(c) $V=\pi r^2 h$, where r = 6.23 cm and h = 4.630 cm

1.60 Write the following numbers in scientific notation:

(a) 131,000.0 (b) 0.00047 (c) 210,006 (d) 2160.5

1.61 Write the following numbers in scientific notation:

(a) 281.0 (b) 0.00380 (c) 4270.8 (d) 58,200.9

1.62 Write the following numbers in standard notation. Use a terminal decimal point when needed:

(a) 5.55×10^3 (b) 1.0070×10^4

(c) 8.85×10^{-7} (d) 3.004×10^{-3}

1.63 Write the following numbers in standard notation. Use a terminal decimal point when needed:

(a) 6.500×10^3 (b) 3.46×10^{-5} (c) 7.5×10^2 (d) 1.8856×10^2

1.64 Convert the following into correct scientific notation:

(a) 802.5×10^2 (b) 1009.8×10^{-6} (c) 0.077×10^{-9}

1.65 Convert the following into correct scientific notation:

(a) 14.3×10^1 (b) 851×10^{-2} (c) 7500×10^{-3}

1.66 Carry out each of the following calculations, paying special attention to significant figures, rounding, and units (J = joule, the SI unit of energy; mol = mole, the SI unit for amount of substance):

(a) $\dfrac{(6.626\times10^{-34}\text{ J·s})(2.9979\times10^8\text{ m/s})}{489\times10^{-9}\text{ m}}$

(b) $\dfrac{(6.022\times10^{23}\text{ molecules/mol})(1.19\times10^2\text{ g})}{46.07\text{ g/mol}}$

(c) $(6.022\times10^{23}\text{ atoms/mol})(2.18\times10^{-18}\text{ J/atom})\left(\dfrac{1}{2^2}-\dfrac{1}{3^2}\right)$,

where the numbers 2 and 3 in the last term are exact.

1.67 Carry out each of the following calculations, paying special attention to significant figures, rounding, and units:

(a) $\dfrac{8.32\times10^7\text{ g}}{\frac{4}{3}(3.1416)(1.95\times10^2\text{ cm})^3}$ (The term $\frac{4}{3}$ is exact.)

(b) $\dfrac{(1.84\times10^2\text{ g})(44.7\text{ m/s})^2}{2}$ (The term 2 is exact.)

(c) $\dfrac{(1.07\times10^{-4}\text{ mol/L})^2(2.6\times10^{-3}\text{ mol/L})}{(8.35\times10^{-5}\text{ mol/L})(1.48\times10^{-2}\text{ mol/L})^3}$

1.68 Which statements include exact numbers?

(a) Angel Falls is 3212 ft high.

(b) There are nine known planets in the Solar System.

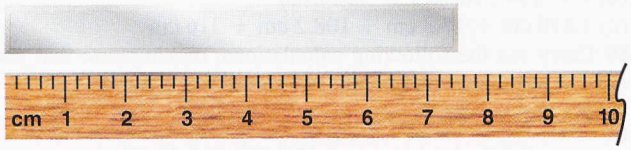
(c) There are 453.59 g in 1 lb.

(d) There are 1000 mm in 1 m.

1.69 Which of the following include exact numbers?
(a) The speed of light in a vacuum is a physical constant; to six significant figures, it is 2.99792×10^8 m/s.
(b) The density of mercury at 25°C is 13.53 g/mL.
(c) There are 3600 s in 1 h.
(d) In 2003, the United States had 50 states.

Problems in Context

1.70 How long is the metal strip shown below? Be sure to answer with the correct number of significant figures.



1.71 These organic solvents are used to clean compact discs:

Solvent	Density (g/mL) at 20°C
Chloroform	1.492
Diethyl ether	0.714
Ethanol	0.789
Isopropanol	0.785
Toluene	0.867

(a) If a 15.00-mL sample of CD cleaner weighs 11.775 g at 20°C, which solvent is most likely to be present?
(b) The chemist analyzing the cleaner calibrates her equipment and finds that the pipet is accurate to ±0.02 mL, and the balance is accurate to ±0.003 g. Is this equipment precise enough to distinguish between ethanol and isopropanol?

1.72 A gathering of 300 families attends a Founder's Day picnic in a small town, and the local Chamber of Commerce provides 3 bagels, 2 donuts, and 4 cans of iced tea to each family. After the picnic, 18 kg of garbage is collected. Which of the numbers—300, 3, 2, 4, 18—are exact numbers? Explain.

1.73 A laboratory instructor gives a sample of amino acid powder to each of four students, I, II, III, and IV, and they weigh the samples. The true value is 8.72 g. Their results for three trials are
I: 8.72 g, 8.74 g, 8.70 g II: 8.56 g, 8.77 g, 8.83 g
III: 8.50 g, 8.48 g, 8.51 g IV: 8.41 g, 8.72 g, 8.55 g
(a) Calculate the average mass from each set of data, and tell which set is the most accurate.
(b) Precision is a measure of the average of the deviations of each piece of data from the average value. Which set of data is the most precise? Is this set also the most accurate?
(c) Which set of data is both the most accurate and most precise?
(d) Which set of data is both the least accurate and least precise?

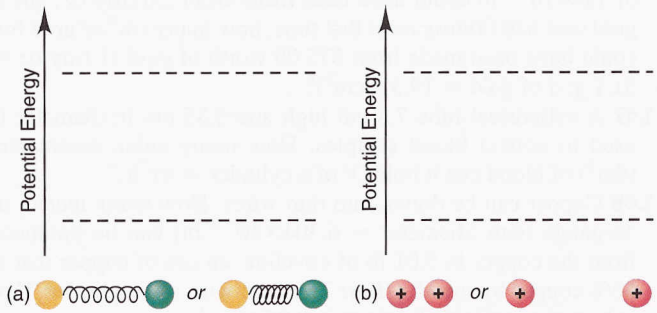
1.74 The following dartboards illustrate the types of errors often seen in measurements. The bull's-eye represents the actual value, and the darts represent the data.

(a) Which experiments yield the same average result?
(b) Which experiment(s) display(s) high precision?
(c) Which experiment(s) display(s) high accuracy?
(d) Which experiment(s) show(s) a systematic error?

Comprehensive Problems

1.75 To make 2.000 gal of a powdered sports drink, a group of students measure out 2.000 gal of water with 500.-mL, 50.-mL, and 5-mL graduated cylinders. Show how they could get closest to 2.000 gal of water, using these cylinders the fewest times.

1.76 Two blank potential energy diagrams (see Figure 1.3, p. 7) appear below. Beneath each diagram are objects to place in the diagram. Draw the objects on the dashed lines to indicate higher or lower potential energy and label each case as more or less stable:



(a) Two balls attached to a relaxed *or* a compressed spring.
(b) Two positive charges near *or* apart from each other.

1.77 Stainless steels are a major component of fine surgical instruments. An engineer, testing a more energy-efficient process for preparing Stainless Steel 304 (d = 7.90 g/cm^3), makes a cube of the steel that is 15.0 mm on each edge and weighs it. If the new process works, what should the mass of the cube be?

1.78 Soft drinks are about as dense as water (1.0 g/cm^3); many common metals, including iron, copper, and silver, have densities around 9.5 g/cm^3. (a) What is the mass of the liquid in a standard 12-oz bottle of diet cola? (b) What is the mass of a dime? (*Hint:* A stack of five dimes has a volume of about 1 cm^3.)

1.79 Suppose your dorm room is 11 ft wide by 12 ft long by 8.5 ft high and has an air conditioner that exchanges air at a rate of 1200 L/min. How long would it take the air conditioner to exchange the air in your room once?

1.80 In 1933, the United States went off the international gold standard, and the price of gold increased from $20.00 to $35.00/troy oz. The twenty-dollar gold piece, known as the double eagle, weighed 33.436 g and was 90.0% gold by mass. (a) What was the value of the gold in the double eagle before and after the price change? (b) How many coins could be made from 50.0 troy oz of gold? (c) How many coins could be made from 2.00 in^3 of gold (1 troy oz = 31.1 g; d of gold = 19.3 g/cm^3)?

1.81 An Olympic-size pool is 50.0 m long and 25.0 m wide. (a) How many gallons of water (d = 1.0 g/mL) are needed to fill the pool to an average depth of 4.8 ft? (b) What is the mass (in kg) of water in the pool?

1.82 At room temperature (20°C) and pressure, the density of air is 1.189 g/L. An object will float in air if its density is less than that of air. In a buoyancy experiment with a new plastic, a chemist creates a rigid, thin-walled ball that weighs 0.12 g and has a volume of 560 cm^3.
(a) Will the ball float if it is evacuated?
(b) Will it float if filled with carbon dioxide (d = 1.830 g/L)?
(c) Will it float if filled with hydrogen (d = 0.0899 g/L)?
(d) Will it float if filled with oxygen (d = 1.330 g/L)?
(e) Will it float if filled with nitrogen (d = 1.165 g/L)?
(f) For any case that will float, how much weight must be added to make the ball sink?

1.83 Asbestos is a fibrous silicate mineral with remarkably high tensile strength. But it is no longer used because airborne asbestos particles can cause lung cancer. Grunerite, a type of asbestos, has a tensile strength of 3.5×10^4 kg/cm^2 (thus, a bar of grunerite with a 1-cm^2 cross-sectional area can hold up to 3.5×10^4 kg). The tensile strengths of aluminum and Steel No. 5137 are 2.5×10^4 lb/in^2 and 5.0×10^4 lb/in^2, respectively. Calculate the cross-sectional area (in cm^2) of bars of aluminum and Steel No. 5137 that have the same tensile strength as a bar of grunerite with a cross-sectional area of 25 mm^2.

1.84 According to the lore of ancient Greece, Archimedes discovered the displacement method of density determination while bathing and used it to find the composition of the king's crown. If a crown weighing 4 lb 13 oz displaces 186 mL of water, is the crown made of pure gold (d = 19.3 g/cm^3)?

1.85 Earth's oceans have an average depth of 3800 m, a total area of 3.63×10^8 km^2, and an average concentration of dissolved gold of 5.8×10^{-9} g/L. (a) How many grams of gold are in the oceans? (b) How many m^3 of gold are in the oceans? (c) If a recent price of gold was $370.00/troy oz, what is the value of gold in the oceans (1 troy oz = 31.1 g; d of gold = 19.3 g/cm^3)?

1.86 Brass is an alloy of copper and zinc. Varying the mass percentages of the two metals produces brasses with different properties. A brass called *yellow zinc* has high ductility and strength and is 34%–37% zinc by mass. (a) Find the mass range (in g) of copper in 174 g of yellow zinc. (b) What is the mass range (in g) of zinc in a sample of yellow zinc that contains 46.5 g of copper?

1.87 For the year 2002, worldwide production of aluminum was 24.4 million metric tons (t). (a) How many pounds of aluminum were produced? (b) What was its volume in cubic feet (1 t = 1000 kg; d of aluminum = 2.70 g/cm^3)?

1.88 Liquid nitrogen is obtained from liquefied air and is used industrially to prepare frozen foods. It boils at 77.36 K. (a) What is this temperature in °C? (b) What is this temperature in °F? (c) At the boiling point, the density of the liquid is 809 g/L and that of the gas is 4.566 g/L. How many liters of liquid nitrogen are produced when 895.0 L of nitrogen gas is liquefied at 77.36 K?

1.89 The speed of sound varies according to the material through which it travels. Sound travels at 5.4×10^3 cm/s through rubber and at 1.97×10^4 ft/s through granite. Calculate each of these speeds in m/s.

1.90 If a raindrop weighs 65 mg on average and 5.1×10^5 raindrops fall on a lawn every minute, what mass (in kg) of rain falls on the lawn in 1.5 h?

1.91 A jogger runs at an average speed of 5.9 mi/h. (a) How fast is she running in m/s? (b) How many kilometers does she run in 98 min? (c) If she starts a run at 11:15 am, what time is it after she covers 4.75×10^4 ft?

1.92 The Environmental Protection Agency (EPA) has proposed a new safety standard for microparticulates in air: for particles up to 2.5 μm in diameter, the maximum allowable amount is 50. μg/m^3. If your 10.0 ft × 8.25 ft × 12.5 ft dorm room just meets the new EPA standard, how many of these particles are in your room? How many are in each 0.500-L breath you take? (Assume the particles are spheres of diameter 2.5 μm and made primarily of soot, a form of carbon with a density of 2.5 g/cm^3.)

1.93 Earth's surface area is 5.10×10^8 km^2, and its crust has a mean thickness of 35 km and mean density of 2.8 g/cm^3. The two most abundant elements in the crust are oxygen (4.55×10^5 g/metric ton, t) and silicon (2.72×10^5 g/t), and the two rarest non-radioactive elements are ruthenium and rhodium, each with an abundance of 1×10^{-4} g/t. What is the total mass of each of these elements in Earth's crust (1 t = 1000 kg)?

1.94 Nutritional tables give the potassium content of a standard apple (about 3 apples/lb) as 159 mg. How many grams of potassium are in 4.25 kg of apples?

1.95 The three states of matter differ greatly in their viscosity, a measure of their resistance to flow. Rank the three states from highest to lowest viscosity. Explain in submicroscopic terms.

1.96 If a temperature scale were based on the freezing point (5.5°C) and boiling point (80.1°C) of benzene and the temperature difference between these points was divided into 50 units (called °X), what would be the freezing and boiling points of water in °X? (See Figure 1.12, p. 23.)

Parts of a Whole Like this part of a larger mosaic, any sample of matter we observe consists of smaller components that give rise to the sample's unique properties. In this chapter, we explore the nature of these components and of their components in turn.

2.9 **Mixtures: Classification and Separation**

Questioning what something is made of was a common practice even among the philosophers of ancient Greece, although we approach the question very differently today. They believed that everything was made of one or, at most, a few elemental substances (elements). Some believed this substance to be water, because rivers and oceans extend everywhere. Others thought it was air, which was "thinned" into fire and "thickened" into clouds, rain, and rock. Still others believed there were four elements—fire, air, water, and earth—whose properties accounted for hotness, wetness, sweetness, and all other characteristics of things.

Democritus (c. 460–370 BC), the father of atomism, took a different approach. He focused on the ultimate components of *all* substances, and his reasoning went something like this: if you cut a piece of, say, copper smaller and smaller, you must eventually reach a particle of copper so small that it can no longer be cut. Therefore, matter is ultimately composed of indivisible particles, with nothing between them but empty space. He called the particles *atoms* (Greek *atomos,* "uncuttable") and proclaimed: "According to convention, there is a sweet and a bitter, a hot and a cold, and according to convention, there is order. In truth, there are atoms and a void." However, Aristotle (384–322 BC), who elaborated the idea of four elements, held that it was impossible for "nothing" to exist, and his influence was so great that the concept of atoms was suppressed for 2000 years.

Finally, in the 17th century, the great English scientist Robert Boyle argued that an element is composed of "simple Bodies, not made of any other Bodies, of which all mixed Bodies are compounded, and into which they are ultimately resolved," a description that is remarkably similar to today's idea of an element, in which the "simple Bodies" are atoms. Boyle's hypothesis began the wonderful process of discovery, debate, and rediscovery that marks scientific inquiry, as exemplified by Lavoisier's work. Further studies in the 18th century gave rise to laws concerning the relative masses of substances that react with each other. Then, at the beginning of the 19th century, John Dalton proposed an atomic model that explained these mass laws and soon led to rapid progress in chemistry. By that century's close, however, further observation exposed the need to revise Dalton's model. A burst of creativity in the early 20th century gave rise to a picture of the atom with a complex internal structure, which led to our current model.

IN THIS CHAPTER . . . We compare the properties and composition of the three types of matter—elements, compounds, and mixtures—on the macroscopic and atomic scales. We examine the mass laws and Dalton's theory to explain them and then cover key experiments that led to our current model of the atom. Atomic structure is described, and then we see how elements are organized and classified in the periodic table. We discuss the two ways elements combine to form compounds, and learn how to derive compound names, formulas, and masses. Finally, we see how mixtures are classified and separated.

2.1 ELEMENTS, COMPOUNDS, AND MIXTURES: AN ATOMIC OVERVIEW

Matter can be broadly classified into three types—elements, compounds, and mixtures. An **element** is the simplest type of matter with unique physical and chemical properties. *An element consists of only one kind of atom.* Therefore, it cannot be broken down into a simpler type of matter by any physical or chemical methods. An element is one kind of **pure substance** (or just **substance**), matter whose composition is fixed. Each element has a name, such as silicon, oxygen, or copper. A sample of silicon contains only silicon atoms. A key point to remember is that the *macroscopic* properties of a piece of silicon, such as color, density, and combustibility, are different from those of a piece of copper because silicon atoms are different from copper atoms; in other words, *each element is unique because the properties of its atoms are unique.*

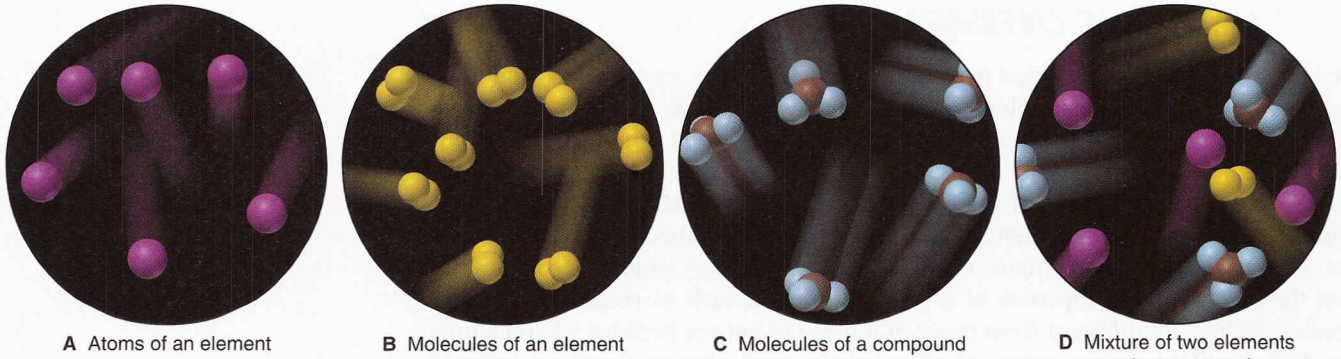
Most elements exist in nature as populations of atoms. Figure 2.1A shows atoms of a gaseous element such as neon. However, several elements occur naturally as molecules: a **molecule** is an independent structural unit consisting of two or more atoms chemically bound together (Figure 2.1B). Oxygen, for example, occurs in air as *diatomic* (two-atom) molecules.

A **compound** is a type of matter composed of *two or more different elements that are chemically bound together.* Be sure you understand that the elements in a compound are not just mixed together; rather, their atoms have joined chemically (Figure 2.1C). Ammonia, water, and carbon dioxide are some common compounds. One defining feature of a compound is that *the elements are present in fixed parts by mass* (fixed mass ratio). Because of this fixed composition, *a compound is also considered a substance.* Any molecule of the compound has the same fixed parts by mass because it consists of *fixed numbers* of atoms of the component elements. For example, any sample of ammonia is 14 parts nitrogen by mass plus 3 parts hydrogen by mass. Since 1 nitrogen atom has 14 times the mass of 1 hydrogen atom, 1 molecule of ammonia always consists of 1 nitrogen atom and 3 hydrogen atoms:

Ammonia is 14 parts N and 3 parts H by mass
1 N atom has 14 times the mass of 1 H atom
Therefore, ammonia has 1 N atom and 3 H atoms.

Another defining feature of a compound is that *its properties are different from those of its component elements.* Table 2.1 shows a striking example. Soft, silvery sodium metal and yellow-green, poisonous chlorine gas have very different properties from the compound they form—white, crystalline sodium chloride, or common table salt! Unlike an element, a compound *can* be broken down into simpler substances—its component elements. For example, an electric current breaks down molten sodium chloride into metallic sodium and chlorine gas. Note that this breakdown is a *chemical change,* not a physical one.

Figure 2.1D depicts a **mixture,** a group of two or more substances (elements and/or compounds) that are physically intermingled. In contrast to a compound, *the components of a mixture* ***can*** *vary in their parts by mass.* Since its composition is not fixed, a mixture is *not* a substance. A mixture of the two compounds sodium chloride and water, for example, can have many different parts by mass of salt to water. Since the components are physically mixed, not chemically combined, a mixture at the atomic scale is merely a group of the individual units that make up its component elements and/or compounds. Therefore, *a mixture retains many of the properties of its components.* Salt water, for instance, is colorless like water and tastes salty like sodium chloride. Unlike compounds, mixtures can be separated into their components by *physical changes;* chemical changes are not needed. For example, the water in salt water can be boiled off, a physical process that leaves behind the sodium chloride.



A Atoms of an element

B Molecules of an element

C Molecules of a compound

D Mixture of two elements and a compound

Figure 2.1 Elements, compounds, and mixtures on the atomic scale. A, Most elements consist of a large collection of identical atoms. **B,** Some elements occur as molecules. **C,** A molecule of a compound consists of characteristic numbers of atoms of two or more elements chemically bound together. **D,** A mixture contains the individual units of two or more elements and/or compounds that are physically intermingled. The samples shown here are gases, but elements, compounds, and mixtures occur as liquids and solids also.

Table 2.1 Some Properties of Sodium, Chlorine, and Sodium Chloride

Property	Sodium	+	Chlorine	→	Sodium Chloride
Melting point	97.8°C		−101°C		801°C
Boiling point	881.4°C		−34°C		1413°C
Color	Silvery		Yellow-green		Colorless (white)
Density	0.97 g/cm^3		0.0032 g/cm^3		2.16 g/cm^3
Behavior in water	Reacts		Dissolves slightly		Dissolves freely

SECTION SUMMARY

All matter exists as either elements, compounds, or mixtures. An element consists of only one type of atom. A compound contains two or more elements in chemical combination; it exhibits different properties from its component elements. The elements of a compound occur in fixed parts by mass because each unit of the compound has fixed numbers of each type of atom. Elements and compounds are referred to as substances because their compositions are fixed. A mixture consists of two or more substances mixed together, not chemically combined. The components retain their individual properties and can be present in any proportions.

2.2 THE OBSERVATIONS THAT LED TO AN ATOMIC VIEW OF MATTER

Any model of the composition of matter had to explain two extremely important chemical observations that were well established by the end of the 18th century: the *law of mass conservation* and the *law of definite (or constant) composition.* As you'll see, John Dalton's atomic theory explained these laws and another observation now known as the *law of multiple proportions.*

Mass Conservation

The most fundamental chemical observation of the 18th century was the **law of mass conservation:** *the total mass of substances does not change during a chemical reaction.* The *number* of substances may change, and by definition their properties must, but the *total amount* of matter remains constant. Lavoisier had first stated this law on the basis of his combustion experiments, in which he found the mass of oxygen plus the mass of mercury equal to the mass of mercuric oxide they formed. Figure 2.2 illustrates mass conservation in a reaction that occurs in water.

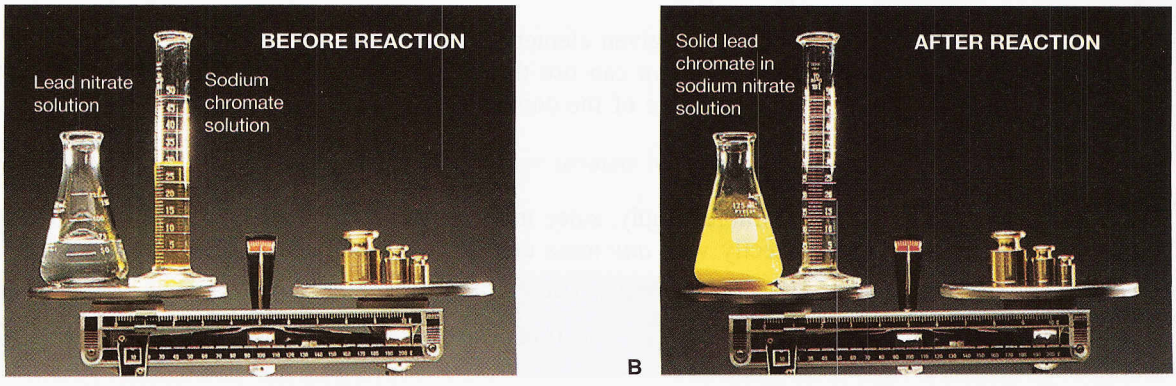


Figure 2.2 The law of mass conservation: mass remains constant during a chemical reaction. The total mass of lead nitrate solution and sodium chromate solution before they react **(A)** is the same as the total mass after they have reacted **(B)** to form lead chromate (yellow solid) and sodium nitrate solution.

Immeasurable Changes in Mass Based on the work of Albert Einstein (1879–1955), we now know that some mass *does* change into energy during a chemical reaction. But the amount is too small to measure, even by the best modern balance. For example, when 100 g of carbon burns in oxygen, carbon dioxide is formed, and only 0.000000036 g (3.6×10^{-8} g) of mass is converted to energy. The energy yields of chemical reactions are relatively so small that, for all practical purposes, mass *is* conserved. As you'll see later, however, energy changes in nuclear reactions are so large that mass changes are measured easily.

Even in a complex biochemical change within an organism, such as the metabolism of the sugar glucose, which involves many reactions, mass is conserved:

180 g glucose + 192 g oxygen gas ⟶ 264 g carbon dioxide + 108 g water

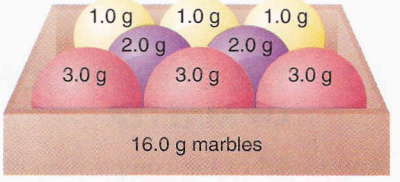
372 g material before change ⟶ 372 g material after change

Mass conservation means that, based on all chemical experience, *matter cannot be created or destroyed.*

Definite Composition

Another fundamental chemical observation is summarized as the **law of definite (or constant) composition:** *no matter what its source, a particular compound is composed of the same elements in the same parts (fractions) by mass.* The **fraction by mass (mass fraction)** is that part of the compound's mass contributed by the element. It is obtained by dividing the mass of each element by the total mass of compound. The **percent by mass (mass percent, mass %)** is the fraction by mass expressed as a percentage.

Let's examine the meanings of these ideas in terms of a box of marbles *(right)*. The box contains three types of marbles: yellow marbles weigh 1.0 g each, purple marbles 2.0 g each, and red marbles 3.0 g each. Each type makes up a fraction of the total mass of marbles, 16.0 g. The *mass fraction* of the yellow marbles is their number times their mass divided by the total mass: (3 × 1.0 g)/16.0 g = 0.19. The *mass percent* (parts per 100 parts) of the yellow marbles is 0.19 × 100 = 19% by mass. The purple marbles have a mass fraction of 0.25 and are 25% of the total by mass, and the red marbles have a mass fraction of 0.56 and are 56% by mass. Similarly, in a compound, each element has a *fixed* mass fraction (and mass percent).



Consider calcium carbonate, the major compound in marble. The following results are obtained for the elemental mass composition of 20.0 g of calcium carbonate (for example, 8.0 g of calcium/20.0 g = 0.40 parts of calcium):

Analysis by Mass (grams/20.0 g)	Mass Fraction (parts/1.00 part)	Percent by Mass (parts/100 parts)
8.0 g calcium	0.40 calcium	40% calcium
2.4 g carbon	0.12 carbon	12% carbon
9.6 g oxygen	0.48 oxygen	48% oxygen
20.0 g	1.00 part by mass	100% by mass

As you can see, the sum of the mass fractions (or mass percents) equals 1.00 part (or 100%) by mass. The law of definite composition tells us that pure samples of calcium carbonate always contain the same elements in the same percents by mass (Figure 2.3).

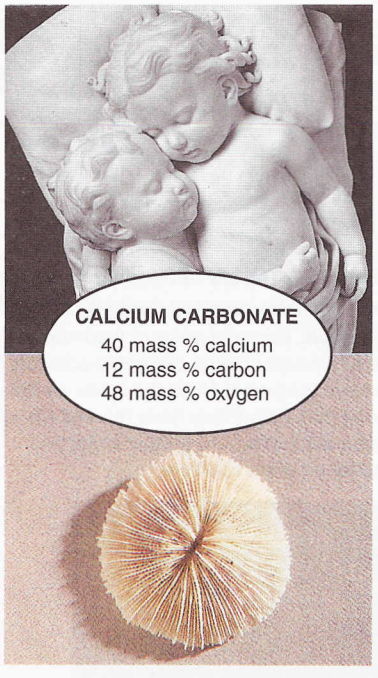


Figure 2.3 The law of definite composition. Calcium carbonate is found naturally in many forms, including marble *(top)*, coral *(bottom)*, chalk, and seashells. The mass percents of its component elements do not change regardless of the compound's source.

Since a given element always constitutes the same mass fraction of a given compound, we can use the mass fraction to find the actual mass of the element in any sample of the compound:

$$\text{Mass of element} = \text{mass of compound} \times \frac{\text{part by mass of element}}{\text{one part by mass of compound}}$$

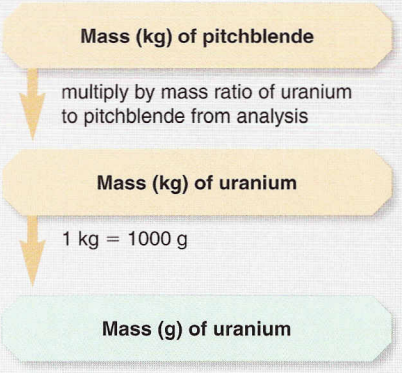
Or, more simply, since mass analysis tells us the parts by mass, we can use that directly with *any* mass unit and skip the need to find the mass fraction first:

$$\text{Mass of element in sample} = \text{mass of compound in sample} \times \frac{\text{mass of element in compound}}{\text{mass of compound}} \quad (2.1)$$

SAMPLE PROBLEM 2.1 Calculating the Mass of an Element in a Compound

Problem Pitchblende is the most commercially important compound of uranium. Analysis shows that 84.2 g of pitchblende contains 71.4 g of uranium, with oxygen as the only other element. How many grams of uranium can be obtained from 102 kg of pitchblende?

Plan We have to find the mass of uranium in a known mass of pitchblende, given the mass of uranium in a different mass of pitchblende. The mass ratio of uranium/pitchblende is the same for any sample of pitchblende. Therefore, as shown by Equation 2.1, we multiply the mass (in kg) of pitchblende by the ratio of uranium to pitchblende that we construct from the mass analysis. This gives the mass (in kg) of uranium, and we just convert kilograms to grams.



Solution Finding the mass (kg) of uranium in 102 kg of pitchblende:

$$\text{Mass (kg) of uranium} = \text{mass (kg) of pitchblende} \times \frac{\text{mass (kg) of uranium in pitchblende}}{\text{mass (kg) of pitchblende}}$$

$$\text{Mass (kg) of uranium} = 102 \text{ kg pitchblende} \times \frac{71.4 \text{ kg uranium}}{84.2 \text{ kg pitchblende}} = 86.5 \text{ kg uranium}$$

Converting the mass of uranium from kg to g:

$$\text{Mass (g) of uranium} = 86.5 \text{ kg uranium} \times \frac{1000 \text{ g}}{1 \text{ kg}}$$

$$= 8.65 \times 10^4 \text{ g uranium}$$

Check The analysis showed that most of the mass of pitchblende is due to uranium, so the large mass of uranium makes sense. Rounding off to check the math gives:

$$\sim 100 \text{ kg pitchblende} \times \frac{70}{85} = 82 \text{ kg uranium}$$

FOLLOW-UP PROBLEM 2.1 How many metric tons (t) of oxygen are combined in a sample of pitchblende that contains 2.3 t of uranium? (*Hint:* Remember that oxygen is the only other element present.)

Multiple Proportions

Dalton described a phenomenon that occurs when two elements form more than one compound. His observation is now called the **law of multiple proportions:** *if elements A and B react to form two compounds, the different masses of B that combine with a fixed mass of A can be expressed as a ratio of small whole numbers.* Consider two compounds that form from carbon and oxygen; for now, let's call them carbon oxides I and II. They have very different properties. For example, measured at the same temperature and pressure, the density of carbon oxide I is 1.25 g/L, whereas that of II is 1.98 g/L. Moreover, I is poisonous and flammable, but II is not. Analysis shows that their compositions by mass are

Carbon oxide I: 57.1 mass % oxygen and 42.9 mass % carbon
Carbon oxide II: 72.7 mass % oxygen and 27.3 mass % carbon

To see the phenomenon of multiple proportions, we use the mass percents of oxygen and of carbon in each compound to find the masses of these elements in a given mass, for example, 100 g, of each compound. Then we divide the mass of oxygen by the mass of carbon in each compound to obtain the mass of oxygen that combines with a fixed mass of carbon:

	Carbon Oxide I	Carbon Oxide II
g oxygen/100 g compound	57.1	72.7
g carbon/100 g compound	42.9	27.3
g oxygen/g carbon	$\frac{57.1}{42.9} = 1.33$	$\frac{72.7}{27.3} = 2.66$

If we then divide the grams of oxygen per gram of carbon in II by that in I, we obtain a ratio of small whole numbers:

$$\frac{2.66 \text{ g oxygen/g carbon in II}}{1.33 \text{ g oxygen/g carbon in I}} = \frac{2}{1}$$

The law of multiple proportions tells us that in two compounds of the same elements, the mass fraction of one element relative to the other element changes in *increments based on ratios of small whole numbers.* In this case, the ratio is 2:1—for a given mass of carbon, II contains *2 times* as much oxygen as I, not 1.583 times, 1.716 times, or any other intermediate amount. As you'll see next, Dalton's theory allows us to explain the composition of carbon oxides I and II on the atomic scale.

SECTION SUMMARY

Three fundamental observations known as the mass laws state that (1) the total mass remains constant during a chemical reaction; (2) any sample of a given compound has the same elements present in the same parts by mass; and (3) in different compounds of the same elements, the masses of one element that combine with a fixed mass of the other can be expressed as a ratio of small whole numbers.

Dalton's Revival of Atomism Although John Dalton, the son of a poor weaver, had no formal education, he established one of the most powerful concepts in science. Dalton began teaching science at 12 years of age, and later studied color blindness, a personal affliction still known as *daltonism.* In 1787, he began his life's work in meteorology, recording daily weather data until his death 57 years later. His studies on humidity and dew point led to a key discovery about the behavior of gases (Section 5.4) and eventually to his atomic theory. In 1803, he stated, "I am nearly persuaded that [the mixing of gases and their solubility in water] depends upon the mass and number of the ultimate particles. . . . An enquiry into the relative masses of [these] particles of bodies is a subject . . . I have lately been prosecuting . . . with remarkable success." The atomic theory was published 5 years later.

2.3 DALTON'S ATOMIC THEORY

With almost 200 years of hindsight, it may be easy to see how the mass laws could be explained by an atomic model—matter existing in indestructible units, each with a particular mass—but it was a major breakthrough in 1808 when John Dalton (1766–1844) presented his atomic theory of matter in *A New System of Chemical Philosophy.*

Postulates of the Atomic Theory

Dalton expressed his theory in a series of postulates. Like most great thinkers, Dalton incorporated the ideas of others into his own to create the new theory. As we go through the postulates, which are presented here in modern terms, let's see which were original and which came from others. (Later, we can examine the key differences between Dalton's postulates and our present understanding.)

1. All matter consists of **atoms,** tiny indivisible particles of an element that cannot be created or destroyed. (Derives from the "eternal, indestructible atoms" of Democritus more than 2000 years earlier and conforms to mass conservation as stated by Lavoisier.)
2. Atoms of one element *cannot* be converted into atoms of another element. In chemical reactions, the atoms of the original substances recombine to form different substances. (Rejects the alchemical belief in the magical transmutation of elements.)
3. Atoms of an element are identical in mass and other properties and are different from atoms of any other element. (Contains Dalton's major new ideas: unique mass and properties for all the atoms of a given element.)
4. Compounds result from the chemical combination of a specific ratio of atoms of different elements. (Follows directly from the fact of definite composition.)

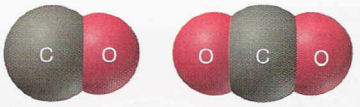
How the Theory Explains the Mass Laws

Let's see how Dalton's postulates explain the mass laws:

- *Mass conservation.* Atoms cannot be created or destroyed (postulate 1) or converted into other types of atoms (postulate 2). Since each type of atom has a fixed mass (postulate 3), a chemical reaction, in which atoms are just combined differently with each other, cannot possibly result in a mass change.

- *Definite composition.* A compound is a combination of a *specific* ratio of different atoms (postulate 4), each of which has a particular mass (postulate 3). Thus, each element in a compound constitutes a fixed fraction of the total mass.
- *Multiple proportions.* Atoms of an element have the same mass (postulate 3) and are indivisible (postulate 1). Because different numbers of B atoms combine with each A atom in different compounds, the masses of element B that combine with a fixed mass of element A give a small, whole-number ratio.

The *simplest* arrangement consistent with the mass data for carbon oxides I and II in our earlier example is that one atom of oxygen combines with one atom of carbon in compound I (carbon monoxide) and that two atoms of oxygen combine with one atom of carbon in compound II (carbon dioxide) (Figure 2.4).



Carbon oxide I (carbon monoxide) Carbon oxide II (carbon dioxide)

Figure 2.4 The atomic basis of the law of multiple proportions. Carbon and oxygen combine to form carbon oxide I (carbon monoxide) and carbon oxide II (carbon dioxide). The masses of oxygen in the two compounds relative to a fixed mass of carbon are in a ratio of small whole numbers.

The Relative Masses of Atoms

After publication of the atomic theory, investigators tried to determine the masses of atoms from the mass fractions of elements in compounds. But an individual atom is so small that the mass of all the atoms of one element can be determined only relative to the mass of all the atoms of another element. But what should the mass standard be? Many conflicts arose, and they were resolved only decades later in an 1860 conference attended by over 140 of the world's leading chemists. There, a list of elements with accurate relative atomic masses was accepted—16 for oxygen, 12 for carbon, and so forth—and chemical formulas such as H_2O for water, NH_3 for ammonia, and CH_4 for methane were put into common use. Dalton's atomic model was crucial to this understanding because it originated the idea that masses of reacting elements could be explained in terms of atoms.

However, the model did not explain why atoms bond as they do: for example, why do two, and not three, H atoms bond with one O atom in water? Also, Dalton's "billiard ball" atom did not account for the charged particles that were being observed in experiments. Clearly, a more complex atomic model was needed.

Atoms? Humbug! Rarely does a major new concept receive unanimous acceptance. Despite the atomic theory's impact, several major scientists denied the existence of atoms for another century. In 1877, Adolf Kolbe, an eminent organic chemist, said, "[Dalton's atoms are] . . . no more than stupid hallucinations . . . mere table-tapping and supernatural explanations." The influential physicist Ernst Mach believed that scientists should look at facts, not hypothetical entities such as atoms. It was not until 1908 that the famous chemist and outspoken opponent of atomism Wilhelm Ostwald wrote, "I am now convinced [by recent] experimental evidence of the discrete or grained nature of matter, which the atomic hypothesis sought in vain for hundreds and thousands of years." He was referring to the discovery of the electron.

SECTION SUMMARY

Dalton's atomic theory explained the mass laws by proposing that all matter consists of indivisible, unchangeable atoms of fixed, unique mass. Mass is constant during a reaction because atoms form new combinations; each compound has a fixed mass fraction of each of its elements because it is composed of a fixed number of each type of atom; and different compounds of the same elements exhibit multiple proportions because they each consist of whole atoms. Studies stimulated by Dalton's model eventually led to consistent values for relative masses of atoms.

2.4 THE OBSERVATIONS THAT LED TO THE NUCLEAR ATOM MODEL

The path of discovery is often winding and unpredictable. Basic research into the nature of electricity eventually led to the discovery of *electrons,* negatively charged particles that are part of all atoms. Soon thereafter, other experiments revealed that the atom has a *nucleus*—a tiny, central core of mass and positive charge. In this section, we examine some key experiments that led to our current model of the atom.

Discovery of the Electron and Its Properties

Nineteenth-century investigators of electricity knew that matter and electric charge were somehow related. When amber is rubbed with fur, or glass with silk, positive and negative charges form—the same charges that make your hair crackle

The Familiar Glow of Colliding Particles The electric and magnetic properties of charged particles that collide with gas particles or hit a phosphor-coated screen have familiar applications. A "neon" sign glows because electrons collide with the gas particles in the tube, causing them to give off light. An aurora display occurs when Earth's magnetic field bends streams of charged particles coming from the Sun, which then collide with gases in the atmosphere. In a television tube or computer monitor, the cathode ray passes back and forth over the coated screen, creating a pattern that the eye sees as a picture.

Animation: Cathode Ray Tube
Online Learning Center

and cling to your comb on a dry day. They also knew that an electric current could decompose certain compounds into their elements.

What they did not know, however, was how electricity could be studied in the *absence* of matter. Some investigators tried passing an electric current from a high-voltage source through nearly evacuated glass tubes fitted with metal electrodes that were sealed in place and connected to an external source of electricity. When the power was turned on, a "ray" could be seen striking the phosphor-coated end of the tube and emitting a glowing spot of light. The rays were called **cathode rays** because they originated at the negative electrode (cathode) and moved to the positive electrode (anode). Cathode rays typically travel in a straight line, but in a magnetic field the path is bent, indicating that the particles are charged, and in an electric field the path bends toward the positive plate. The ray is identical no matter what metal is used as the cathode (Figure 2.5). It was concluded that cathode rays consist of negatively charged particles found in all matter. The rays appear when these particles collide with the few remaining gas molecules in the evacuated tube. Cathode ray particles were later named *electrons*.

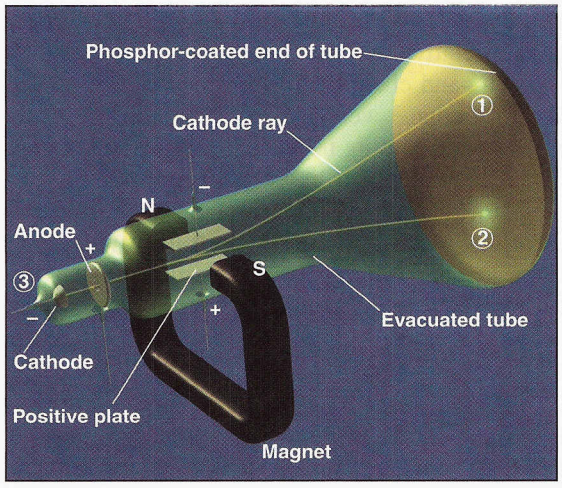


Figure 2.5 Experiments to determine the properties of cathode rays. A cathode ray forms when high voltage is applied to a partially evacuated tube. The ray passes through a hole in the anode and hits the coated end of the tube to produce a glow.

OBSERVATION	CONCLUSION
1. Ray bends in magnetic field	Consists of charged particles
2. Ray bends toward positive plate in electric field	Consists of negative particles
3. Ray is identical for any cathode	Particles found in all matter

Just over a century ago, in 1897, J. J. Thomson (1856–1940) used magnetic and electric fields to measure the ratio of the cathode ray particle's mass to its charge. By comparing this value with the mass/charge ratio for the lightest charged particle in solution, Thomson estimated that the cathode ray particle weighed less than $\frac{1}{1000}$ as much as hydrogen, the lightest atom! He was shocked because this implied that, contrary to Dalton's atomic theory, *atoms are divisible into even smaller particles*. Thomson concluded, "We have in the cathode rays matter in a new state, . . . in which the subdivision of matter is carried much further . . . ; this matter being the substance from which the chemical elements are built up." Fellow scientists reacted at first with disbelief, and some even thought Thomson was joking.

In 1909, the American physicist Robert Millikan (1868–1953) measured the *charge* of the electron. He did so by observing the movement of tiny droplets of the "highest grade clock oil" in an apparatus that contained electrically charged plates and an x-ray source (Figure 2.6). Here is a description of the basis of the experiment: X-rays knocked electrons from gas molecules in the air, and as an oil droplet fell through a hole in the positive (upper) plate, the electrons stuck to the drop, giving it a negative charge. With the electric field off, Millikan measured the mass of the droplet from its rate of fall. By turning on the field and

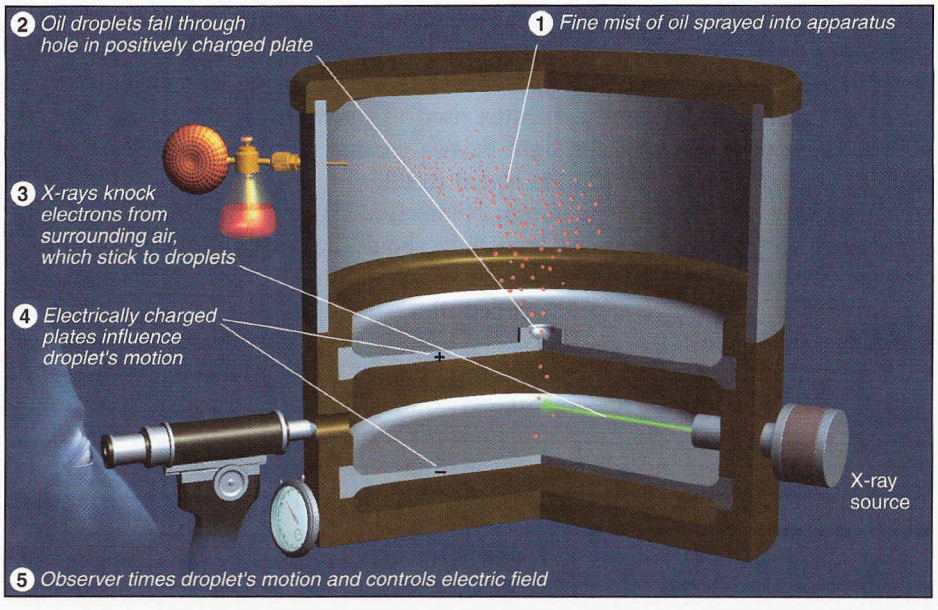

Figure 2.6 Millikan's oil-drop experiment for measuring an electron's charge. The motion of a given oil droplet depends on the variation in electric field and the total charge on the droplet, which depends in turn on the number of attached electrons. Millikan reasoned that the total charge must be some whole-number multiple of the charge of the electron.

Animation: Millikan Oil Drop
Online Learning Center

varying its strength, he could make the drop fall more slowly, rise, or pause suspended. From these data, Millikan calculated the total charge of the droplet.

After studying many droplets, Millikan calculated that the various charges of the droplets were always some *whole-number multiple of a minimum charge*. He reasoned that different oil droplets picked up different numbers of electrons, so this minimum charge must be that of the electron itself. The value, which he calculated over 95 years ago, is within 1% of the modern value of the electron's charge, -1.602×10^{-19} C (C stands for *coulomb,* the SI unit of charge). Using the electron's mass/charge ratio from work by Thomson and others and this value for the electron's charge, let's calculate the electron's *extremely* small mass the way Millikan did:

$$\text{Mass of electron} = \frac{\text{mass}}{\text{charge}} \times \text{charge} = \left(-5.686\times10^{-12}\ \frac{\text{kg}}{\text{C}}\right)(-1.602\times10^{-19}\ \text{C})$$
$$= 9.109\times10^{-31}\ \text{kg} = 9.109\times10^{-28}\ \text{g}$$

Discovery of the Atomic Nucleus

Clearly, the properties of the electron posed problems about the inner structure of atoms. If everyday matter is electrically neutral, the atoms that make it up must be neutral also. But if atoms contain negatively charged electrons, what positive charges balance them? And if an electron has such an incredibly tiny mass, what accounts for an atom's much larger mass? To address these issues, Thomson proposed a model of a spherical atom composed of diffuse, positively charged matter, in which electrons were embedded like "raisins in a plum pudding."

Near the turn of the 20th century, French scientists discovered radioactivity, the emission of particles and/or radiation from atoms of certain elements. Just a few years later, in 1910, the New Zealand–born physicist Ernest Rutherford (1871–1937) used one type of radioactive particle in a series of experiments that solved this dilemma of atomic structure.

Figure 2.7 is a three-part representation of Rutherford's experiment. Tiny, dense, positively charged alpha (α) particles emitted from radium were aimed, like minute projectiles, at thin gold foil. The figure illustrates (A) the "plum-pudding" hypothesis, (B) the apparatus used to measure the deflection (scattering) of the α particles from the light flashes created when the particles struck a circular, coated screen, and (C) the actual result.

With Thomson's model in mind, Rutherford expected only minor, if any, deflections of the α particles because they should act as tiny, dense, positively charged "bullets" and go right through the gold atoms. According to the model, the embedded electrons could not deflect the α particles any more than a Ping-Pong ball could deflect a speeding baseball. Initial results confirmed this, but soon the unexpected happened. As Rutherford recalled: "Then I remember two or three days later Geiger [one of his coworkers] coming to me in great excitement and saying, 'We have been able to get some of the α particles coming backwards . . .' It was quite the most incredible event that has ever happened to me in my life. It was almost as incredible as if you fired a 15-inch shell at a piece of tissue paper and it came back and hit you."

The data showed that very few α particles were deflected at all, and that only 1 in 20,000 was deflected by more than 90° ("coming backwards"). It seemed that these few α particles were being repelled by something small, dense, and positive within the gold atoms. From the mass, charge, and velocity of the α particles, the frequency of these large-angle deflections, and the properties of electrons, Rutherford calculated that *an atom is mostly space occupied by electrons,* but in the center of that space is a tiny region, which he called the **nucleus,** that contains *all the positive charge and essentially all the mass of the atom.* He proposed that positive particles lay within the nucleus and called them *protons,* and then calculated the magnitude of the nuclear charge with remarkable accuracy. Rutherford's model explained the charged nature of matter, but it could not account for all the atom's mass. After more than 20 years, this issue was resolved when, in 1932, James Chadwick discovered the *neutron,* an uncharged dense particle that also resides in the nucleus.

Animation: Rutherford's Experiment
Online Learning Center

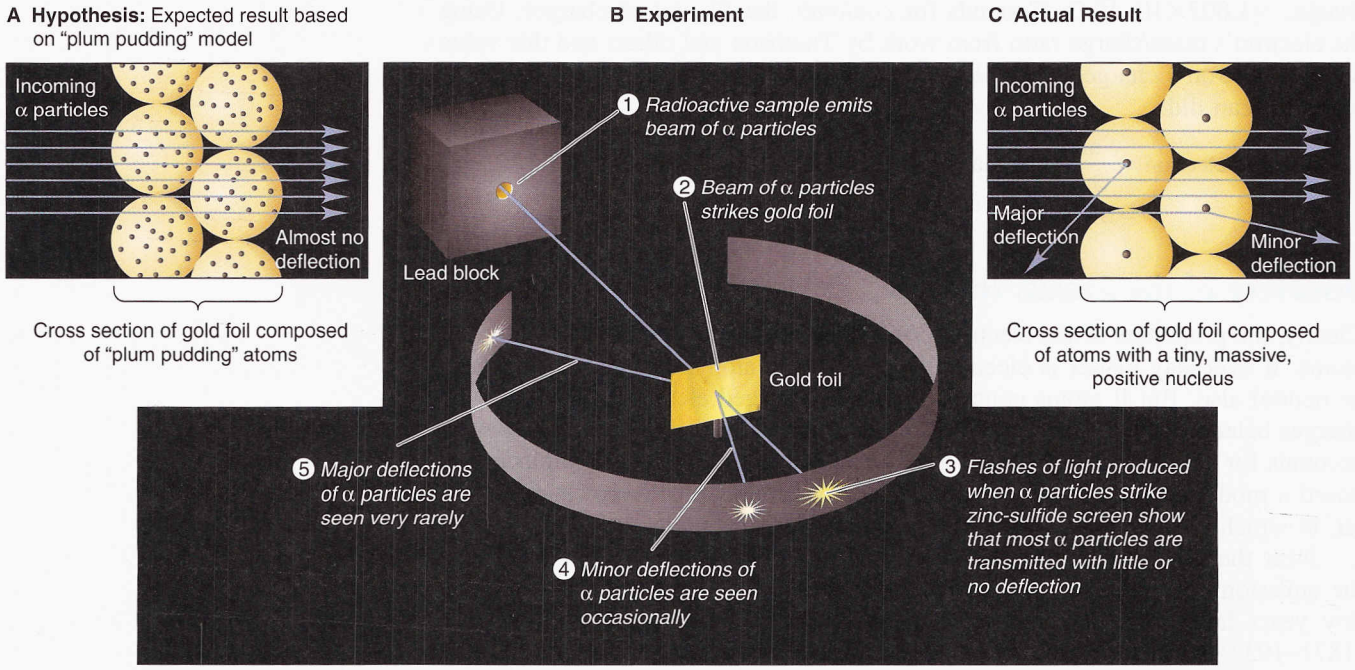

Figure 2.7 Rutherford's α-scattering experiment and discovery of the atomic nucleus. A, HYPOTHESIS: Atoms consist of electrons embedded in diffuse, positively charged matter, so the speeding α particles should pass through the gold foil with, at most, minor deflections. **B,** EXPERIMENT: α Particles emit a flash of light when they pass through the gold atoms and hit a phosphor-coated screen. **C,** RESULTS: Occasional minor deflections and very infrequent major deflections are seen. This means very high mass and positive charge are concentrated in a small region within the atom, the nucleus.

SECTION SUMMARY

Several major discoveries at the turn of the 20th century led to our current model of atomic structure. Cathode rays were shown to consist of negative particles (electrons) that exist in all matter. J. J. Thomson measured their mass/charge ratio and concluded that they are much smaller and lighter than atoms. Robert Millikan determined the charge of the electron, which he combined with other data to calculate its mass. Ernest Rutherford proposed that atoms consist of a tiny, massive, positive nucleus surrounded by electrons.

2.5 THE ATOMIC THEORY TODAY

For nearly 200 years, scientists have known that all matter consists of atoms, and they have learned astonishing things about them. Dalton's hard, impenetrable spheres have given way to atoms with "fuzzy," indistinct boundaries and an elaborate internal architecture of subatomic particles. In this section, we examine our current model and begin to see how the properties of these particles affect the properties of atoms. Then we'll see how Dalton's theory stands up today.

Structure of the Atom

An *atom* is an electrically neutral, spherical entity composed of a positively charged central nucleus surrounded by one or more negatively charged electrons (Figure 2.8). The electrons move rapidly within the available atomic volume, held there by the attraction of the nucleus. The nucleus is incredibly dense: it contributes 99.97% of the atom's mass but occupies only about 1 ten-trillionth of its volume. (A nucleus the size of a period on this page would weigh about 100 tons, as much as 50 cars!) An atom's diameter ($\sim 10^{-10}$ m) is about 10,000 times the diameter of its nucleus ($\sim 10^{-14}$ m).

An atomic nucleus consists of protons and neutrons (the only exception is the simplest hydrogen nucleus, which is a single proton). The **proton** ($\mathbf{p^+}$) has a positive charge, and the **neutron** ($\mathbf{n^0}$) has no charge; thus, the positive charge of the nucleus results from its protons. The *magnitude* of charge possessed by a proton is equal to that of an **electron** ($\mathbf{e^-}$), but the *signs* of the charges are opposite.

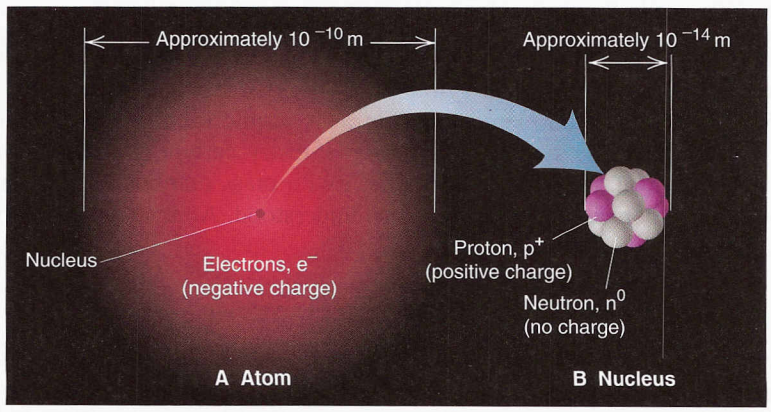

Figure 2.8 **General features of the atom. A,** A "cloud" of rapidly moving, negatively charged electrons occupies virtually all the atomic volume and surrounds the tiny, central nucleus. **B,** The nucleus contains virtually all the mass of the atom and consists of positively charged protons and uncharged neutrons. If the nucleus were actually the size in the figure (~1 cm across), the atom would be about 100 m across—slightly more than the length of a football field!

Table 2.2 Properties of the Three Key Subatomic Particles

Name (Symbol)	Charge		Mass		Location in Atom
	Relative	Absolute (C)*	Relative (amu)†	Absolute (g)	
Proton (p^+)	1+	$+1.60218\times10^{-19}$	1.00727	1.67262×10^{-24}	Nucleus
Neutron (n^0)	0	0	1.00866	1.67493×10^{-24}	Nucleus
Electron (e^-)	1−	-1.60218×10^{-19}	0.00054858	9.10939×10^{-28}	Outside nucleus

*The coulomb (C) is the SI unit of charge.
†The atomic mass unit (amu) equals 1.66054×10^{-24} g; discussed later in this section.

An atom is neutral because the number of protons in the nucleus equals the number of electrons surrounding the nucleus. Some properties of these three subatomic particles are listed in Table 2.2.

Atomic Number, Mass Number, and Atomic Symbol

The **atomic number (*Z*)** of an element equals the number of protons in the nucleus of each of its atoms. *All atoms of a particular element have the same atomic number, and each element has a different atomic number from that of any other element.* All carbon atoms ($Z = 6$) have 6 protons, all oxygen atoms ($Z = 8$) have 8 protons, and all uranium atoms ($Z = 92$) have 92 protons. There are currently 114 known elements, of which 90 occur in nature; the remaining 24 have been synthesized by nuclear processes.

The total number of protons and neutrons in the nucleus of an atom is its **mass number (*A*).** Each proton and each neutron contributes one unit to the mass number. Thus, a carbon atom with 6 protons and 6 neutrons in its nucleus has a mass number of 12, and a uranium atom with 92 protons and 146 neutrons in its nucleus has a mass number of 238.

The nuclear mass and charge are often included with the **atomic symbol** (or *element symbol*). Every element has a symbol based on its English, Latin, or Greek name, such as C for carbon, O for oxygen, S for sulfur, and Na for sodium (Latin *natrium*). The atomic number (Z) is written as a left *sub*script and the mass number (A) as a left *super*script to the symbol, so element X would be ${}^{A}_{Z}\mathrm{X}$. Since the mass number is the sum of protons and neutrons, the number of neutrons (N) equals the mass number minus the atomic number:

$$\text{Number of neutrons} = \text{mass number} - \text{atomic number}, \quad \text{or} \quad N = A - Z \tag{2.2}$$

Thus, a chlorine atom, which is symbolized as ${}^{35}_{17}\mathrm{Cl}$, has $A = 35$, $Z = 17$, and $N = 35 - 17 = 18$. Each element has its own atomic number, so we know the atomic number from the symbol. For example, every carbon atom has 6 protons. Therefore, instead of writing ${}^{12}_{6}\mathrm{C}$ for carbon with mass number 12, we can write ${}^{12}\mathrm{C}$ (spoken "carbon twelve"), with $Z = 6$ understood. Another way to write this atom is carbon-12.

Naming an Element Element names have a variety of origins. Carbon comes from coal (Latin *carbo*, "ember"). Mercury (Hg) is named for the planet, but its symbol comes from its earlier name *hydragyrum* (Latin, "liquid silver"). Some names are based on a chemical action, such as hydrogen (Greek *hydros*, "water," and *genes*, "producer"), or on an obvious property, such as chlorine (Greek *chloros*, "yellow-green"). Sometimes, an element name refers to a country, as in germanium for Germany and americium for America. Ytterbium, yttrium, erbium, and terbium are all named for Ytterby, the Swedish town where these elements were discovered. Paying homage to great scientists led to the names of many synthetic elements, such as einsteinium for Albert Einstein and curium for Marie and Pierre Curie.

Isotopes and Atomic Masses of the Elements

All atoms of an element are identical in atomic number but not in mass number. **Isotopes** of an element are atoms that have *different numbers of neutrons* and therefore different mass numbers. For example, all carbon atoms ($Z = 6$) have 6 protons and 6 electrons, but only 98.89% of naturally occurring carbon atoms have 6 neutrons in the nucleus ($A = 12$). A small percentage (1.11%) have 7 neutrons in the nucleus ($A = 13$), and even fewer (less than 0.01%) have 8 ($A = 14$). These are carbon's three naturally occurring isotopes—${}^{12}\mathrm{C}$, ${}^{13}\mathrm{C}$, and ${}^{14}\mathrm{C}$. Five other carbon isotopes—${}^{9}\mathrm{C}$, ${}^{10}\mathrm{C}$, ${}^{11}\mathrm{C}$, ${}^{15}\mathrm{C}$, and ${}^{16}\mathrm{C}$—have been observed in

the laboratory. Figure 2.9 depicts the atomic number, mass number, and symbol for four atoms, two of which are isotopes of the same element.

A key point is that the chemical properties of an element are primarily determined by the number of electrons, so *all isotopes of an element have nearly identical chemical behavior,* even though they have different masses.

SAMPLE PROBLEM 2.2 Determining the Number of Subatomic Particles in the Isotopes of an Element

Problem Silicon (Si) is essential to the computer industry as a major component of semiconductor chips. It has three naturally occurring isotopes: ^{28}Si, ^{29}Si, and ^{30}Si. Determine the numbers of protons, neutrons, and electrons in each silicon isotope.

Plan The mass number (A) of each of the three isotopes is given, so we know the sum of protons and neutrons. From the elements list on the text's inside front cover, we find the atomic number (Z, number of protons), which equals the number of electrons. We obtain the number of neutrons from Equation 2.2.

Solution From the elements list, the atomic number of silicon is 14. Therefore,

^{28}Si has 14p$^+$, 14e$^-$, and 14n^0 (28 − 14)
^{29}Si has 14p$^+$, 14e$^-$, and 15n^0 (29 − 14)
^{30}Si has 14p$^+$, 14e$^-$, and 16n^0 (30 − 14)

FOLLOW-UP PROBLEM 2.2 How many protons, neutrons, and electrons are in **(a)** $^{11}_{5}$Q? **(b)** $^{41}_{20}$X? **(c)** $^{131}_{53}$Y? What element symbols do Q, X, and Y represent?

The mass of an atom is measured *relative* to the mass of an atomic standard. The modern atomic mass standard is the carbon-12 atom. Its mass is defined as *exactly* 12 atomic mass units. Thus, the **atomic mass unit (amu)** is $\frac{1}{12}$ the mass of a carbon-12 atom. Based on this standard, the ^{1}H atom has a mass of 1.008 amu; in other words, a ^{12}C atom has almost 12 times the mass of an ^{1}H atom. We will continue to use the term *atomic mass unit* in the text, although the name of the unit has been changed to the **dalton (Da);** thus, one ^{12}C atom has a mass of 12 daltons (12 Da, or 12 amu). The atomic mass unit, which is a unit of relative mass, has an absolute mass of 1.66054×10^{-24} g.

The isotopic makeup of an element is determined by **mass spectrometry,** a method for measuring the relative masses and abundances of atomic-scale particles very precisely (see the Tools of the Laboratory essay on the next page). For example, using a mass spectrometer, we measure the mass ratio of ^{28}Si to ^{12}C as

$$\frac{\text{Mass of } ^{28}\text{Si atom}}{\text{Mass of } ^{12}\text{C standard}} = 2.331411$$

From this mass ratio, we find the **isotopic mass** of the ^{28}Si atom, the mass of the isotope relative to the mass of the standard carbon-12 isotope:

$$\text{Isotopic mass of } ^{28}\text{Si} = \text{measured mass ratio} \times \text{mass of } ^{12}\text{C}$$
$$= 2.331411 \times 12 \text{ amu} = 27.97693 \text{ amu}$$

Along with the isotopic mass, the mass spectrometer gives the relative abundance (fraction) of each isotope in a sample of the element. For example, the percent abundance of ^{28}Si is 92.23%. Such measurements provide data for obtaining the **atomic mass** (also called *atomic weight*) of an element, the *average* of the masses of its naturally occurring isotopes weighted according to their abundances.

Each naturally occurring isotope of an element contributes a certain portion to the atomic mass. For instance, as just noted, 92.23% of Si atoms are ^{28}Si. Using this percent abundance as a fraction and multiplying by the isotopic mass of ^{28}Si gives the portion of the atomic mass of Si contributed by ^{28}Si:

$$\text{Portion of Si atomic mass from } ^{28}\text{Si} = 27.97693 \text{ amu} \times 0.9223 = 25.8031 \text{ amu}$$
(retaining two additional significant figures)

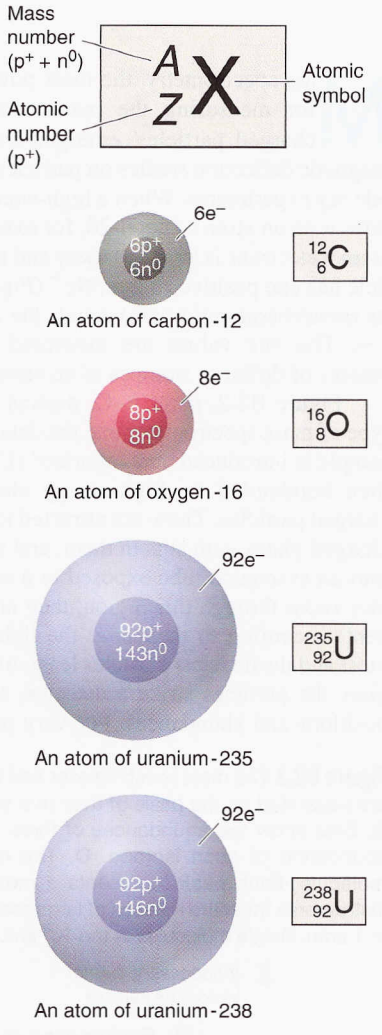

Figure 2.9 Depicting the atom. Atoms of carbon-12, oxygen-16, uranium-235, and uranium-238 are shown (nuclei not drawn to scale) with their symbolic representations. The sum of the number of protons (Z) and the number of neutrons (N) equals the mass number (A). An atom is neutral, so the number of protons in the nucleus equals the number of electrons around the nucleus. The two uranium atoms are isotopes of the element.

Mass Spectrometry

Mass spectrometry, the most powerful technique for measuring the mass and abundance of charged particles, emerged from electric and magnetic deflection studies on particles formed in cathode ray experiments. When a high-energy electron collides with an atom of neon-20, for example, one of the atom's electrons is knocked away and the resulting particle has one positive charge, Ne^+ (Figure B2.1). Thus, its mass/charge ratio (m/e) equals the mass divided by 1+. The m/e values are measured to identify the masses of different isotopes of an element.

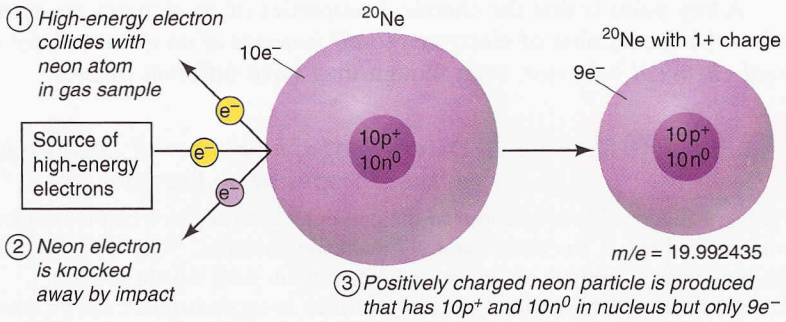

Figure B2.1 Formation of a positively charged neon (Ne) particle.

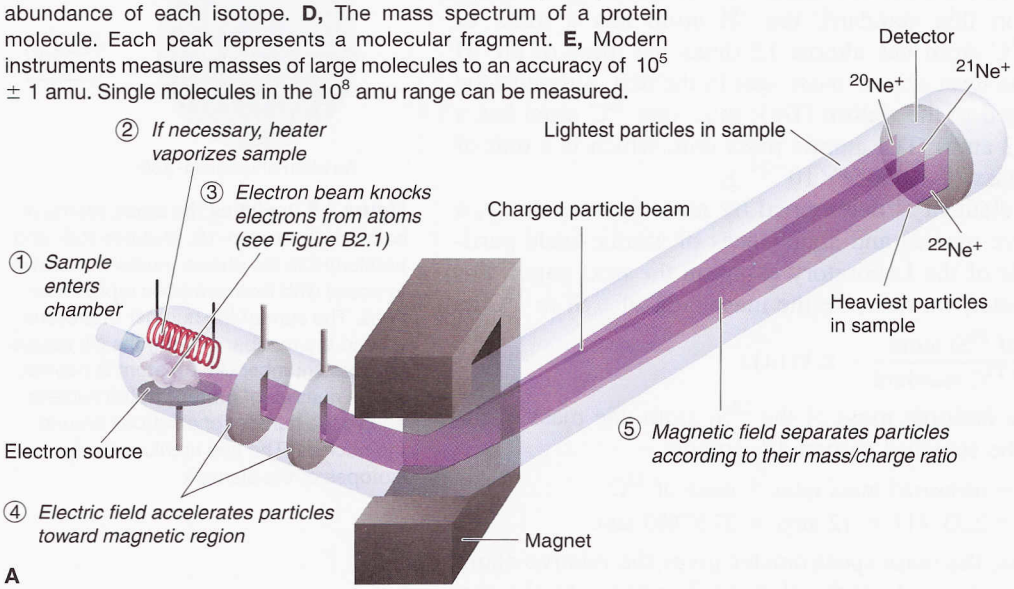
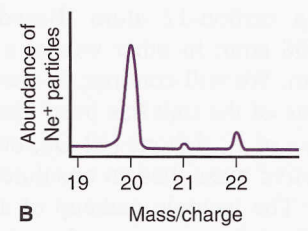
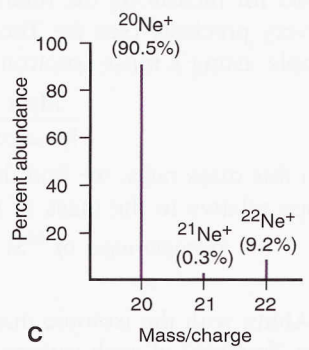
Figure B2.2, parts A–C, depicts the core of one type of mass spectrometer and the data it provides. The sample is introduced and vaporized (if liquid or solid), then bombarded by high-energy electrons to form positively charged particles. These are attracted toward a series of negatively charged plates with slits in them, and some particles pass through into an evacuated tube exposed to a magnetic field. As the particles zoom through this region, they are deflected (their paths are bent) according to their m/e: the lightest particles are deflected most and the heaviest particles least. At the end of the magnetic region, the particles strike a detector, which records their relative positions and abundances. For very precise work, such as determining isotopic masses and abundances, the instrument is calibrated with a substance of known amount and mass.

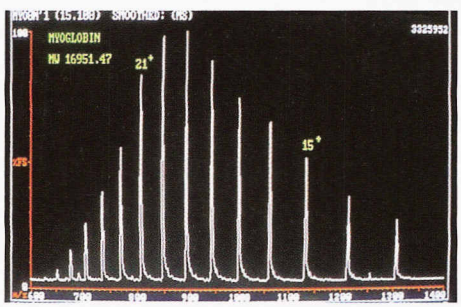
Mass spectrometry is also used in structural chemistry and separations science to measure the mass of virtually any atom, molecule, or molecular fragment. The technique is employed by biochemists determining protein structures (Figure B2.2, parts D and E), materials scientists examining catalyst surfaces, forensic chemists analyzing criminal evidence, pharmaceutical chemists designing new drugs, industrial chemists investigating petroleum components, and many others. In fact, John B. Fenn and Koichi Tanaka shared part of the 2002 Nobel Prize in chemistry for developing methods to study proteins by mass spectrometry.

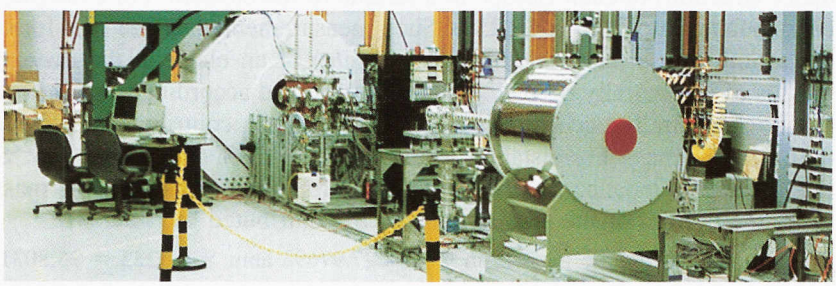
Figure B2.2 The mass spectrometer and its data. A, Charged particles are separated on the basis of their m/e values. Ne is the sample here. **B,** Data show the abundances of three Ne isotopes. **C,** The percent abundance of each isotope. **D,** The mass spectrum of a protein molecule. Each peak represents a molecular fragment. **E,** Modern instruments measure masses of large molecules to an accuracy of $10^5 \pm 1$ amu. Single molecules in the 10^8 amu range can be measured.











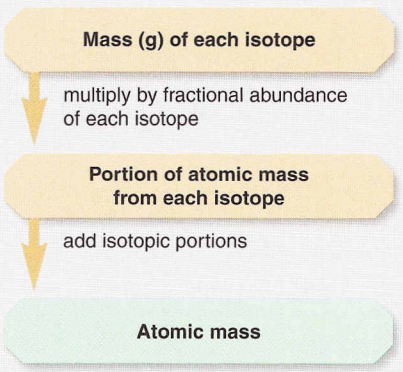
Similar calculations give the portions contributed by ^{29}Si (28.976495 amu × 0.0467 = 1.3532 amu) and by ^{30}Si (29.973770 amu × 0.0310 = 0.9292 amu), and adding the three portions together (rounding to two decimal places at the end) gives the atomic mass of silicon:

$$\begin{aligned}\text{Atomic mass of Si} &= 25.8031 \text{ amu} + 1.3532 \text{ amu} + 0.9292 \text{ amu} \\ &= 28.0855 \text{ amu} = 28.09 \text{ amu}\end{aligned}$$

SAMPLE PROBLEM 2.3 Calculating the Atomic Mass of an Element

Problem Silver (Ag; $Z = 47$) has 46 known isotopes, but only two occur naturally, ^{107}Ag and ^{109}Ag. Given the following mass spectrometric data, calculate the atomic mass of Ag:

Isotope	Mass (amu)	Abundance (%)
^{107}Ag	106.90509	51.84
^{109}Ag	108.90476	48.16



Plan From the mass and abundance of the two Ag isotopes, we have to find the atomic mass of Ag (weighted average of the isotopic masses). We multiply each isotopic mass by its fractional abundance to find the portion of the atomic mass contributed by each isotope. The sum of the isotopic portions is the atomic mass.

Solution Finding the portion of the atomic mass from each isotope:

$$\begin{aligned}\text{Portion of atomic mass from } ^{107}\text{Ag:} &= \text{isotopic mass} \times \text{fractional abundance} \\ &= 106.90509 \text{ amu} \times 0.5184 = 55.42 \text{ amu} \\ \text{Portion of atomic mass from } ^{109}\text{Ag:} &= 108.90476 \text{ amu} \times 0.4816 = 52.45 \text{ amu}\end{aligned}$$

Finding the atomic mass of silver:

$$\text{Atomic mass of Ag} = 55.42 \text{ amu} + 52.45 \text{ amu} = 107.87 \text{ amu}$$

Check The individual portions seem right: ~100 amu × 0.50 = 50 amu. The portions should be almost the same because the two isotopic abundances are almost the same. We rounded each portion to four significant figures because that is the number of significant figures in the abundance values. This is the correct atomic mass (to two decimal places), as shown in the list of elements (*inside front cover*).

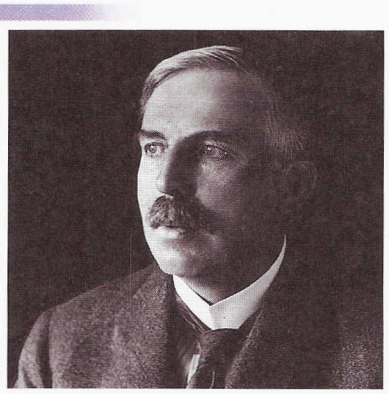
Comment Averages must be interpreted carefully. Although the average number of children in an American family in 1985 was 2.4, no family actually had 2.4 children; similarly, no individual silver atom has a mass of 107.87 amu. But for most laboratory purposes, we consider a sample of silver to consist of atoms with this average mass.

FOLLOW-UP PROBLEM 2.3 Boron (B; $Z = 5$) has two naturally occurring isotopes. Find the percent abundances of ^{10}B and ^{11}B given the atomic mass of B = 10.81 amu, the isotopic mass of ^{10}B = 10.0129 amu, and the isotopic mass of ^{11}B = 11.0093 amu. (*Hint:* The sum of the fractional abundances is 1. If x = abundance of ^{10}B, then $1 - x$ = abundance of ^{11}B.)

A Modern Reassessment of the Atomic Theory

We began discussing the atomic basis of matter with Dalton's model, which proved inaccurate in several respects. What happens to a model whose postulates are found by later experiment to be incorrect? No model can predict every possible future observation, but a powerful model evolves and remains useful. Let's reexamine the atomic theory in light of what we know now:

1. *All matter is composed of atoms.* We now know that atoms *are* divisible and composed of smaller, subatomic particles (electrons, protons, and neutrons), but the atom is still the smallest body that *retains the unique identity* of an element.
2. *Atoms of one element cannot be converted into atoms of another element in a chemical reaction.* We now know that, in *nuclear* reactions, atoms of one element often change into atoms of another, but this *never* happens in a *chemical* reaction.



The Heresy of Radioactive "Transmutation" In 1902, Rutherford performed a series of experiments with radioactive elements that shocked the scientific world. When a radioactive atom of thorium ($Z = 90$) emits an α particle ($Z = 2$), it becomes an atom of radium ($Z = 88$), which then emits another α particle and becomes an atom of radon ($Z = 86$). He proposed that when an atom emits an α particle, it turns into a different atom—one element changes into another! Many viewed this conclusion as a return to alchemy, and, as with Thomson's discovery that atoms contain smaller particles, Rutherford's findings fell on disbelieving ears.

3. *All atoms of an element have the same number of protons and electrons, which determines the chemical behavior of the element.* We now know that isotopes of an element differ in the number of neutrons, and thus in mass number, but a sample of the element is treated as though its atoms have an *average* mass.
4. *Compounds are formed by the chemical combination of two or more elements in specific ratios.* We now know that a few compounds can have slight variations in their atom ratios, but this postulate remains essentially unchanged.

Even today, our picture of the atom is being revised. Although we are confident about the distribution of electrons within the atom (Chapters 7 and 8), the interactions among protons and neutrons within the nucleus are still on the frontier of discovery (Chapter 24).

SECTION SUMMARY

An atom has a central nucleus, which contains positively charged protons and uncharged neutrons and is surrounded by negatively charged electrons. An atom is neutral because the number of electrons equals the number of protons. An atom is represented by the notation ${}^{A}_{Z}X$, in which Z is the atomic number (number of protons), A the mass number (sum of protons and neutrons), and X the atomic symbol. An element occurs naturally as a mixture of isotopes, atoms with the same number of protons but different numbers of neutrons. Each isotope has a mass relative to the ${}^{12}C$ mass standard. The atomic mass of an element is the average of its isotopic masses weighted according to their natural abundances and is determined by modern instruments, especially the mass spectrometer.

2.6 ELEMENTS: A FIRST LOOK AT THE PERIODIC TABLE

At the end of the 18th century, Lavoisier compiled a list of the 23 elements known at that time; by 1870, 65 were known; by 1925, 88; today, there are 114 and still counting! These elements combine to form millions of compounds, so we clearly need some way to organize what we know about their behavior. By the mid-19th century, enormous amounts of information concerning reactions, properties, and atomic masses of the elements had been accumulated. Several researchers noted recurring, or *periodic,* patterns of behavior and proposed schemes to organize the elements according to some fundamental property.

In 1871, the Russian chemist Dmitri Mendeleev published the most successful of these organizing schemes, a table that listed the elements by increasing atomic mass, arranged so that elements with similar chemical properties fell in the same column. The modern **periodic table of the elements,** based on Mendeleev's earlier version, is one of the great classifying schemes in science and has become an indispensable tool to chemists. Throughout your study of chemistry, the periodic table will guide you through an otherwise dizzying amount of chemical and physical behavior.

Organization of the Periodic Table A modern version of the periodic table appears in Figure 2.10 and inside the front cover. It is formatted as follows:

1. Each element has a box that contains its atomic number, atomic symbol, and atomic mass. The boxes lie in order of *increasing atomic number* (number of protons) as you move from left to right.
2. The boxes are arranged into a grid of **periods** (horizontal rows) and **groups** (vertical columns). Each period has a number from 1 to 7. Each group has a number from 1 to 8 *and* either the letter A or B. A new system, with group

numbers from 1 to 18 but no letters, appears in parentheses under the number-letter designations. (Most chemists still use the number-letter system, so the text retains it, but shows the new numbering system in parentheses.)

3. The eight A groups (two on the left and six on the right) contain the *main-group,* or *representative, elements*. The ten B groups, located between Groups 2A(2) and 3A(13), contain the *transition elements*. Two horizontal series of *inner transition elements,* the lanthanides and the actinides, fit *between* the elements in Group 3B(3) and Group 4B(4) and are usually placed below the main body of the table.

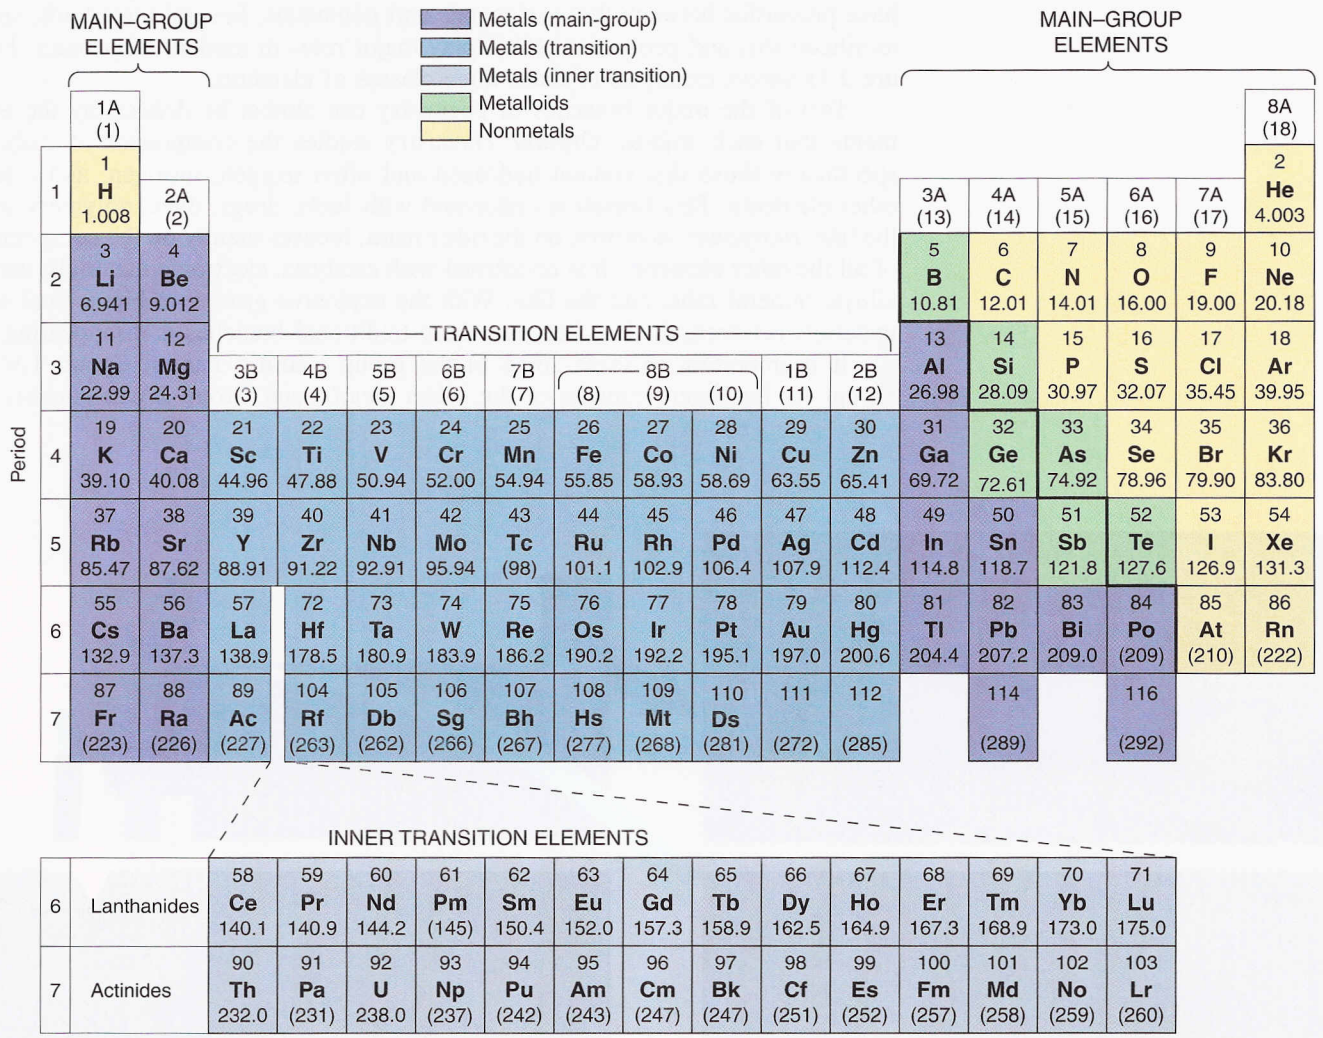


Figure 2.10 The modern periodic table. The table consists of element boxes arranged by *increasing* atomic number into groups (vertical columns) and periods (horizontal rows). Each box contains the atomic number, atomic symbol, and atomic mass. (A mass in parentheses is the mass number of the most stable isotope of that element.) The periods are numbered 1 to 7. The groups (sometimes called *families*) have a number-letter designation and a new group number in parentheses. The A groups are the main-group elements; the B groups are the transition elements. Two series of inner transition elements are placed below the main body of the table but actually fit between the elements indicated. Metals lie below and to the left of the thick "staircase" line [top of 3A(13) to bottom of 6A(16)] and include main-group metals *(purple-blue),* transition elements *(blue),* and inner transition elements *(gray-blue).* Nonmetals *(yellow)* lie to the right of the line. Metalloids *(green)* lie along the line. We discuss the placement of hydrogen in Chapter 14. As of late 2004, elements 111, 112, 114, and 116 had not yet been named.

At this point in the text, the clearest distinction among the elements is their classification as metals, nonmetals, or metalloids. The "staircase" line that runs from the top of Group 3A(13) to the bottom of Group 6A(16) is a dividing line for this classification. The **metals** (three shades of blue) appear in the large lower-left portion of the table. About three-quarters of the elements are metals, including many main-group elements and all the transition and inner transition elements. They are generally shiny solids at room temperature (mercury is the only liquid) that conduct heat and electricity well and can be tooled into sheets (malleable) and wires (ductile). The **nonmetals** (yellow) appear in the small upper-right portion of the table. They are generally gases or dull, brittle solids at room temperature (bromine is the only liquid) and conduct heat and electricity poorly. Along the staircase line lie the **metalloids** (green; also called **semimetals**), elements that have properties between those of metals and nonmetals. Several metalloids, such as silicon (Si) and germanium (Ge), play major roles in modern electronics. Figure 2.11 shows examples of these three classes of elements.

Two of the major branches of chemistry can almost be defined by the elements that each studies. *Organic chemistry* studies the compounds of carbon, specifically those that contain hydrogen and often oxygen, nitrogen, and a few other elements. This branch is concerned with fuels, drugs, dyes, polymers, and the like. *Inorganic chemistry,* on the other hand, focuses mainly on the compounds of all the other elements. It is concerned with catalysts, electronic materials, metal alloys, mineral salts, and the like. With the explosive growth in biomedical and materials research, the line between these traditional branches is disappearing.

It is important to learn some of the group (family) names. Group 1A(1), except for hydrogen, consists of the *alkali metals,* and Group 2A(2) consists of

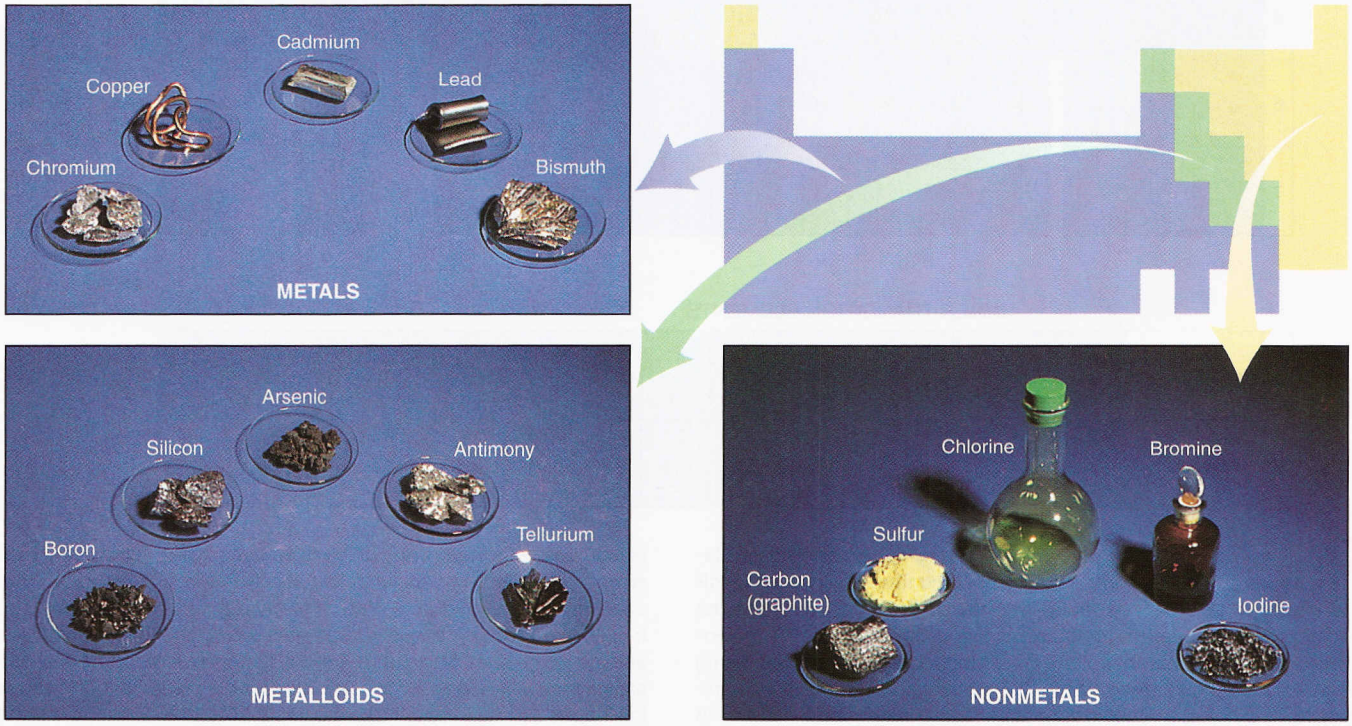

Figure 2.11 Metals, metalloids, and nonmetals.

the *alkaline earth metals*. Both groups of metals are highly reactive elements. The *halogens*, Group 7A(17), are highly reactive nonmetals, whereas the *noble gases*, Group 8A(18), are relatively unreactive nonmetals. Other main groups [3A(13) to 6A(16)] are often named for the first element in the group; for example, Group 6A is the *oxygen family*.

A key point that we return to many times is that, in general, *elements in a group have* ***similar*** *chemical properties and elements in a period have* ***different*** *chemical properties*. We begin applying the organizing power of the periodic table in the next section, where we discuss how elements combine to form compounds.

SECTION SUMMARY

In the periodic table, the elements are arranged by atomic number into horizontal periods and vertical groups. Because of the periodic recurrence of certain key properties, elements within a group have similar behavior, whereas elements in a period have dissimilar behavior. Nonmetals appear in the upper-right portion of the table, metalloids lie along a staircase line, and metals fill the rest of the table.

2.7 COMPOUNDS: INTRODUCTION TO BONDING

The overwhelming majority of elements occur in chemical combination with other elements. In fact, only a few elements occur free in nature. The noble gases—helium (He), neon (Ne), argon (Ar), krypton (Kr), xenon (Xe), and radon (Rn)—occur in air as separate atoms. In addition to occurring in compounds, oxygen (O), nitrogen (N), and sulfur (S) occur in the most common elemental form as the molecules O_2, N_2, and S_8, and carbon (C) occurs in vast, nearly pure deposits of coal. Some of the metals, such as copper (Cu), silver (Ag), gold (Au), and platinum (Pt), may also occur uncombined with other elements. But these few exceptions reinforce the general rule that elements occur combined in compounds.

It is the electrons of the atoms of interacting elements that are involved in compound formation. Elements combine in two general ways:

1. *Transferring electrons* from the atoms of one element to those of another to form **ionic compounds**
2. *Sharing electrons* between atoms of different elements to form **covalent compounds**

These processes generate **chemical bonds,** the forces that hold the atoms of elements together in a compound. We'll introduce compound formation next and have much more to say about it in later chapters.

The Formation of Ionic Compounds

Ionic compounds are composed of **ions,** charged particles that form when an atom (or small group of atoms) gains or loses one or more electrons. The simplest type of ionic compound is a **binary ionic compound,** one composed of just two elements. It typically forms *when a metal reacts with a nonmetal*. Each metal atom loses a certain number of its electrons and becomes a **cation,** a positively charged ion. The nonmetal atoms gain the electrons lost by the metal atoms and become **anions,** negatively charged ions. In effect, the metal atoms *transfer electrons* to the nonmetal atoms. The resulting cations and anions attract each other through electrostatic forces and form the ionic compound. *All binary ionic compounds are solids*. A cation or anion derived from a single atom is called a **monatomic ion;** we'll discuss polyatomic ions, those derived from a small group of atoms, later.

The formation of the binary ionic compound sodium chloride, common table salt, is depicted in Figure 2.12, from the elements through the atomic-scale electron transfer to the compound. In the electron transfer, a sodium atom, which is neutral because it has the same number of protons as electrons, *loses* 1 electron and forms a sodium cation, Na^+. (The charge on the ion is written as a *right superscript*.) A chlorine atom *gains* the electron and becomes a chloride anion, Cl^-. (The name change from the nonmetal atom to the ion is discussed in the next section.) Even the tiniest visible grain of table salt contains an enormous number of sodium and chloride ions. The oppositely charged ions (Na^+ and Cl^-) attract each other, and the similarly charged ions (Na^+ and Na^+, or Cl^- and Cl^-) repel each other. The resulting solid aggregation is a regular array of alternating Na^+ and Cl^- ions that extends in all three dimensions.

Animation: Formation of an Ionic Compound
Online Learning Center

The strength of the ionic bonding depends to a great extent on the net strength of these attractions and repulsions and is described by *Coulomb's law,* which can be expressed as follows: *the energy of attraction (or repulsion) between two particles is directly proportional to the product of the charges and inversely proportional to the distance between them.*

$$\text{Energy} \propto \frac{\text{charge 1} \times \text{charge 2}}{\text{distance}}$$

In other words, ions with higher charges attract (or repel) each other more strongly than ions with lower charges. Likewise, smaller ions attract (or repel) each other more strongly than larger ions, because their charges are closer together. These effects are summarized in Figure 2.13.

Ionic compounds are neutral; that is, they possess no net charge. For this to occur, they must contain equal numbers of positive and negative *charges* but not necessarily equal numbers of positive and negative *ions*. Because Na^+ and Cl^- each bear a unit charge (1+ or 1−), equal numbers of the ions are present in sodium chloride. However, in sodium oxide, for example, twice as many Na^+ ions balance the 2− charge of the oxide ions, O^{2-}.

Can we predict the number of electrons a given atom will lose or gain when it forms an ion? In the formation of sodium chloride, for example, why does each

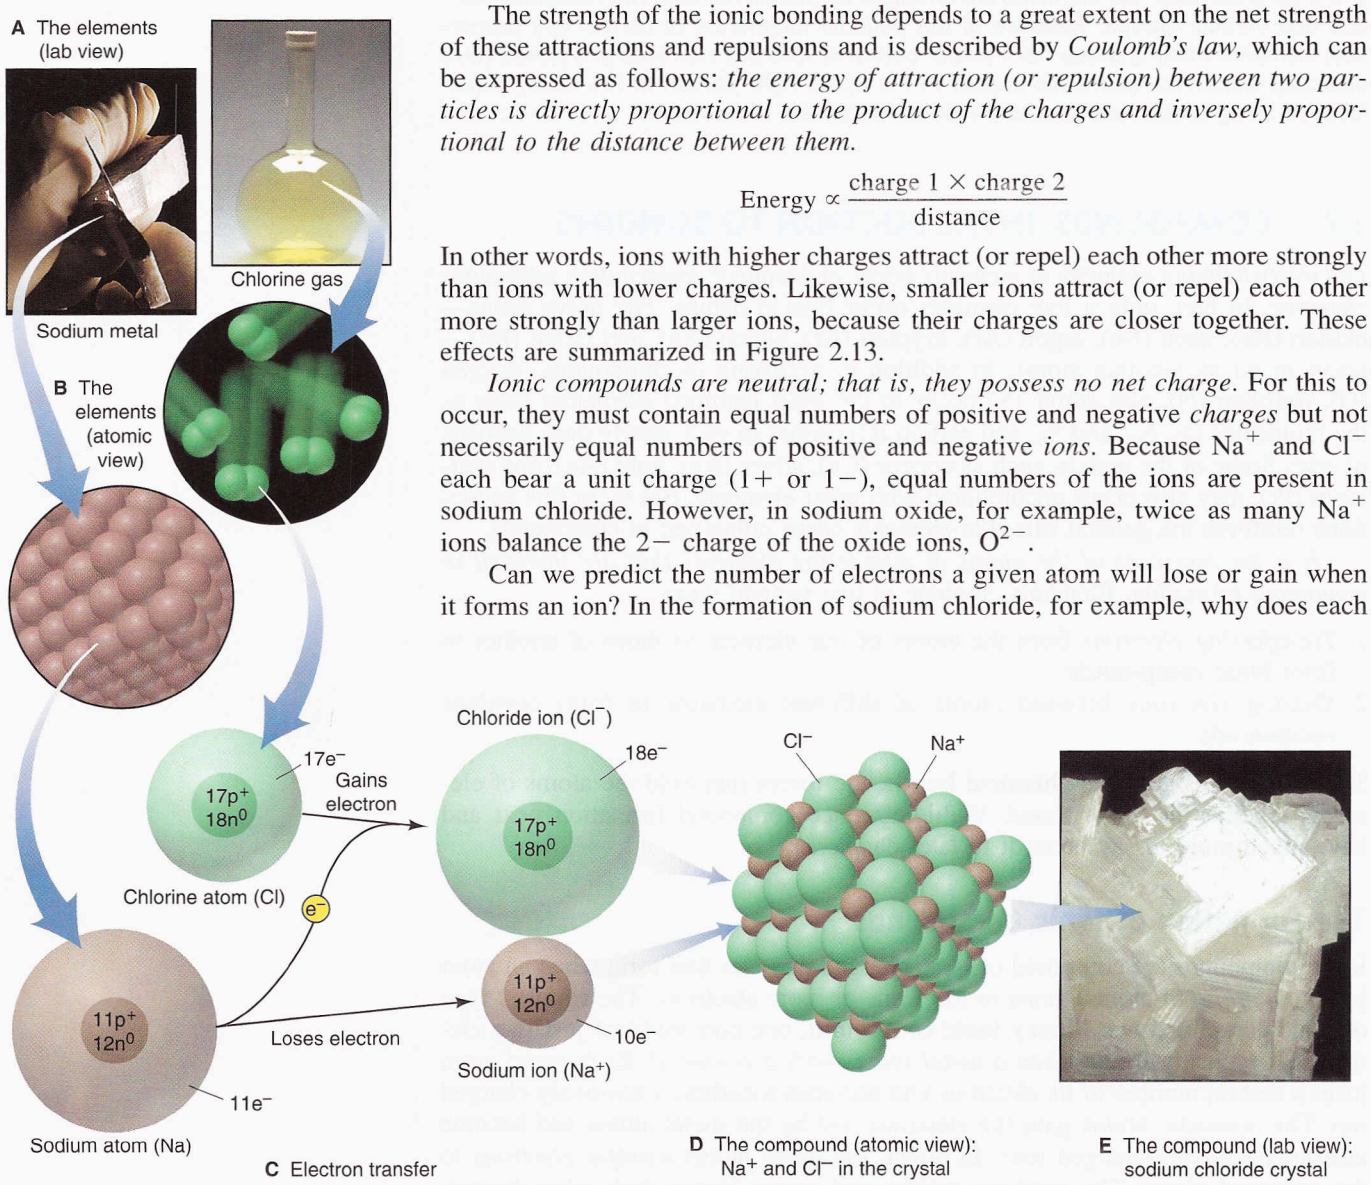

Figure 2.12 The formation of an ionic compound. A, The two elements as seen in the laboratory. **B,** The elements as they might appear on the atomic scale. **C,** The neutral sodium atom loses one electron to become a sodium cation (Na^+), and the chlorine atom gains one electron to become a chloride anion (Cl^-). (Note that when atoms lose electrons, they become ions that are smaller, and when they gain electrons, they become ions that are larger.) **D,** Na^+ and Cl^- ions attract each other and lie in a three-dimensional crystalline array. **E,** This cubic array is reflected in the structure of crystalline NaCl, which occurs naturally as the mineral halite, hence the name *halogens* for the Group 7A(17) elements.

sodium atom give up only 1 of its 11 electrons? Why doesn't each chlorine atom gain two electrons, instead of just one? For A-group elements, the periodic table provides an answer. We generally find that metals lose electrons and nonmetals gain electrons to *form ions with the same number of electrons as in the nearest noble gas* [Group 8A(18)]. Noble gases have a stability (low reactivity) that is related to their number (and arrangement) of electrons. A sodium atom ($11e^-$) can attain the stability of neon ($10e^-$), the nearest noble gas, by losing one electron. Similarly, by gaining one electron, a chlorine atom ($17e^-$) attains the stability of argon ($18e^-$), its nearest noble gas. Thus, when an element located near a noble gas forms a monatomic ion, *it gains or loses enough electrons to attain the same number as that noble gas*. Specifically, the elements in Group 1A(1) lose one electron, those in Group 2A(2) lose two, and aluminum in Group 3A(13) loses three; the elements in Group 7A(17) gain one electron, oxygen and sulfur in Group 6A(16) gain two, and nitrogen in Group 5A(15) gains three.

With the periodic table printed on a two-dimensional surface, as in Figure 2.10, it is easy to get the false impression that the elements in Group 7A(17) are "closer" to the noble gases than the elements in Group 1A(1). Actually, both groups are only one electron away from having the same number of electrons as the noble gases. To make this point, Figure 2.14 shows a modified periodic table that is cut and rejoined, with the noble gases in the center. Now you can see that fluorine (F; $Z = 9$) has one electron fewer and sodium (Na; $Z = 11$) has one electron more than the noble gas neon (Ne; $Z = 10$); thus, they form the F^- and Na^+ ions. Similarly, oxygen (O; $Z = 8$) gains two electrons and magnesium (Mg; $Z = 12$) loses two to form the O^{2-} and Mg^{2+} ions and attain the same number of electrons as neon.

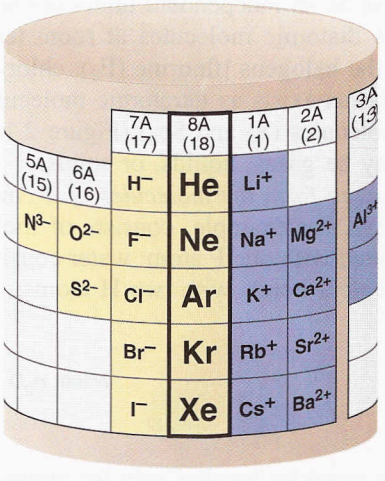

Figure 2.13 Factors that influence the strength of ionic bonding. For ions of a given size, strength of attraction *(arrows)* increases with higher ionic charge *(left to right)*. For ions of a given charge, strength of attraction increases with smaller ionic size *(bottom to top)*.

Figure 2.14 The relationship between ions formed and the nearest noble gas. This periodic table was redrawn to show the positions of other nonmetals *(yellow)* and metals *(blue)* relative to the noble gases and to show the ions these elements form. The ionic charge equals the number of electrons lost (+) or gained (−) to attain the same number of electrons as the nearest noble gas. Species in the same row have the same number of electrons. For example, H^-, He, and Li^+ all have two electrons. [Note that H is shown here in Group 7A(17).]

SAMPLE PROBLEM 2.4 Predicting the Ion an Element Forms

Problem What monatomic ions do the following elements form?
(a) Iodine ($Z = 53$) **(b)** Calcium ($Z = 20$) **(c)** Aluminum ($Z = 13$)

Plan We use the given Z value to find the element in the periodic table and see where its group lies relative to the noble gases. Elements in groups that lie *after* the noble gases *lose* electrons to attain the same number as the nearest noble gas and become positive ions; those in groups that lie *before* the noble gases *gain* electrons and become negative ions.

Solution **(a)** I^- Iodine ($_{53}I$) is a nonmetal in Group 7A(17), one of the halogens. Like any member of this group, it gains 1 electron to have the same number as the nearest Group 8A(18) member, in this case $_{54}Xe$.

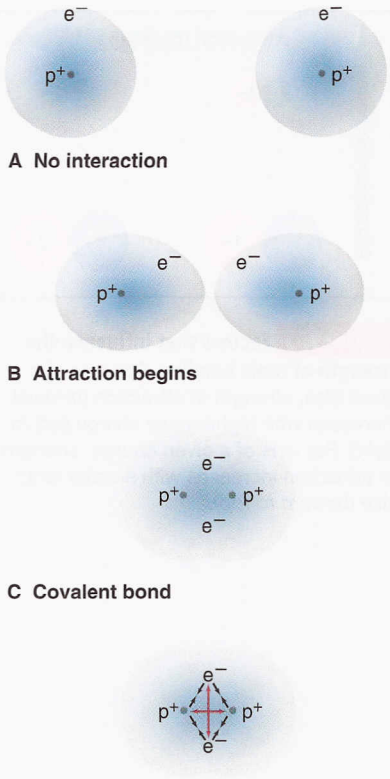

Figure 2.15 Formation of a covalent bond between two H atoms. A, The distance is too great for the atoms to affect each other. **B,** As the distance decreases, the nucleus of each atom begins to attract the electron of the other. **C,** The covalent bond forms when the two nuclei mutually attract the pair of electrons at some optimum distance. **D,** The H_2 molecule is more stable than the separate atoms because the attractive forces *(black arrows)* between each nucleus and the two electrons are greater than the repulsive forces *(red arrows)* between the electrons and between the nuclei.

(b) Ca^{2+} Calcium ($_{20}Ca$) is a member of Group 2A(2), the alkaline earth metals. Like any Group 2A member, it loses 2 electrons to attain the same number as the nearest noble gas, in this case, $_{18}Ar$.

(c) Al^{3+} Aluminum ($_{13}Al$) is a metal in the boron family [Group 3A(13)] and thus loses 3 electrons to attain the same number as its nearest noble gas, $_{10}Ne$.

FOLLOW-UP PROBLEM 2.4 What monatomic ion does each of the following elements form: **(a)** $_{16}S$; **(b)** $_{37}Rb$; **(c)** $_{56}Ba$?

The Formation of Covalent Compounds

Covalent compounds form when elements share electrons, which usually occurs between nonmetals. Even though relatively few nonmetals exist, they interact in many combinations to form a very large number of covalent compounds.

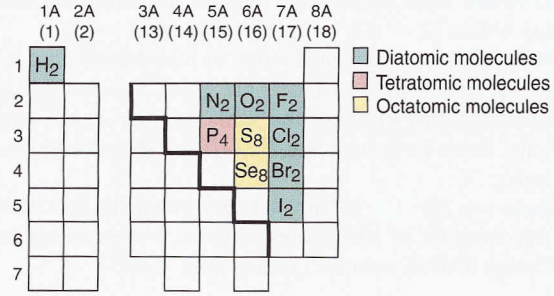
The simplest case of electron sharing occurs not in a compound but between two hydrogen atoms (H; $Z = 1$). Imagine two separated H atoms approaching each other, as in Figure 2.15. As they get closer, the nucleus of each atom attracts the electron of the other atom more and more strongly, and the separated atoms begin to interpenetrate each other. At some optimum distance between the nuclei, the two atoms form a **covalent bond,** a pair of electrons mutually attracted by the two nuclei. The result is a hydrogen molecule, in which each electron no longer "belongs" to a particular H atom: the two electrons are *shared* by the two nuclei. Repulsions between the nuclei and between the electrons also occur, but the net attraction is greater than the net repulsion. (We discuss the properties of covalent bonds in great detail in Chapter 9.)

A sample of hydrogen gas consists of these diatomic molecules (H_2)—pairs of atoms that are chemically bound and behave as an independent unit—*not* separate H atoms. Other nonmetals that exist as diatomic molecules at room temperature are nitrogen (N_2), oxygen (O_2), and the halogens [fluorine (F_2), chlorine (Cl_2), bromine (Br_2), and iodine (I_2)]. Phosphorus exists as tetratomic molecules (P_4), and sulfur and selenium as octatomic molecules (S_8 and Se_8) (Figure 2.16). At room temperature, covalent substances may be gases, liquids, or solids.

Atoms of different elements share electrons to form the molecules of a covalent compound. A sample of hydrogen fluoride, for example, consists of molecules in which one H atom forms a covalent bond with one F atom; water consists of molecules in which one O atom forms covalent bonds with two H atoms:

(As you'll see in Chapter 9, covalent bonding provides another way for atoms to attain the same number of electrons as the nearest noble gas.)

Figure 2.16 Elements that occur as molecules.



Distinguishing the Entities in Covalent and Ionic Substances There is a key distinction between the chemical entities in covalent and ionic substances. *Most covalent substances consist of molecules.* A cup of water, for example, consists of individual water molecules lying near each other. In contrast, under ordinary conditions, *no molecules exist in a sample of an ionic compound.* A piece of sodium chloride, for example, is a continuous array of oppositely charged sodium and chloride ions, *not* a collection of individual "sodium chloride molecules."

Another key distinction exists between the particles attracting each other. Covalent bonding involves the mutual attraction between two (positively charged) nuclei and the two (negatively charged) electrons that reside between them. Ionic bonding involves the mutual attraction between positive and negative ions.

Polyatomic Ions: Covalent Bonds Within Ions Many ionic compounds contain **polyatomic ions,** which consist of two or more atoms bonded *covalently* and have a net positive or negative charge. For example, the ionic compound calcium carbonate is an array of polyatomic carbonate anions and monatomic calcium cations attracted to each other. The carbonate ion consists of a carbon atom covalently bonded to three oxygen atoms, and two additional electrons give the ion its 2− charge (Figure 2.17). In many reactions, a polyatomic ion stays together as a unit.

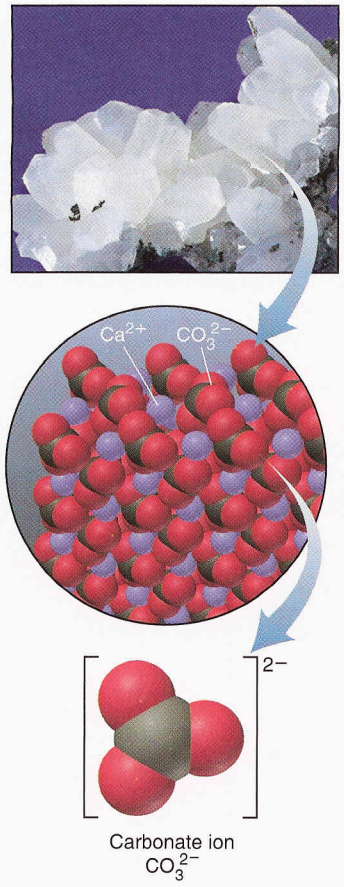


Figure 2.17 A polyatomic ion. Calcium carbonate is a three-dimensional array of monatomic calcium cations *(purple spheres)* and polyatomic carbonate anions. As the bottom structure shows, each carbonate ion consists of four covalently bonded atoms.

The Elements of Life

About one-quarter of all the elements have known roles in organisms. As you can see in Figure 2.18, metals, nonmetals, and metalloids are among these essential elements. But, except for some diatomic oxygen and nitrogen molecules inhaled into the lungs, none of the elements in organisms occurs in pure form; rather, they appear in compounds or as ions in solution.

The elements of life are often classified by the amount present in organisms. The four nonmetals carbon (C), oxygen (O), hydrogen (H), and nitrogen (N) are the *building-block elements* because they make up a major portion of biological molecules. Over 99% of the atoms in organisms are C, O, H, and N; in humans, they account for over 96% by mass of body weight. The nonmetals O and H make up the water in organisms, of course, and together with C occur in all four major classes of biological molecules—carbohydrates, fats, proteins, and nucleic acids. All proteins and nucleic acids also contain N.

The seven *major minerals* (or *macronutrients*) range from around 2% by mass for calcium (Ca) to around 0.14% by mass for chlorine (Cl). The alkali metals sodium and potassium and the halogen chlorine are dissolved in cell fluids as the

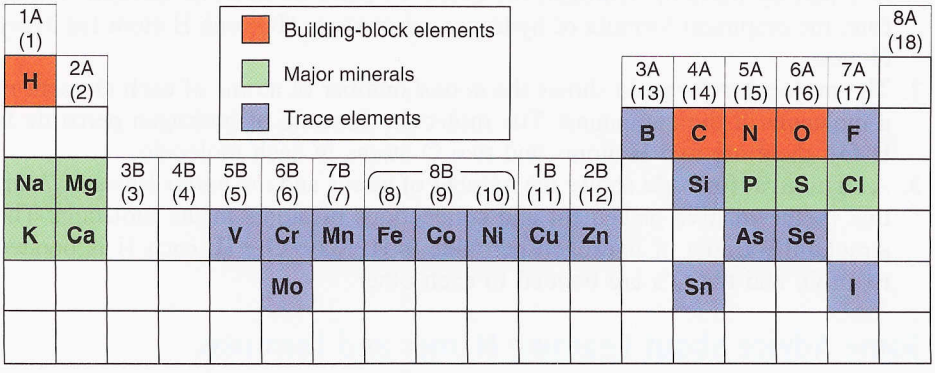

Figure 2.18 A biological periodic table. The building-block elements and major minerals are required by all organisms. Most organisms, including humans, require the trace elements as well. Many other elements (not shown) are found in organisms but have no known role.

ions Na^+, K^+, and Cl^-. The alkaline earth metals magnesium and calcium occur as Mg^{2+} and Ca^{2+}, most often bound to proteins or, in the case of calcium, in bones and teeth. Sulfur (S) occurs mostly in proteins, but phosphorus (P) also occurs in nucleic acids, many fats, and sugars, and as part of a polyatomic ion in bone and cell fluids.

The *trace elements* (or *micronutrients*) are present in much lower amounts, with iron (Fe) most abundant at only 0.005% by mass. Most are associated with protein functions. We look more closely at the trace elements in Chapter 23.

SECTION SUMMARY

Although a few elements occur uncombined in nature, the great majority exist in compounds. Ionic compounds form when a metal *transfers electrons* to a nonmetal, and the resulting positive and negative ions attract each other to form a three-dimensional array. In many cases, metal atoms lose and nonmetal atoms gain enough electrons to attain the same number of electrons as in atoms of the nearest noble gas. Covalent compounds form when elements, usually nonmetals, *share electrons.* Each covalent bond is an electron pair mutually attracted by two atomic nuclei. Monatomic ions are derived from single atoms. Polyatomic ions consist of two or more covalently bonded atoms that have a net positive or negative charge due to a deficit or excess of electrons. The elements in organisms are found as ions or, most often, bonded in large biomolecules. Four building-block elements (C, O, H, N) form these compounds, while seven other elements (major minerals, or macronutrients) are also common, and many others (trace elements, or micronutrients) occur in tiny amounts and play specific roles.

2.8 COMPOUNDS: FORMULAS, NAMES, AND MASSES

Names and formulas of compounds form the vocabulary of the chemical language; now it's time for you to begin speaking and writing this language. In this discussion, you'll learn the names and formulas of ionic and simple covalent compounds and how to calculate the mass of a unit of a compound from its formula.

Types of Chemical Formulas

In a **chemical formula,** element symbols and numerical subscripts show the type and number of each atom present in the smallest unit of the substance. There are several types of chemical formulas for a compound:

1. The **empirical formula** shows the *relative* number of atoms of each element in the compound. It is the simplest type of formula and is derived from the masses of the component elements. For example, in hydrogen peroxide, there is 1 part by mass of hydrogen for every 16 parts by mass of oxygen. Therefore, the empirical formula of hydrogen peroxide is HO: one H atom for every O atom.
2. The **molecular formula** shows the *actual* number of atoms of each element in a molecule of the compound. The molecular formula of hydrogen peroxide is H_2O_2; there are two H atoms and two O atoms in each molecule.
3. A **structural formula** shows the number of atoms and *the bonds between them;* that is, the relative placement and connections of atoms in the molecule. The structural formula of hydrogen peroxide is H—O—O—H; each H is bonded to an O, and the O's are bonded to each other.

Some Advice about Learning Names and Formulas

Perhaps in the future, systematic names for compounds will be used by everyone. However, many reference books, chemical supply catalogs, and practicing chemists still use many common (trivial) names, so you should learn them as well.

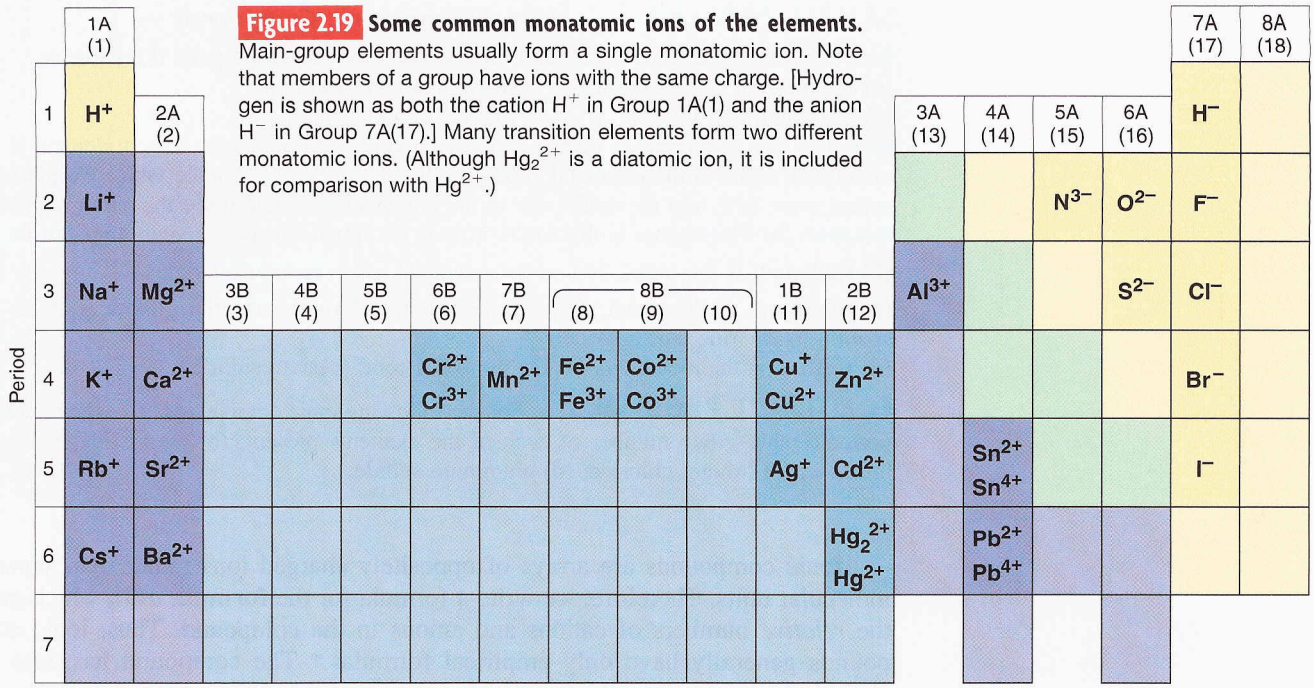

Figure 2.19 Some common monatomic ions of the elements. Main-group elements usually form a single monatomic ion. Note that members of a group have ions with the same charge. [Hydrogen is shown as both the cation H^+ in Group 1A(1) and the anion H^- in Group 7A(17).] Many transition elements form two different monatomic ions. (Although Hg_2^{2+} is a diatomic ion, it is included for comparison with Hg^{2+}.)

Here are some points to note about ion formulas:

- Members of a periodic table group have the same ionic charge; for example, Li, Na, and K are all in Group 1A and all have a 1+ charge.
- For A-group cations, ion charge = group number: for example, Na^+ is in Group 1A, Ba^{2+} in Group 2A. (Exceptions in Figure 2.19 are Sn^{2+} and Pb^{2+}.)
- For anions, ion charge = group number minus 8: for example, S is in Group 6A (6 − 8 = −2), so the ion is S^{2-}.

Here are some suggestions about how to learn names and formulas:

1. Memorize the A-group monatomic ions of Table 2.3 (all except Ag^+, Zn^{2+}, and Cd^{2+}) according to their positions in Figure 2.19. These ions have the same number of electrons as an atom of the nearest noble gas.
2. Consult Table 2.4 (page 65) and Figure 2.19 for some metals that form two different monatomic ions.
3. Divide the tables of names and charges into smaller batches, and learn a batch each day. Try flash cards, with the name on one side and the ion formula on the other. The most common ions are shown in **boldface** in Tables 2.3, 2.4, and 2.5, so you can focus on learning them first.

Names and Formulas of Ionic Compounds

All ionic compound names give the positive ion (cation) first and the negative ion (anion) second.

Compounds Formed from Monatomic Ions Let's first consider binary ionic compounds, those composed of ions of two elements.

- *The name of the cation is the same as the name of the metal.* Many metal names end in *-ium*.
- *The name of the anion takes the root of the nonmetal name and adds the suffix -ide.*

For example, the anion formed from bro*mine* is named brom*ide* (brom+ide). Therefore, the compound formed from the metal calcium and the nonmetal bromine is calcium bromide.

Table 2.3 Common Monatomic Ions*

Charge	Formula	Name
Cations		
1+	H^+	hydrogen
	Li^+	**lithium**
	Na^+	**sodium**
	K^+	**potassium**
	Cs^+	cesium
	Ag^+	**silver**
2+	**Mg^{2+}**	**magnesium**
	Ca^{2+}	**calcium**
	Sr^{2+}	strontium
	Ba^{2+}	**barium**
	Zn^{2+}	**zinc**
	Cd^{2+}	cadmium
3+	Al^{3+}	**aluminum**
Anions		
1−	H^-	hydride
	F^-	**fluoride**
	Cl^-	**chloride**
	Br^-	**bromide**
	I^-	**iodide**
2−	**O^{2-}**	**oxide**
	S^{2-}	**sulfide**
3−	N^{3-}	nitride

*Listed by charge; those in **boldface** are most common.

SAMPLE PROBLEM 2.5 Naming Binary Ionic Compounds

Problem Name the ionic compound formed from the following pairs of elements:
(a) Magnesium and nitrogen **(b)** Iodine and cadmium
(c) Strontium and fluorine **(d)** Sulfur and cesium

Plan The key to naming a binary ionic compound is to recognize which element is the metal and which is the nonmetal. When in doubt, check the periodic table. We place the cation name first, add the suffix *-ide* to the nonmetal root, and place the anion name last.

Solution **(a)** Magnesium is the metal; *nitr-* is the nonmetal root: magnesium nitride

(b) Cadmium is the metal; *iod-* is the nonmetal root: cadmium iodide

(c) Strontium is the metal; *fluor-* is the nonmetal root: strontium fluoride (Note the spelling is fl*uo*ride, not fl*ou*ride.)

(d) Cesium is the metal; *sulf-* is the nonmetal root: cesium sulfide

FOLLOW-UP PROBLEM 2.5 For the following ionic compounds, give the name and periodic table group number of each of the elements present: **(a)** zinc oxide; **(b)** silver bromide; **(c)** lithium chloride; **(d)** aluminum sulfide.

Ionic compounds are arrays of oppositely charged ions rather than separate molecular units. Therefore, we write a formula for the **formula unit,** which gives the *relative* numbers of cations and anions in the compound. Thus, ionic compounds generally have only empirical formulas.* The compound has zero net charge, so the positive charges of the cations must balance the negative charges of the anions. For example, calcium bromide is composed of Ca^{2+} ions and Br^- ions; therefore, two Br^- balance each Ca^{2+}. The formula is $CaBr_2$, not Ca_2Br. In this and all other formulas,

- The subscript refers to the element *preceding* it.
- The *subscript 1 is understood* from the presence of the element symbol alone (that is, we do not write Ca_1Br_2).
- The charge (without the sign) of one ion becomes the subscript of the other:

gives Ca_1Br_2 or $CaBr_2$

Reduce the subscripts to the smallest whole numbers that retain the ratio of ions. Thus, for example, from the ions Ca^{2+} and O^{2-} we have Ca_2O_2, which we reduce to the formula CaO (but see the footnote).

SAMPLE PROBLEM 2.6 Determining Formulas of Binary Ionic Compounds

Problem Write empirical formulas for the compounds named in Sample Problem 2.5.

Plan We write the empirical formula by finding the smallest number of each ion that gives the neutral compound. These numbers appear as *right subscripts* to the element symbol.

Solution

(a) Mg^{2+} and N^{3-}; three Mg^{2+} ions (6+) balance two N^{3-} ions (6−): Mg_3N_2

(b) Cd^{2+} and I^-; one Cd^{2+} ion (2+) balances two I^- ions (2−): CdI_2

(c) Sr^{2+} and F^-; one Sr^{2+} ion (2+) balances two F^- ions (2−): SrF_2

(d) Cs^+ and S^{2-}; two Cs^+ ions (2+) balance one S^{2-} ion (2−): Cs_2S

Comment Note that ion charges do *not* appear in the compound formula. That is, for cadmium iodide, we do *not* write $Cd^{2+}I_2^-$.

FOLLOW-UP PROBLEM 2.6 Write the formulas of the compounds named in Follow-up Problem 2.5.

*Compounds of the mercury(I) ion, such as Hg_2Cl_2, and peroxides of the alkali metals, such as Na_2O_2, are the only two common exceptions. Their empirical formulas are HgCl and NaO, respectively.

Table 2.4 Some Metals That Form More Than One Monatomic Ion*

Element	Ion Formula	Systematic Name	Common (Trivial) Name
Chromium	Cr^{2+}	chromium(II)	chromous
	Cr^{3+}	**chromium(III)**	chromic
Cobalt	Co^{2+}	cobalt(II)	
	Co^{3+}	cobalt(III)	
Copper	**Cu^{+}**	**copper(I)**	cuprous
	Cu^{2+}	**copper(II)**	cupric
Iron	**Fe^{2+}**	**iron(II)**	ferrous
	Fe^{3+}	**iron(III)**	ferric
Lead	**Pb^{2+}**	**lead(II)**	
	Pb^{4+}	lead(IV)	
Mercury	Hg_2^{2+}	mercury(I)	mercurous
	Hg^{2+}	**mercury(II)**	mercuric
Tin	**Sn^{2+}**	**tin(II)**	stannous
	Sn^{4+}	tin(IV)	stannic

*Listed alphabetically by metal name; those in **boldface** are most common.

Compounds with Metals That Can Form More Than One Ion Many metals, particularly the transition elements (B groups), can form more than one ion, each with a particular charge. Table 2.4 shows some examples. Names of compounds containing these elements include a *Roman numeral within parentheses* immediately after the metal ion's name to indicate its ionic charge. For example, iron can form Fe^{2+} and Fe^{3+} ions. The two compounds that iron forms with chlorine are $FeCl_2$, named iron(II) chloride (spoken "iron two chloride"), and $FeCl_3$, named iron(III) chloride.

In common names, the Latin root of the metal is followed by either of two suffixes:

- The suffix *-ous* for the ion with the lower charge
- The suffix *-ic* for the ion with the higher charge

Thus, iron(II) chloride is also called ferr*ous* chloride and iron(III) chloride is fer*ric* chloride. (You can easily remember this naming relationship because there is an ***o*** in *-**ous*** and *lower,* and an ***i*** in *-**ic*** and *higher.*)

SAMPLE PROBLEM 2.7 Determining Names and Formulas of Ionic Compounds of Elements That Form More Than One Ion

Problem Give the systematic names for the formulas or the formulas for the names of the following compounds: **(a)** tin(II) fluoride; **(b)** CrI_3; **(c)** ferric oxide; **(d)** CoS.

Solution **(a)** Tin(II) is Sn^{2+}; fluoride is F^-. Two F^- ions balance one Sn^{2+} ion: tin(II) fluoride is SnF_2. (The common name is stannous fluoride.)

(b) The anion is I^-, iodide, and the formula shows three I^-. Therefore, the cation must be Cr^{3+}, chromium(III): CrI_3 is chromium(III) iodide. (The common name is chromic iodide.)

(c) Ferric is the common name for iron(III), Fe^{3+}; oxide ion is O^{2-}. To balance the ionic charges, the formula of ferric oxide is Fe_2O_3. (The systematic name is iron(III) oxide.)

(d) The anion is sulfide, S^{2-}, which requires that the cation be Co^{2+}. The name is cobalt(II) sulfide.

FOLLOW-UP PROBLEM 2.7 Give the systematic names for the formulas or the formulas for the names of the following compounds: **(a)** lead(IV) oxide; **(b)** Cu_2S; **(c)** $FeBr_2$; **(d)** mercuric chloride.

Table 2.5 Common Polyatomic Ions*

Formula	Name
Cations	
NH_4^+	**ammonium**
H_3O^+	**hydronium**
Anions	
CH_3COO^- (or $C_2H_3O_2^-$)	**acetate**
CN^-	cyanide
OH^-	**hydroxide**
ClO^-	hypochlorite
ClO_2^-	chlorite
ClO_3^-	**chlorate**
ClO_4^-	**perchlorate**
NO_2^-	nitrite
NO_3^-	**nitrate**
MnO_4^-	**permanganate**
CO_3^{2-}	**carbonate**
HCO_3^-	**hydrogen carbonate** (or **bicarbonate**)
CrO_4^{2-}	chromate
$Cr_2O_7^{2-}$	**dichromate**
O_2^{2-}	peroxide
PO_4^{3-}	**phosphate**
HPO_4^{2-}	hydrogen phosphate
$H_2PO_4^-$	dihydrogen phosphate
SO_3^{2-}	sulfite
SO_4^{2-}	**sulfate**
HSO_4^-	hydrogen sulfate (or bisulfate)

*Boldface ions are most common.

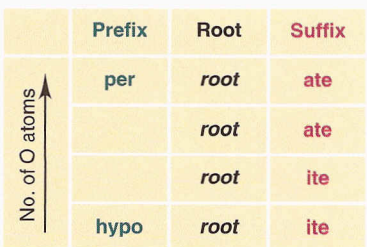

Figure 2.20 Naming oxoanions. Prefixes and suffixes indicate the number of O atoms in the anion.

Compounds Formed from Polyatomic Ions Ionic compounds in which one or both of the ions are polyatomic are very common. Table 2.5 gives the formulas and the names of some common polyatomic ions. Remember that *the polyatomic ion stays together as a charged unit.* The formula for potassium nitrate is KNO_3: each K^+ balances one NO_3^-. The formula for sodium carbonate is Na_2CO_3: two Na^+ balance one CO_3^{2-}. *When two or more of the same polyatomic ion are present in the formula unit, that ion appears in parentheses with the subscript written outside.* For example, calcium nitrate, which contains one Ca^{2+} and two NO_3^- ions, has the formula $Ca(NO_3)_2$. Parentheses and a subscript are *not* used unless *more than one* of the polyatomic ions is present; thus, sodium nitrate is $NaNO_3$, *not* $Na(NO_3)$.

Families of Oxoanions As Table 2.5 shows, most polyatomic ions are **oxoanions,** those in which an element, usually a nonmetal, is bonded to one or more oxygen atoms. There are several families of two or four oxoanions that differ only in the number of oxygen atoms. A simple naming convention is used with these ions.

With two oxoanions in the family:

- The ion with *more* O atoms takes the nonmetal root and the suffix *-ate*.
- The ion with *fewer* O atoms takes the nonmetal root and the suffix *-ite*.

For example, SO_4^{2-} is the sulf*ate* ion; SO_3^{2-} is the sulf*ite* ion; similarly, NO_3^- is nitr*ate*, and NO_2^- is nitr*ite*.

With four oxoanions in the family (usually a halogen bonded to O), as Figure 2.20 shows:

- The ion with *most* O atoms has the prefix *per-*, the nonmetal root, and the suffix *-ate*.
- The ion with *one fewer* O atom has just the root and the suffix *-ate*.
- The ion with *two fewer* O atoms has just the root and the suffix *-ite*.
- The ion with *least (three fewer)* O atoms has the prefix *hypo-*, the root, and the suffix *-ite*.

For example, for the four chlorine oxoanions,

ClO_4^- is *per*chlor*ate*, ClO_3^- is chlor*ate*, ClO_2^- is chlor*ite*, ClO^- is *hypo*chlor*ite*

Hydrated Ionic Compounds Ionic compounds called **hydrates** have a specific number of water molecules associated with each formula unit. In their formulas, this number is shown after a centered dot. It is indicated in the systematic name by a Greek numerical prefix before the word *hydrate*. Table 2.6 shows these prefixes. For example, Epsom salt has the formula $MgSO_4 \cdot 7H_2O$ and the name magnesium sulfate *hepta*hydrate. Similarly, the mineral gypsum has the formula $CaSO_4 \cdot 2H_2O$ and the name calcium sulfate *di*hydrate. The water molecules, referred to as "waters of hydration," are part of the hydrate's structure. Heating can remove some or all of them, leading to a different substance. For example, when heated strongly, blue copper(II) sulfate pentahydrate ($CuSO_4 \cdot 5H_2O$) is converted to white copper(II) sulfate ($CuSO_4$).

SAMPLE PROBLEM 2.8 Determining Names and Formulas of Ionic Compounds Containing Polyatomic Ions

Problem Give the systematic names for the formulas or the formulas for the names of the following compounds:

(a) $Fe(ClO_4)_2$ **(b)** Sodium sulfite **(c)** $Ba(OH)_2 \cdot 8H_2O$

Solution **(a)** ClO_4^- is perchlorate; since it has a 1− charge, the cation must be Fe^{2+}. The name is iron(II) perchlorate. (The common name is ferrous perchlorate.)

(b) Sodium is Na^+; sulfite is SO_3^{2-}. Therefore, two Na^+ ions balance one SO_3^{2-} ion. The formula is Na_2SO_3. **(c)** Ba^{2+} is barium; OH^- is hydroxide. There are eight (*octa-*) water molecules in each formula unit. The name is barium hydroxide octahydrate.

FOLLOW-UP PROBLEM 2.8 Give the systematic names for the formulas or the formulas for the names of the following compounds:
(a) Cupric nitrate trihydrate **(b)** Zinc hydroxide **(c)** LiCN

SAMPLE PROBLEM 2.9 Recognizing Incorrect Names and Formulas of Ionic Compounds

Problem Something is wrong with the second part of each statement. Provide the correct name or formula.
(a) $Ba(C_2H_3O_2)_2$ is called barium diacetate.
(b) Sodium sulfide has the formula $(Na)_2SO_3$.
(c) Iron(II) sulfate has the formula $Fe_2(SO_4)_3$.
(d) Cesium carbonate has the formula $Cs_2(CO_3)$.

Solution **(a)** The charge of the Ba^{2+} ion *must* be balanced by *two* $C_2H_3O_2^-$ ions, so the prefix *di-* is unnecessary. For ionic compounds, we do not indicate the number of ions with numerical prefixes. The correct name is barium acetate.
(b) Two mistakes occur here. The sodium ion is monatomic, so it does *not* require parentheses. The sulfide ion is S^{2-}, *not* SO_3^{2-} (called "sulfite"). The correct formula is Na_2S.
(c) The Roman numeral refers to the charge of the ion, *not* the number of ions in the formula. Fe^{2+} is the cation, so it requires one SO_4^{2-} to balance its charge. The correct formula is $FeSO_4$.
(d) Parentheses are *not* required when only one polyatomic ion of a kind is present. The correct formula is Cs_2CO_3.

FOLLOW-UP PROBLEM 2.9 State why the second part of each statement is incorrect, and correct it:
(a) Ammonium phosphate is $(NH_3)_4PO_4$.
(b) Aluminum hydroxide is $AlOH_3$.
(c) $Mg(HCO_3)_2$ is manganese(II) carbonate.
(d) $Cr(NO_3)_3$ is chromic(III) nitride.
(e) $Ca(NO_2)_2$ is cadmium nitrate.

Table 2.6 Numerical Prefixes for Hydrates and Binary Covalent Compounds

Number	Prefix
1	mono-
2	di-
3	tri-
4	tetra-
5	penta-
6	hexa-
7	hepta-
8	octa-
9	nona-
10	deca-

Acid Names from Anion Names Acids are an important group of hydrogen-containing compounds that have been used in chemical reactions since before alchemical times. In the laboratory, acids are typically used in water solution. When naming them and writing their formulas, we consider them as anions connected to the number of hydrogen ions (H^+) needed for charge neutrality. The two common types of acids are binary acids and oxoacids:

1. *Binary acid* solutions form when certain gaseous compounds dissolve in water. For example, when gaseous hydrogen chloride (HCl) dissolves in water, it forms a solution called hydrochloric acid. The name consists of the following parts:

Prefix *hydro-* + nonmetal *root* + suffix *-ic* + separate word *acid*
hydro + chlor + ic + acid

or hydrochloric acid. This naming pattern holds for many compounds in which hydrogen combines with an anion that has an *-ide* suffix.
2. *Oxoacid* names are similar to those of the oxoanions, except for two suffix changes:
   - *-ate* in the anion becomes *-ic* in the acid
   - *-ite* in the anion becomes *-ous* in the acid

   The oxoanion prefixes *hypo-* and *per-* are kept. Thus,

BrO_4^- is *per*brom*ate*, and $HBrO_4$ is *per*brom*ic* acid
IO_2^- is iod*ite*, and HIO_2 is iod*ous* acid

SAMPLE PROBLEM 2.10 Determining Names and Formulas of Anions and Acids

Problem Name the following anions and give the names and formulas of the acids derived from them: **(a)** Br^-; **(b)** IO_3^-; **(c)** CN^-; **(d)** SO_4^{2-}; **(e)** NO_2^-.

Solution **(a)** The anion is bromide; the acid is hydrobromic acid, HBr.

(b) The anion is iodate; the acid is iodic acid, HIO_3.

(c) The anion is cyanide; the acid is hydrocyanic acid, HCN.

(d) The anion is sulfate; the acid is sulfuric acid, H_2SO_4. (In this case, the suffix is added to the element name *sulfur,* not to the root, *sulf-*.)

(e) The anion is nitrite; the acid is nitrous acid, HNO_2.

Comment We added *two* H^+ ions to the sulfate ion to obtain sulfuric acid because it has a 2− charge.

FOLLOW-UP PROBLEM 2.10 Write the formula for the name or name for the formula of each acid: **(a)** chloric acid; **(b)** HF; **(c)** acetic acid; **(d)** sulfurous acid; **(e)** HBrO.

Names and Formulas of Binary Covalent Compounds

Binary covalent compounds are formed by the combination of two elements, usually nonmetals. Several are so familiar, such as ammonia (NH_3), methane (CH_4), and water (H_2O), that we use their common names, but most are named in a systematic way:

1. The element with the lower group number in the periodic table is the first word in the name; the element with the higher group number is the second word. (*Exception:* When the compound contains oxygen and any of the halogens chlorine, bromine, and iodine, the halogen is named first.)
2. If both elements are in the same group, the one with the higher period number is named first.
3. The second element is named with its root and the suffix *-ide*.
4. Covalent compounds have Greek numerical prefixes (see Table 2.6) to indicate the number of atoms of each element in the compound. The first word has a prefix *only* when more than one atom of the element is present; the second word *usually* has a numerical prefix.

SAMPLE PROBLEM 2.11 Determining Names and Formulas of Binary Covalent Compounds

Problem **(a)** What is the formula of carbon disulfide? **(b)** What is the name of PCl_5? **(c)** Give the name and formula of the compound whose molecules each consist of two N atoms and four O atoms.

Solution **(a)** The prefix *di-* means "two." The formula is CS_2.

(b) P is the symbol for phosphorus; there are five chlorine atoms, which is indicated by the prefix *penta-*. The name is phosphorus pentachloride.

(c) Nitrogen (N) comes first in the name (lower group number). The compound is dinitrogen tetraoxide, N_2O_4.

FOLLOW-UP PROBLEM 2.11 Give the name or formula for **(a)** SO_3; **(b)** SiO_2; **(c)** dinitrogen monoxide; **(d)** selenium hexafluoride.

SAMPLE PROBLEM 2.12 Recognizing Incorrect Names and Formulas of Binary Covalent Compounds

Problem Explain what is wrong with the name or formula in the second part of each statement and correct it: **(a)** SF_4 is monosulfur pentafluoride. **(b)** Dichlorine heptaoxide is Cl_2O_6. **(c)** N_2O_3 is dinitrotrioxide.

Solution **(a)** There are two mistakes. *Mono-* is not needed if there is only one atom of the first element, and the prefix for four is *tetra-*, not *penta-*. The correct name is sulfur tetrafluoride.

(b) The prefix *hepta-* indicates seven, not six. The correct formula is Cl_2O_7.

(c) The full name of the first element is needed, and a space separates the two element names. The correct name is dinitrogen trioxide.

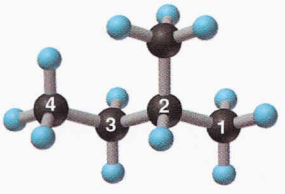
FOLLOW-UP PROBLEM 2.12 Explain what is wrong with the second part of each statement and correct it: **(a)** S_2Cl_2 is disulfurous dichloride. **(b)** Nitrogen monoxide is N_2O. **(c)** $BrCl_3$ is trichlorine bromide.

An Introduction to Naming Organic Compounds

Organic compounds typically have complex structural formulas that consist of chains, branches, and/or rings of carbon atoms bonded to hydrogen atoms and, often, to atoms of oxygen, nitrogen, and a few other elements. At this point, we'll look at one or two basic principles for naming them. Much more on the rules of organic nomenclature appears in Chapter 15.

Hydrocarbons, the simplest type of organic compound, contain *only* carbon and hydrogen. *Alkanes* are the simplest type of hydrocarbon; many function as important fuels, such as methane, propane, butane, and the mixture of alkanes in gasoline. The simplest alkanes to name are the *straight-chain alkanes* because the carbon chains have no branches. Alkanes are named with a *root,* based on the number of C atoms in the chain, followed by the suffix *-ane*. Table 2.7 gives the names, molecular formulas, and space-filling models (discussed shortly) of the first 10 straight-chain alkanes. Note that the roots of the four smallest ones are new, but those for the larger ones are the same as the Greek prefixes (Table 2.6).

Alkanes (and other organic compounds) *with* branches have a *prefix* in the name as well. *The prefix names the length of the branch and numbers the carbon atom in the main chain that the branch is attached to.* A prefix consists of a root plus the ending *-yl*. Thus, for example, the compound with a one-carbon ("meth") branch attached to the second carbon of the main chain of butane is *2-methylbutane,* where "2-methyl" is the prefix (see margin).

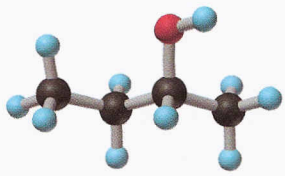


2-methylbutane

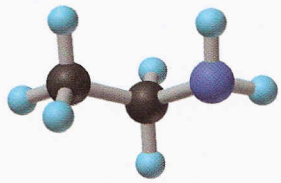
Organic compounds other than alkanes have names derived from a particular region of the molecule, called the *functional group,* which consists of one or a

Table 2.7 The First 10 Straight-Chain Alkanes

Name	Formula	Model
Methane	CH_4	
Ethane	C_2H_6	
Propane	C_3H_8	
Butane	C_4H_{10}	
Pentane	C_5H_{12}	
Hexane	C_6H_{14}	
Heptane	C_7H_{16}	
Octane	C_8H_{18}	
Nonane	C_9H_{20}	
Decane	$C_{10}H_{22}$	



2-butanol



ethanamine

pentanoic acid

few atoms bonded in a specific way. *The functional group determines how the compound reacts.* The *alcohol* functional group is a hydroxyl group, O—H, in place of one of the H atoms in the hydrocarbon; an *amine* has an amino group, $—NH_2$; a *carboxylic acid* has a carboxyl group, —COOH; and so forth. Each functional group has its own suffix. Thus, the compound with a hydroxyl group attached to the second carbon in butane is called *2-butanol* (see margin); the compound with an amino group bonded to a two-carbon chain is *ethanamine;* the compound with a carboxyl group bonded to a four-carbon chain is *pentanoic acid* (the C of the carboxyl group counts as one of the carbons). We'll examine the types of reactions the different functional groups undergo in Chapter 15.

Molecular Masses from Chemical Formulas

In Section 2.5, we calculated the atomic mass of an element. Using the formula of a compound to see the number of atoms of each element and the periodic table, we calculate the **molecular mass** (also called *molecular weight*) of a formula unit of the compound as the sum of the atomic masses:

$$\text{Molecular mass} = \text{sum of atomic masses} \qquad (2.3)$$

The molecular mass of a water molecule (using atomic masses to four significant figures from the periodic table) is

$$\begin{aligned}\text{Molecular mass of } H_2O &= (2 \times \text{atomic mass of H}) + (1 \times \text{atomic mass of O}) \\ &= (2 \times 1.008 \text{ amu}) + 16.00 \text{ amu} = 18.02 \text{ amu}\end{aligned}$$

Ionic compounds are treated the same, but because they do not consist of molecules, we use the term *formula mass* for an ionic compound. To calculate its formula mass, *the number of atoms of each element inside the parentheses is multiplied by the subscript outside the parentheses.* For barium nitrate, $Ba(NO_3)_2$,

$$\begin{aligned}&\text{Formula mass of } Ba(NO_3)_2 \\ &= (1 \times \text{atomic mass of Ba}) + (2 \times \text{atomic mass of N}) + (6 \times \text{atomic mass of O}) \\ &= 137.3 \text{ amu} + (2 \times 14.01 \text{ amu}) + (6 \times 16.00 \text{ amu}) = 261.3 \text{ amu}\end{aligned}$$

Note that atomic, not ionic, masses are used. Although masses of ions differ from those of their atoms by the masses of the electrons, electron loss equals electron gain in the compound, so electron mass is balanced.

SAMPLE PROBLEM 2.13 Calculating the Molecular Mass of a Compound

Problem Using data in the periodic table, calculate the molecular (or formula) mass of:
(a) Tetraphosphorus trisulfide **(b)** Ammonium nitrate

Plan We first write the formula, then multiply the number of atoms (or ions) of each element by its atomic mass, and find the sum.

Solution **(a)** The formula is P_4S_3.

$$\begin{aligned}\text{Molecular mass} &= (4 \times \text{atomic mass of P}) + (3 \times \text{atomic mass of S}) \\ &= (4 \times 30.97 \text{ amu}) + (3 \times 32.07 \text{ amu}) = 220.09 \text{ amu}\end{aligned}$$

(b) The formula is NH_4NO_3. We count the total number of N atoms even though they belong to different ions:

$$\begin{aligned}&\text{Formula mass} \\ &= (2 \times \text{atomic mass of N}) + (4 \times \text{atomic mass of H}) + (3 \times \text{atomic mass of O}) \\ &= (2 \times 14.01 \text{ amu}) + (4 \times 1.008 \text{ amu}) + (3 \times 16.00 \text{ amu}) = 80.05 \text{ amu}\end{aligned}$$

Check You can often find large errors by rounding atomic masses to the nearest 5 and adding: **(a)** $(4 \times 30) + (3 \times 30) = 210 \approx 220.09$. The sum has two decimal places because the atomic masses have two. **(b)** $(2 \times 15) + 4 + (3 \times 15) = 79 \approx 80.05$.

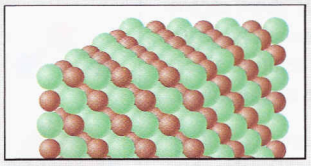
FOLLOW-UP PROBLEM 2.13 What is the formula and molecular (or formula) mass of each of the following compounds: **(a)** hydrogen peroxide; **(b)** cesium chloride; **(c)** sulfuric acid; **(d)** potassium sulfate?

In the next sample problem, we use molecular depictions to find the formula, name, and mass.

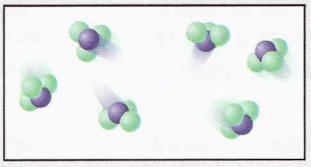
SAMPLE PROBLEM 2.14 Naming Compounds from Their Depictions

Problem Each box contains a representation of a binary compound. Determine its formula, name, and molecular (formula) mass.

(a)



(b)



Plan Each of the compounds contains only two elements, so to find the formula, we find the simplest whole-number ratio of one atom to the other. Then we determine the name (see Sample Problems 2.7 and 2.11) and the mass (see Sample Problem 2.13).

Solution **(a)** There is one brown (sodium) for each green (fluorine), so the formula is NaF. A metal and nonmetal form an ionic compound, in which the metal is named first: sodium fluoride.

$$\text{Formula mass} = (1 \times \text{atomic mass of Na}) + (1 \times \text{atomic mass of F})$$
$$= 22.99 \text{ amu} + 19.00 \text{ amu} = 41.99 \text{ amu}$$

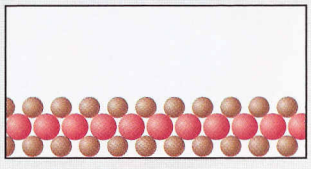
(b) There are three green (fluorine) for each blue (nitrogen), so the formula is NF_3. Two nonmetals form a covalent compound. Nitrogen has a lower group number, so it is named first: nitrogen trifluoride.

$$\text{Molecular mass} = (1 \times \text{atomic mass of N}) + (3 \times \text{atomic mass of F})$$
$$= 14.01 \text{ amu} + (3 \times 19.00 \text{ amu}) = 71.01 \text{ amu}$$

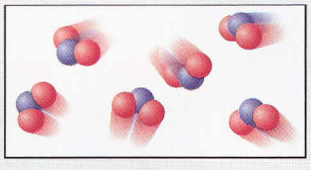
Check **(a)** For binary ionic compounds, we predict ionic charges from the periodic table (see Figure 2.14). Na forms a 1+ ion, and F forms a 1− ion, so the charges balance with one Na^+ per F^-. Also, ionic compounds are solids, consistent with the picture. **(b)** Covalent compounds often occur as individual molecules, as in the picture. Rounding in **(a)** gives 25 + 20 = 45; in **(b)**, we get 15 + (3 × 20) = 75, so there are no large errors.

FOLLOW-UP PROBLEM 2.14 Each box contains a representation of a binary compound. Determine its name, formula, and molecular (formula) mass.

(a)



(b)



The Gallery on the next page shows some of the ways that chemists picture molecules and the enormous range of molecular sizes.

SECTION SUMMARY

Chemical formulas describe the simplest atom ratio (empirical formula), actual atom number (molecular formula), and atom arrangement (structural formula) of one unit of a compound. An ionic compound is named with cation first and anion second. For metals that can form more than one ion, the charge is shown with a Roman numeral. Oxoanions have suffixes, and sometimes prefixes, attached to the element root name to indicate the number of oxygen atoms. Names of hydrates give the number of associated water molecules with a numerical prefix. Acid names are based on anion names. Names of covalent compounds have the element that is leftmost or lower down in the periodic table first, and prefixes show the number of each atom. The molecular (or formula) mass of a compound is the sum of the atomic masses in the formula. Molecules are three-dimensional objects that range in size from H_2 to biological and synthetic macromolecules.

GALLERY

Picturing Molecules

The most exciting thing about learning chemistry is training your mind to imagine a molecular world, one filled with tiny objects of various shapes. Molecules are depicted in a variety of useful ways, as shown at right for the water molecule:

All molecules are minute, with their relative sizes depending on composition. A water molecule is small because it consists of only three atoms. Many air pollutants, such as ozone, carbon monoxide, and nitrogen dioxide, also consist of small molecules.

Ozone (O_3, 48.00 amu) contributes to smog; natural component of stratosphere that absorbs harmful solar radiation.

Carbon monoxide (CO, 28.01 amu), toxic component of car exhaust and cigarette smoke.

Nitrogen dioxide (NO_2, 46.01 amu) forms from nitrogen monoxide and contributes to smog and acid rain.

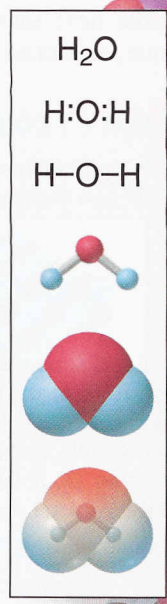
Chemical formulas show only the relative numbers of atoms.

Electron-dot and *bond-line formulas* show a bond between atoms as either a pair of dots or a line.

Ball-and-stick models show atoms as spheres and bonds as sticks, with accurate angles and relative sizes, but distances are exaggerated.

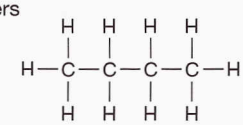
Space-filling models are accurately scaled-up versions of molecules, but they do not show bonds.

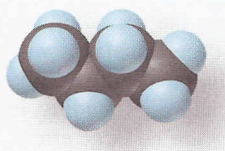
Electron-density models show the ball-and-stick model within the space-filling shape and color the regions of high *(red)* and low *(blue)* electron charge.

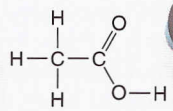


Many household chemicals, such as butane, acetic acid, and aspirin, consist of somewhat larger molecules. The biologically essential molecule heme is larger still.

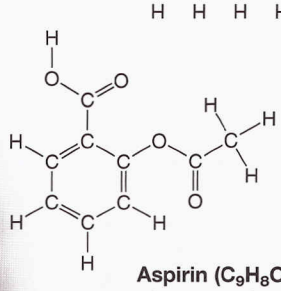
Butane (C_4H_{10}, 58.12 amu), fuel for cigarette lighters and camping stoves.

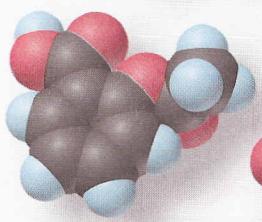




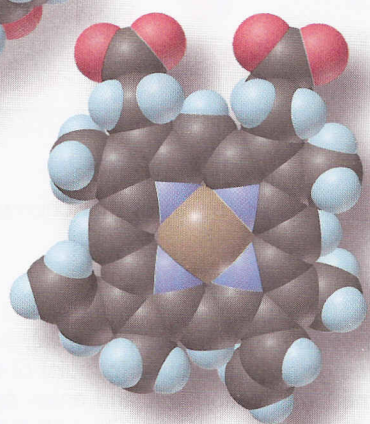


Acetic acid (CH_3COOH, 60.05 amu), component of vinegar.





Aspirin ($C_9H_8O_4$, 180.15 amu), most common pain reliever in the world.



Heme ($C_{34}H_{32}FeN_4O_4$, 616.49 amu), part of the blood protein hemoglobin, which carries oxygen through the body.

Very large molecules, called macromolecules, can be synthetic, like nylon, or natural, like DNA, and typically consist of thousands of atoms.

Nylon-66 (~15,000 amu), relatively small, synthetic macromolecule used to make textiles and tires.

Deoxyribonucleic acid (DNA, ~10,000,000 amu), cellular macromolecule that contains genetic information.

2.9 MIXTURES: CLASSIFICATION AND SEPARATION

Although chemists pay a great deal of attention to pure substances, this form of matter almost never occurs around us. In the natural world, *matter usually occurs as mixtures*. A sample of clean air, for example, consists of many elements and compounds physically mixed together, including oxygen (O_2), nitrogen (N_2), carbon dioxide (CO_2), the six noble gases [Group 8A(18)], and water vapor (H_2O). The oceans are complex mixtures of dissolved ions and covalent substances, including Na^+, Mg^{2+}, Cl^-, SO_4^{2-}, O_2, CO_2, and of course H_2O. Rocks and soils are mixtures of numerous compounds—such as calcium carbonate ($CaCO_3$), silicon dioxide (SiO_2), aluminum oxide (Al_2O_3), and iron(III) oxide (Fe_2O_3)—perhaps a few elements (gold, silver, and carbon in the form of diamond), and petroleum and coal, which are complex mixtures themselves. Living things contain thousands of substances: carbohydrates, lipids, proteins, nucleic acids, and many simpler ionic and covalent compounds.

There are two broad classes of mixtures. A **heterogeneous mixture** has one or more visible boundaries between the components. Thus, its composition is *not* uniform. Many rocks are heterogeneous, showing individual grains and flecks of different minerals. In some cases, as in milk and blood, the boundaries can be seen only with a microscope. A **homogeneous mixture** has no visible boundaries because the components are mixed as individual atoms, ions, and molecules. Thus, its composition *is* uniform. A mixture of sugar dissolved in water is homogeneous, for example, because the sugar molecules and water molecules are uniformly intermingled on the molecular level. We have no way to tell visually whether an object is a substance (element or compound) or a homogeneous mixture.

A homogeneous mixture is also called a **solution.** Although we usually think of solutions as liquid, they can exist in all three physical states. For example, air is a gaseous solution of mostly oxygen and nitrogen molecules, and wax is a solid solution of several fatty substances. Solutions in water, called **aqueous solutions,** are especially important in chemistry and comprise a major portion of the environment and of all organisms.

Recall that mixtures differ fundamentally from compounds in three ways: (1) the proportions of the components can vary; (2) the individual properties of the components are observable; and (3) the components can be separated by physical means. In some cases, if we apply enough energy to the components of the mixture, they react with each other chemically and form a compound, after which their individual properties are no longer observable. Figure 2.21 shows such a case with a mixture of iron and sulfur.

In order to investigate the properties of substances, chemists have devised many procedures for separating a mixture into its component elements and compounds. Indeed, the laws and models of chemistry could never have been formulated without this ability. Many of Dalton's critics, who thought they had found compounds with varying composition, were unknowingly studying mixtures! The Tools of the Laboratory essay on the next two pages describes some of the more common laboratory separation methods.

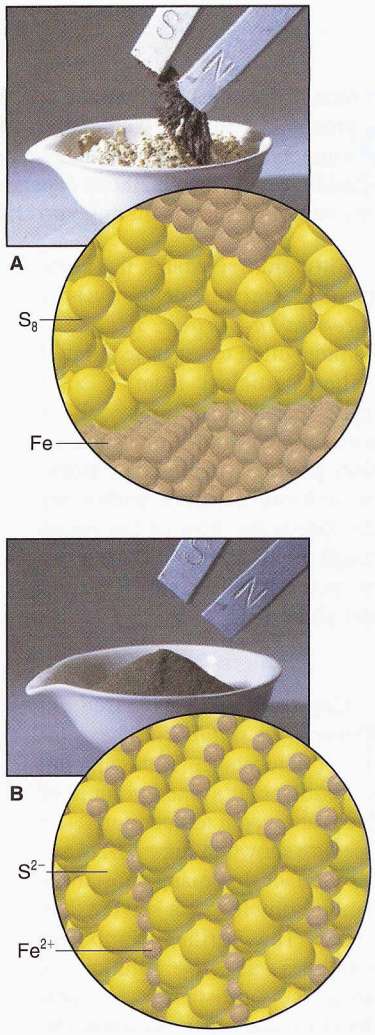


Figure 2.21 The distinction between mixtures and compounds. A, A *mixture* of iron and sulfur can be separated with a magnet because only the iron is magnetic. The blow-up shows separate regions of the two elements. **B,** After strong heating, the *compound* iron(II) sulfide forms, which is no longer magnetic. The blow-up shows the structure of the compound, in which there are no separate regions of the elements.

SECTION SUMMARY

Heterogeneous mixtures have visible boundaries between the components. Homogeneous mixtures have no visible boundaries because mixing occurs at the molecular level. A solution is a homogeneous mixture and can occur in any physical state. Mixtures (not compounds) can have variable proportions, can be separated physically, and retain their components' properties. Common physical separation processes include filtration, crystallization, extraction, chromatography, and distillation.

Basic Separation Techniques

Some of the most challenging and time-consuming laboratory procedures involve separating mixtures and purifying the components. Several common separation techniques are described here. All these methods depend on the *physical properties* of the substances in the mixture; no chemical changes occur.

Filtration separates the components of a mixture on the basis of *differences in particle size.* It is used most often to separate a liquid (smaller particles) from a solid (larger particles). Figure B2.3 shows simple filtration of a solid reaction product. In vacuum filtration, reduced pressure within the flask speeds the flow of the liquid through the filter. Filtration is a key step in the purification of the tap water you drink.

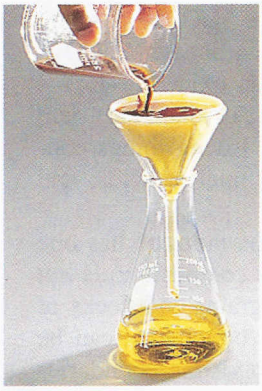

Figure B2.3 Filtration.

Crystallization is based on *differences in solubility.* The *solubility* of a substance is the amount that dissolves in a fixed volume of solvent at a given temperature. The procedure shown in Figure B2.4 applies the fact that many substances are more soluble in hot solvent than in cold. The purified compound crystallizes as the solution is cooled. Key substances in computer chips and other electronic devices are purified by a type of crystallization.

Figure B2.4 Crystallization.

Distillation separates components through *differences in* ***volatility,*** the tendency of a substance to become a gas. Ether, for example, is more volatile than water, which is much more volatile than sodium chloride. The simple distillation apparatus shown in Figure B2.5 is used to separate components with *large* differences in volatility, such as water from dissolved ionic compounds. As the mixture boils, the vapor is richer in the more volatile component, which is condensed and collected separately. Separating components with small volatility differences requires many vaporization-condensation steps (discussed in Chapter 13).

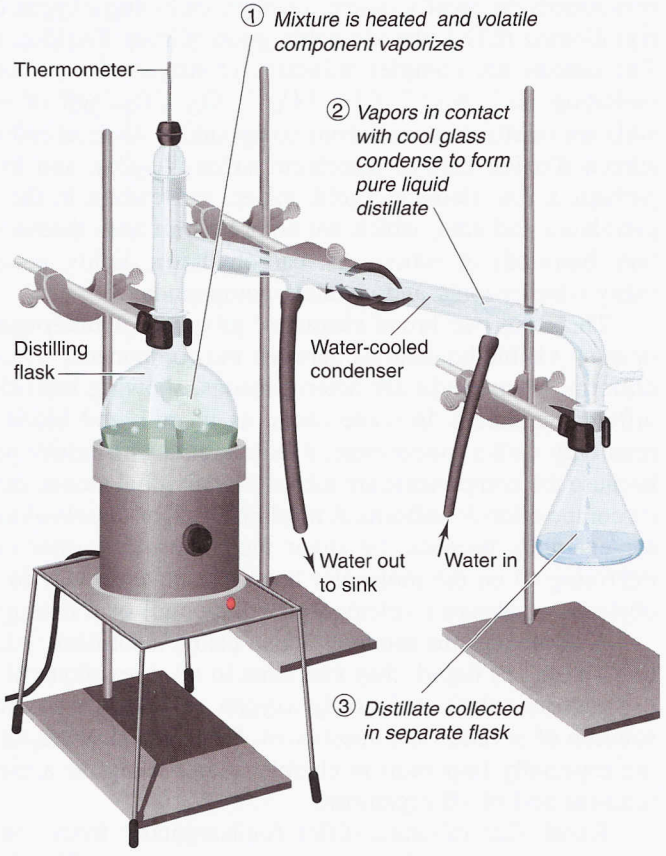

Figure B2.5 Distillation.

Extraction is also based on *differences in solubility.* In a typical procedure, a natural (often plant or animal) material is ground in a blender with a solvent that extracts (dissolves) soluble compound(s) embedded in insoluble material. This extract is separated further by the addition of a second solvent that does not dissolve in the first. After shaking in a separatory funnel, some components are extracted into the new solvent. Figure B2.6 shows the extraction of plant pigments from water into hexane, an organic solvent.

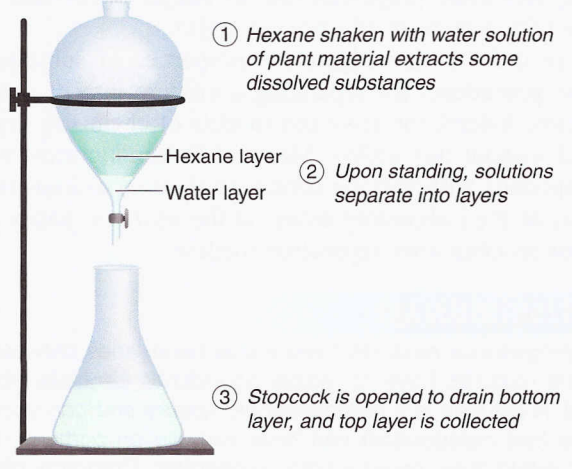

Figure B2.6 Extraction.

Chromatography is a third technique based on *differences in solubility.* The mixture is dissolved in a gas or liquid called the *mobile phase,* and the components are separated as this phase moves over a solid (or viscous liquid) surface called the *stationary phase*. A component with low solubility in the stationary phase spends less time there, thus moving faster than a component that is highly soluble in that phase. Figure B2.7 depicts the separation of a mixture of pigments in ink.

Many types of chromatography are used to separate a wide variety of substances, from simple gases to biological macromolecules. In *gas-liquid chromatography (GLC),* the mobile phase is an inert gas, such as helium, that carries the previously vaporized components into a long tube that contains the stationary phase (Figure B2.8, part A). The components emerge separately and reach a detector to create a chromatogram. A typical chromatogram has numerous peaks of specific position and height, each of which represents the amount of a given component (Figure B2.8, part B).

The principle of *high-performance (high-pressure) liquid chromatography (HPLC)* is very similar. However, in this technique the mixture is not vaporized, so a more diverse group of components, which may include nonvolatile compounds, can be separated (Figure B2.9).

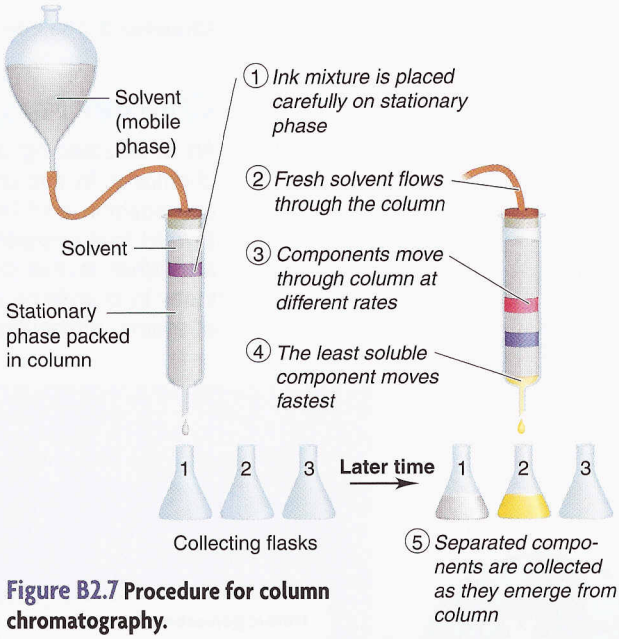

Figure B2.7 Procedure for column chromatography.

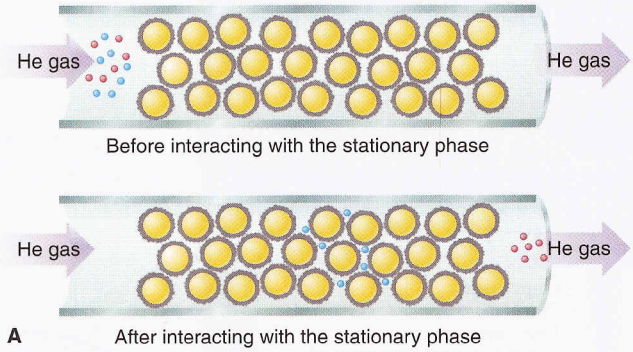

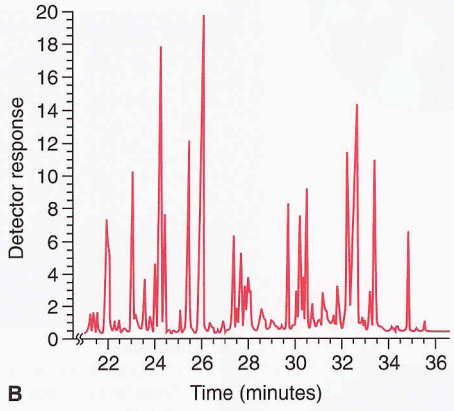

Figure B2.8 Principle of gas-liquid chromatography (GLC). A, The mobile phase *(purple arrow)* carries the sample mixture into a tube packed with the stationary phase *(gray outline on yellow spheres),* and each component dissolves in the stationary phase to a different extent. A component *(red)* that dissolves less readily than another *(blue)* emerges from the tube sooner. **B,** A typical gas-liquid chromatogram of a complex mixture displays each component as a peak.

Figure B2.9 A high-performance liquid chromatograph.

Chapter Perspective

An understanding of matter at the observable and atomic levels is the essence of chemistry. In this chapter, you have learned how matter is classified in terms of its composition and how it is named in words and formulas, which are major steps toward that understanding. Figure 2.22 provides a visual review of many key terms and ideas in this chapter. In Chapter 3, we explore one of the central quantitative ideas in chemistry: how the observable amount of a substance relates to the number of atoms, molecules, or ions that make it up.

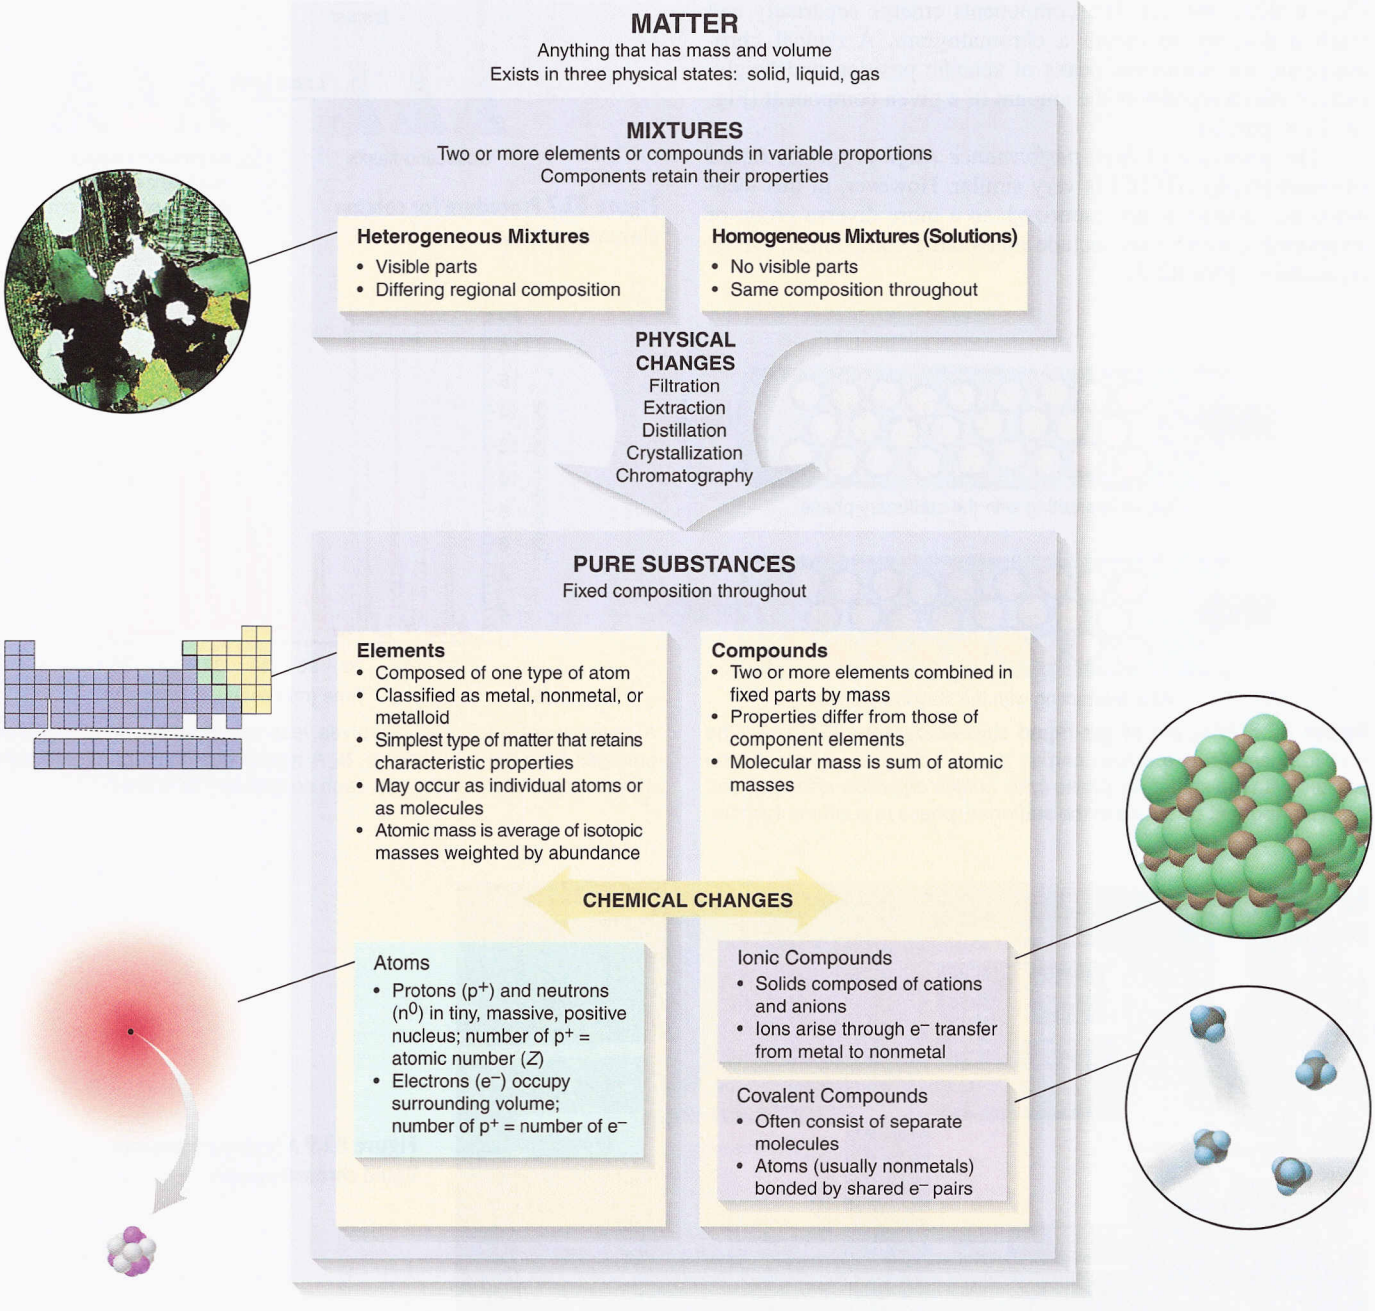

Figure 2.22 The classification of matter from a chemical point of view. Mixtures are separated by physical changes into elements and compounds. Chemical changes are required to convert elements into compounds, and vice versa.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The defining characteristics of the three types of matter—element, compound, and mixture—on the macroscopic and atomic levels (2.1)
2. The significance of the three mass laws—mass conservation, definite composition, and multiple proportions (2.2)
3. The postulates of Dalton's atomic theory and how it explains the mass laws (2.3)
4. The major contribution of experiments by Thomson, Millikan, and Rutherford concerning atomic structure (2.4)
5. The structure of the atom, the main features of the subatomic particles, and the importance of isotopes (2.5)
6. The format of the periodic table and general location and characteristics of metals, metalloids, and nonmetals (2.6)
7. The essential features of ionic and covalent bonding and the distinction between them (2.7)
8. The types of mixtures and their properties (2.9)

Master These Skills

1. Using the mass ratio of element to compound to find the mass of an element in a compound (SP 2.1)
2. Using atomic notation to express the subatomic makeup of an isotope (SP 2.2)
3. Calculating an atomic mass from isotopic composition (SP 2.3)
4. Predicting the monatomic ion formed from a main-group element (SP 2.4)
5. Naming and writing the formula of an ionic compound formed from the ions in Tables 2.3 to 2.5 (SP 2.5 to 2.10 and 2.14)
6. Naming and writing the formula of an inorganic binary covalent compound (SP 2.11, 2.12, and 2.14)
7. Calculating the molecular mass of a compound (SP 2.13)

Key Terms

Section 2.1
element (39)
pure substance (39)
molecule (40)
compound (40)
mixture (40)

Section 2.2
law of mass conservation (41)
law of definite (or constant) composition (42)
fraction by mass (mass fraction) (42)

Key Equations and Relationships

2.1 Finding the mass of an element in a given mass of compound (42):

Mass of element in sample

$$= \text{mass of compound in sample} \times \frac{\text{mass of element}}{\text{mass of compound}}$$

2.2 Calculating the number of neutrons in an atom (50):

$$\text{Number of neutrons} = \text{mass number} - \text{atomic number}$$

or

$$N = A - Z$$

2.3 Determining the molecular mass of a formula unit of a compound (70):

$$\text{Molecular mass} = \text{sum of atomic masses}$$

Highlighted Figures and Tables

These figures (F) and tables (T) provide a review of key ideas. Entries in color contain frequently used data.

F2.1 Elements, compounds, and mixtures on atomic scale (40)
F2.8 General features of the atom (49)
T2.2 Properties of the three key subatomic particles (50)
F2.10 The modern periodic table (55)
F2.13 Factors that influence the strength of ionic bonding (59)
F2.14 The relationship between ions formed and the nearest noble gas (59)
F2.15 Formation of a covalent bond between two H atoms (60)
F2.19 Some common monatomic ions of the elements (63)
T2.3 Common monatomic ions (63)
T2.4 Some metals that form more than one monatomic ion (65)
T2.5 Common polyatomic ions (66)
T2.6 Numerical prefixes for hydrates and binary covalent compounds (67)
F2.22 Classification of matter from a chemical point of view (76)

Brief Solutions to Follow-up Problems

2.1 Mass (t) of pitchblende

$$= 2.3 \text{ ~~t uranium~~} \times \frac{84.2 \text{ t pitchblende}}{71.4 \text{ ~~t uranium~~}} = 2.7 \text{ t pitchblende}$$

Mass (t) of oxygen

$$= 2.7 \text{ ~~t pitchblende~~} \times \frac{(84.2 - 71.4 \text{ t oxygen})}{84.2 \text{ ~~t pitchblende~~}} = 0.41 \text{ t oxygen}$$

2.2 (a) Q = B; $5p^+$, $6n^0$, $5e^-$
(b) X = Ca; $20p^+$, $21n^0$, $20e^-$
(c) Y = I; $53p^+$, $78n^0$, $53e^-$
2.3 $10.0129x + [11.0093(1 - x)] = 10.81$; $0.9964x = 0.1993$; $x = 0.2000$ and $1 - x = 0.8000$; % abundance of $^{10}B = 20.00\%$; % abundance of $^{11}B = 80.00\%$
2.4 (a) S^{2-}; (b) Rb^+; (c) Ba^{2+}
2.5 (a) Zinc [Group 2B(12)] and oxygen [Group 6A(16)]
(b) Silver [Group 1B(11)] and bromine [Group 7A(17)]
(c) Lithium [Group 1A(1)] and chlorine [Group 7A(17)]
(d) Aluminum [Group 3A(13)] and sulfur [Group 6A(16)]
2.6 (a) ZnO; (b) AgBr; (c) LiCl; (d) Al_2S_3
2.7 (a) PbO_2; (b) copper(I) sulfide (cuprous sulfide); (c) iron(II) bromide (ferrous bromide); (d) $HgCl_2$
2.8 (a) $Cu(NO_3)_2 \cdot 3H_2O$; (b) $Zn(OH)_2$; (c) lithium cyanide
2.9 (a) $(NH_4)_3PO_4$; ammonium is NH_4^+ and phosphate is PO_4^{3-}.
(b) $Al(OH)_3$; parentheses are needed around the polyatomic ion OH^-.
(c) Magnesium hydrogen carbonate; Mg^{2+} is magnesium and can have only a 2+ charge, so it does not need (II); HCO_3^- is hydrogen carbonate (or bicarbonate).
(d) Chromium(III) nitrate; the *-ic* ending is not used with Roman numerals; NO_3^- is nitr*ate*.
(e) Calcium nitrite; Ca^{2+} is calcium and NO_2^- is nitr*ite*.
2.10 (a) $HClO_3$; (b) hydrofluoric acid; (c) CH_3COOH (or $HC_2H_3O_2$); (d) H_2SO_3; (e) hypobromous acid
2.11 (a) Sulfur trioxide; (b) silicon dioxide; (c) N_2O; (d) SeF_6
2.12 (a) Disulfur dichloride; the *-ous* suffix is not used.
(b) NO; the name indicates one nitrogen.
(c) Bromine trichloride; Br is in a higher period in Group 7A(17), so it is named first.
2.13 (a) H_2O_2, 34.02 amu; (b) CsCl, 168.4 amu; (c) H_2SO_4, 98.09 amu; (d) K_2SO_4, 174.27 amu
2.14 (a) Na_2O. This is an ionic compound, so the name is sodium oxide.

Formula mass
= (2 × atomic mass of Na) + (1 × atomic mass of O)
= (2 × 22.99 amu) + 16.00 amu = 61.98 amu

(b) NO_2. This is a covalent compound, and N has the lower group number, so the name is nitrogen dioxide.

Molecular mass
= (1 × atomic mass of N) + (2 × atomic mass of O)
= 14.01 amu + (2 × 16.00 amu) = 46.01 amu

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Elements, Compounds, and Mixtures: An Atomic Overview

Concept Review Questions

2.1 What is the key difference between an element and a compound?
2.2 List two differences between a compound and a mixture.
2.3 Which of the following are pure substances? Explain.
(a) Calcium chloride, used to melt ice on roads, consists of two elements, calcium and chlorine, in a fixed mass ratio.
(b) Sulfur consists of sulfur atoms combined into octatomic molecules.
(c) Baking powder, a leavening agent, contains 26% to 30% sodium hydrogen carbonate and 30% to 35% calcium dihydrogen phosphate by mass.
(d) Cytosine, a component of DNA, consists of H, C, N, and O atoms bonded in a specific arrangement.
2.4 Classify each substance in Problem 2.3 as an element, compound, or mixture, and explain your answers.
2.5 Explain the following statement: The smallest particles unique to an element may be atoms or molecules.

2.6 Explain the following statement: The smallest particles unique to a compound cannot be atoms.

2.7 Can the relative amounts of the components of a mixture vary? Can the relative amounts of the components of a compound vary? Explain.

Problems in Context

2.8 The tap water found in many areas of the United States leaves white deposits when it evaporates. Is this tap water a mixture or a compound? Explain.

2.9 Samples of illicit "street" drugs often contain an inactive component, such as ascorbic acid (vitamin C). After obtaining a sample of cocaine, government chemists calculate the mass of vitamin C per gram of drug sample, and use it to track the drug's distribution. For example, if different samples of cocaine obtained on the streets of New York, Los Angeles, and Paris all contain 0.6384 g of vitamin C per gram of sample, they very likely come from a common source. Is this street sample a compound, element, or mixture? Explain.

The Observations That Led to an Atomic View of Matter

(Sample Problem 2.1)

Concept Review Questions

2.10 Why was it necessary for separation techniques and methods of chemical analysis to be developed before the laws of definite composition and multiple proportions could be formulated?

2.11 To which classes of matter—element, compound, and/or mixture—do the following apply: (a) law of mass conservation; (b) law of definite composition; (c) law of multiple proportions?

2.12 In our modern view of matter and energy, is the law of mass conservation still relevant to chemical reactions? Explain.

2.13 Identify the mass law that each of the following observations demonstrates, and explain your reasoning:
(a) A sample of potassium chloride from Chile contains the same percent by mass of potassium as one from Poland.
(b) A flashbulb contains magnesium and oxygen before use and magnesium oxide afterward, but its mass does not change.
(c) Arsenic and oxygen form one compound that is 65.2 mass % arsenic and another that is 75.8 mass % arsenic.

2.14 (a) Does the percent by mass of each element in a compound depend on the amount of compound? Explain. (b) Does the mass of each element in a compound depend on the amount of compound? Explain.

2.15 Does the percent by mass of the elements in a compound depend on the amounts of the elements used to make the compound? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

2.16 State the mass law(s) demonstrated by the following experimental results, and explain your reasoning:
Experiment 1: A student heats 1.00 g of a blue compound and obtains 0.64 g of a white compound and 0.36 g of a colorless gas.
Experiment 2: A second student heats 3.25 g of the same blue compound and obtains 2.08 g of a white compound and 1.17 g of a colorless gas.

2.17 State the mass law(s) demonstrated by the following experimental results, and explain your reasoning:
Experiment 1: A student heats 1.27 g of copper and 3.50 g of iodine to produce 3.81 g of a white compound, and 0.96 g of iodine remains.
Experiment 2: A second student heats 2.55 g of copper and 3.50 g of iodine to form 5.25 g of a white compound, and 0.80 g of copper remains.

2.18 Fluorite, a mineral of calcium, is a compound of the metal with fluorine. Analysis shows that a 2.76-g sample of fluorite contains 1.42 g of calcium. Calculate the (a) mass of fluorine in the sample; (b) mass fractions of calcium and fluorine in fluorite; (c) mass percents of calcium and fluorine in fluorite.

2.19 Galena, a mineral of lead, is a compound of the metal with sulfur. Analysis shows that a 2.34-g sample of galena contains 2.03 g of lead. Calculate the (a) mass of sulfur in the sample; (b) mass fractions of lead and sulfur in galena; (c) mass percents of lead and sulfur in galena.

2.20 Magnesium oxide (MgO) forms when the metal burns in air. (a) If 1.25 g of MgO contains 0.754 g of Mg, what is the mass ratio of magnesium to oxide? (b) How many grams of Mg are in 435 g of MgO?

2.21 Zinc sulfide (ZnS) occurs in the zincblende and wurtzite crystal structures. (a) If 2.54 g of ZnS contains 1.70 g of Zn, what is the mass ratio of zinc to sulfide? (b) How many kilograms of Zn are in 2.45 kg of ZnS?

2.22 A compound of copper and sulfur contains 88.39 g of metal and 44.61 g of nonmetal. How many grams of copper are in 5264 kg of compound? How many grams of sulfur?

2.23 A compound of iodine and cesium contains 63.94 g of metal and 61.06 g of nonmetal. How many grams of cesium are in 38.77 g of compound? How many grams of iodine?

2.24 Show, with calculations, how the following data illustrate the law of multiple proportions:
Compound 1: 47.5 mass % sulfur and 52.5 mass % chlorine
Compound 2: 31.1 mass % sulfur and 68.9 mass % chlorine

2.25 Show, with calculations, how the following data illustrate the law of multiple proportions:
Compound 1: 77.6 mass % xenon and 22.4 mass % fluorine
Compound 2: 63.3 mass % xenon and 36.7 mass % fluorine

Problems in Context

2.26 Dolomite is a carbonate of magnesium and calcium. Analysis shows that 7.81 g of dolomite contains 1.70 g of Ca. Calculate the mass percent of Ca in dolomite. On the basis of the mass percent of Ca, and neglecting all other factors, which is the richer source of Ca, dolomite or fluorite (see Problem 2.18)?

2.27 The mass percent of sulfur in a sample of coal is a key factor in the environmental impact of the coal because the sulfur combines with oxygen when the coal is burned and the oxide can then be incorporated into acid rain. Which of the following coals would have the smallest environmental impact?

	Mass (g) of Sample	Mass (g) of Sulfur in Sample
Coal A	378	11.3
Coal B	495	19.0
Coal C	675	20.6

Dalton's Atomic Theory

Concept Review Questions

2.28 Which of Dalton's postulates about atoms are inconsistent with later observations? Do these inconsistencies mean that Dalton was wrong? Is Dalton's model still useful? Explain.

2.29 Use Dalton's theory to explain why potassium nitrate from India or Italy has the same mass percents of K, N, and O.

The Observations That Led to the Nuclear Atom Model

Concept Review Questions

2.30 Thomson was able to determine the mass/charge ratio of the electron but not its mass. How did Millikan's experiment allow determination of the electron's mass?

2.31 The following charges on individual oil droplets were obtained during an experiment similar to Millikan's. Determine a charge for the electron (in C, coulombs), and explain your answer: -3.204×10^{-19} C; -4.806×10^{-19} C; -8.010×10^{-19} C; -1.442×10^{-18} C.

2.32 Describe Thomson's model of the atom. How might it account for the production of cathode rays?

2.33 When Rutherford's coworkers bombarded gold foil with α particles, they obtained results that overturned the existing (Thomson) model of the atom. Explain.

The Atomic Theory Today

(Sample Problems 2.2 and 2.3)

Concept Review Questions

2.34 Define *atomic number* and *mass number*. Which can vary without changing the identity of the element?

2.35 Choose the correct answer. The difference between the mass number of an isotope and its atomic number is (a) directly related to the identity of the element; (b) the number of electrons; (c) the number of neutrons; (d) the number of isotopes.

2.36 Even though several elements have only one naturally occurring isotope and all atomic nuclei have whole numbers of protons and neutrons, no atomic mass is a whole number. Use the data from Table 2.2 to explain this fact.

Skill-Building Exercises *(grouped in similar pairs)*

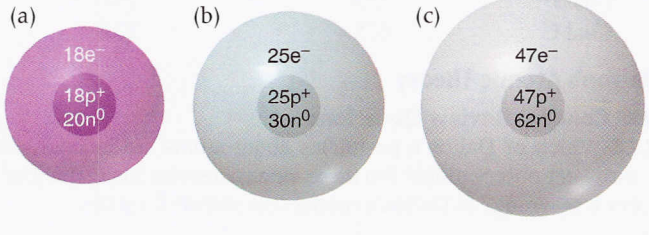
2.37 Argon has three naturally occurring isotopes, ^{36}Ar, ^{38}Ar, and ^{40}Ar. What is the mass number of each? How many protons, neutrons, and electrons are present in each?

2.38 Chlorine has two naturally occurring isotopes, ^{35}Cl and ^{37}Cl. What is the mass number of each isotope? How many protons, neutrons, and electrons are present in each?

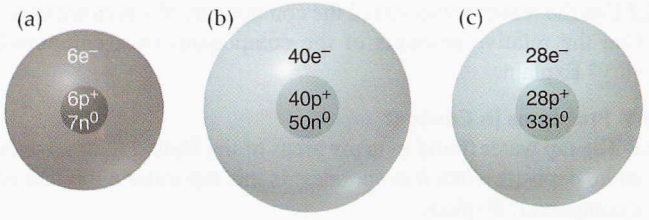
2.39 Do both members of the following pairs have the same number of protons? Neutrons? Electrons?
(a) $^{16}_{8}$O and $^{17}_{8}$O (b) $^{40}_{18}$Ar and $^{41}_{19}$K (c) $^{60}_{27}$Co and $^{60}_{28}$Ni
Which pair(s) consist(s) of atoms with the same Z value? N value? A value?

2.40 Do both members of the following pairs have the same number of protons? Neutrons? Electrons?
(a) $^{3}_{1}$H and $^{3}_{2}$He (b) $^{14}_{6}$C and $^{15}_{7}$N (c) $^{19}_{9}$F and $^{18}_{9}$F
Which pair(s) consist(s) of atoms with the same Z value? N value? A value?

2.41 Write the $^{A}_{Z}$X notation for each atomic depiction:



2.42 Write the $^{A}_{Z}$X notation for each atomic depiction:



2.43 Draw atomic depictions similar to those in Problem 2.41 for (a) $^{48}_{22}$Ti; (b) $^{79}_{34}$Se; (c) $^{11}_{5}$B.

2.44 Draw atomic depictions similar to those in Problem 2.41 for (a) $^{207}_{82}$Pb; (b) $^{9}_{4}$Be; (c) $^{75}_{33}$As.

2.45 Gallium has two naturally occurring isotopes, ^{69}Ga (isotopic mass 68.9256 amu, abundance 60.11%) and ^{71}Ga (isotopic mass 70.9247 amu, abundance 39.89%). Calculate the atomic mass of gallium.

2.46 Magnesium has three naturally occurring isotopes, ^{24}Mg (isotopic mass 23.9850 amu, abundance 78.99%), ^{25}Mg (isotopic mass 24.9858 amu, abundance 10.00%), and ^{26}Mg (isotopic mass 25.9826 amu, abundance 11.01%). Calculate the atomic mass of magnesium.

2.47 Chlorine has two naturally occurring isotopes, ^{35}Cl (isotopic mass 34.9689 amu) and ^{37}Cl (isotopic mass 36.9659 amu). If chlorine has an atomic mass of 35.4527 amu, what is the percent abundance of each isotope?

2.48 Copper has two naturally occurring isotopes, ^{63}Cu (isotopic mass 62.9396 amu) and ^{65}Cu (isotopic mass 64.9278 amu). If copper has an atomic mass of 63.546 amu, what is the percent abundance of each isotope?

Elements: A First Look at the Periodic Table

Concept Review Questions

2.49 How can iodine ($Z = 53$) have a higher atomic number yet a lower atomic mass than tellurium ($Z = 52$)?

2.50 Correct each of the following statements:
(a) In the modern periodic table, the elements are arranged in order of increasing atomic mass.
(b) Elements in a period have similar chemical properties.
(c) Elements can be classified as either metalloids or nonmetals.

2.51 What class of elements lies along the "staircase" line in the periodic table? How do their properties compare with those of metals and nonmetals?

2.52 What are some characteristic properties of elements to the left of the elements along the "staircase"? To the right?

2.53 The elements in Groups 1A(1) and 7A(17) are all quite reactive. What is a major difference between them?

Skill-Building Exercises *(grouped in similar pairs)*

2.54 Give the name, atomic symbol, and group number of the element with the following Z value, and classify it as a metal, metalloid, or nonmetal:
(a) $Z = 32$ (b) $Z = 16$ (c) $Z = 2$ (d) $Z = 3$ (e) $Z = 42$

2.55 Give the name, atomic symbol, and group number of the element with the following Z value, and classify it as a metal, metalloid, or nonmetal:
(a) $Z = 33$ (b) $Z = 20$ (c) $Z = 35$ (d) $Z = 19$ (e) $Z = 12$

2.56 Fill in the blanks:
(a) The symbol and atomic number of the heaviest alkaline earth metal are _____ and _____.
(b) The symbol and atomic number of the lightest metalloid in Group 5A(15) are _____ and _____.
(c) Group 1B(11) consists of the *coinage metals*. The symbol and atomic mass of the coinage metal whose atoms have the fewest electrons are _____ and _____.
(d) The symbol and atomic mass of the halogen in Period 4 are _____ and _____.

2.57 Fill in the blanks:
(a) The symbol and atomic number of the heaviest noble gas are _____ and _____.
(b) The symbol and group number of the Period 5 transition element whose atoms have the fewest protons are _____ and _____.
(c) The elements in Group 6A(16) are sometimes called the *chalcogens*. The symbol and atomic number of the only metallic chalcogen are _____ and _____.
(d) The symbol and number of protons of the Period 4 alkali metal atom are _____ and _____.

Compounds: Introduction to Bonding

(Sample Problem 2.4)

Concept Review Questions

2.58 Describe the type and nature of the bonding that occurs between reactive metals and nonmetals.

2.59 Describe the type and nature of the bonding that often occurs between two nonmetals.

2.60 How can ionic compounds be neutral if they consist of positive and negative ions?

2.61 Given that the ions in LiF and in MgO are of similar size, which compound has stronger ionic bonding? Use Coulomb's law in your explanation.

2.62 Are molecules present in a sample of BaF_2? Explain.

2.63 Are ions present in a sample of SO_3? Explain.

2.64 The monatomic ions of Groups 1A(1) and 7A(17) are all singly charged. In what major way do they differ? Why?

2.65 Describe the formation of solid magnesium chloride ($MgCl_2$) from large numbers of magnesium and chlorine atoms.

2.66 Describe the formation of solid potassium sulfide (K_2S) from large numbers of potassium and sulfur atoms.

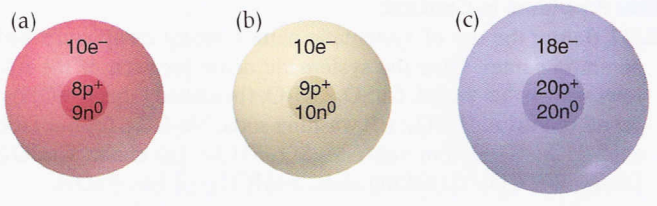
2.67 Does potassium nitrate (KNO_3) incorporate ionic bonding, covalent bonding, or both? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

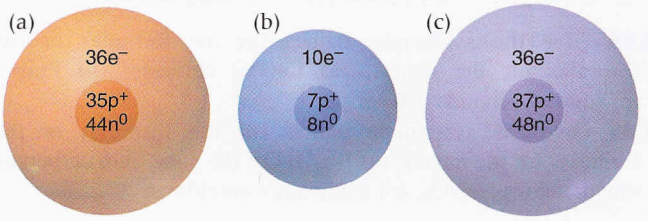
2.68 What monatomic ions do potassium ($Z = 19$) and iodine ($Z = 53$) form?

2.69 What monatomic ions do barium ($Z = 56$) and selenium ($Z = 34$) form?

2.70 For each ionic depiction, give the name of the parent atom, its mass number, and its group and period numbers:



2.71 For each ionic depiction, give the name of the parent atom, its mass number, and its group and period numbers:



2.72 An ionic compound forms when lithium ($Z = 3$) reacts with oxygen ($Z = 8$). If a sample of the compound contains 5.3×10^{20} lithium ions, how many oxide ions does it contain?

2.73 An ionic compound forms when calcium ($Z = 20$) reacts with iodine ($Z = 53$). If a sample of the compound contains 7.4×10^{21} calcium ions, how many iodide ions does it contain?

2.74 The radii of the sodium and potassium ions are 102 pm and 138 pm, respectively. Which compound has stronger ionic attractions, sodium chloride or potassium chloride?

2.75 The radii of the lithium and magnesium ions are 76 pm and 72 pm, respectively. Which compound has stronger ionic attractions, lithium oxide or magnesium oxide?

Compounds: Formulas, Names, and Masses

(Sample Problems 2.5 to 2.14)

Concept Review Questions

2.76 What is the difference between an empirical formula and a molecular formula? Can they ever be the same?

2.77 How is a structural formula similar to a molecular formula? How is it different?

2.78 Consider a mixture of 10 billion O_2 molecules and 10 billion H_2 molecules. In what way is this mixture similar to a sample containing 10 billion hydrogen peroxide (H_2O_2) molecules? In what way is it different?

2.79 For what type(s) of compound do we use Roman numerals in the name?

2.80 For what type(s) of compound do we use Greek numerical prefixes in the name?

2.81 For what type of compound are we unable to write a molecular formula?

Skill-Building Exercises *(grouped in similar pairs)*

2.82 Write an empirical formula for each of the following:
(a) Hydrazine, a rocket fuel, molecular formula N_2H_4
(b) Glucose, a sugar, molecular formula $C_6H_{12}O_6$

2.83 Write an empirical formula for each of the following:
(a) Ethylene glycol, car antifreeze, molecular formula $C_2H_6O_2$
(b) Peroxodisulfuric acid, a compound used to make bleaching agents, molecular formula $H_2S_2O_8$

2.84 Give the name and formula of the compound formed from the following elements: (a) lithium and nitrogen; (b) oxygen and strontium; (c) aluminum and chlorine.

2.85 Give the name and formula of the compound formed from the following elements: (a) rubidium and bromine; (b) sulfur and barium; (c) calcium and fluorine.

2.86 Give the name and formula of the compound formed from the following elements:
(a) ${}_{12}L$ and ${}_{9}M$ (b) ${}_{11}L$ and ${}_{16}M$ (c) ${}_{17}L$ and ${}_{38}M$

2.87 Give the name and formula of the compound formed from the following elements:
(a) $_3$Q and $_{35}$R (b) $_8$Q and $_{13}$R (c) $_{19}$Q and $_{53}$R

2.88 Give the systematic names for the formulas or the formulas for the names: (a) tin(IV) chloride; (b) $FeBr_3$; (c) cuprous bromide; (d) Mn_2O_3.

2.89 Give the systematic names for the formulas or the formulas for the names: (a) Na_2HPO_4; (b) potassium carbonate dihydrate; (c) $NaNO_2$; (d) ammonium perchlorate.

2.90 Give the systematic names for the formulas or the formulas for the names: (a) CoO; (b) mercury(I) chloride; (c) $Pb(C_2H_3O_2)_2 \cdot 3H_2O$; (d) chromic oxide.

2.91 Give the systematic names for the formulas or the formulas for the names: (a) $Sn(SO_3)_2$; (b) potassium dichromate; (c) $FeCO_3$; (d) copper(II) nitrate.

2.92 Correct each of the following formulas:
(a) Barium oxide is BaO_2.
(b) Iron(II) nitrate is $Fe(NO_3)_3$.
(c) Magnesium sulfide is $MnSO_3$.

2.93 Correct each of the following names:
(a) CuI is cobalt(II) iodide.
(b) $Fe(HSO_4)_3$ is iron(II) sulfate.
(c) $MgCr_2O_7$ is magnesium dichromium heptaoxide.

2.94 Give the name and formula for the acid derived from each of the following anions:
(a) hydrogen sulfate (b) IO_3^- (c) cyanide (d) HS^-

2.95 Give the name and formula for the acid derived from each of the following anions:
(a) perchlorate (b) NO_3^- (c) bromite (d) F^-

2.96 Many chemical names are similar at first glance. Give the formulas of the species in each set: (a) ammonium ion and ammonia; (b) magnesium sulfide, magnesium sulfite, and magnesium sulfate; (c) hydrochloric acid, chloric acid, and chlorous acid; (d) cuprous bromide and cupric bromide.

2.97 Give the formulas of the compounds in each set: (a) lead(II) oxide and lead(IV) oxide; (b) lithium nitride, lithium nitrite, and lithium nitrate; (c) strontium hydride and strontium hydroxide; (d) magnesium oxide and manganese(II) oxide.

2.98 Give the name and formula of the compound whose molecules consist of two sulfur atoms and four fluorine atoms.

2.99 Give the name and formula of the compound whose molecules consist of two iodine atoms and seven oxygen atoms.

2.100 Correct the name to match the formula of the following compounds: (a) calcium(II) chloride, $CaCl_2$; (b) copper(II) oxide, Cu_2O; (c) stannous fluoride, SnF_4; (d) hydrogen chloride acid, HCl.

2.101 Correct the formula to match the name of the following compounds: (a) iron(III) oxide, Fe_3O_4; (b) chloric acid, HCl; (c) mercuric oxide, Hg_2O; (d) dichlorine pentaoxide, Cl_2O_7.

2.102 Give the number of atoms of the specified element in a formula unit of each of the following compounds, and calculate the molecular (formula) mass:
(a) Oxygen in aluminum sulfate, $Al_2(SO_4)_3$
(b) Hydrogen in ammonium hydrogen phosphate, $(NH_4)_2HPO_4$
(c) Oxygen in the mineral azurite, $Cu_3(OH)_2(CO_3)_2$

2.103 Give the number of atoms of the specified element in a formula unit of each of the following compounds, and calculate the molecular (formula) mass:
(a) Hydrogen in ammonium benzoate, $C_6H_5COONH_4$
(b) Nitrogen in hydrazinium sulfate, $N_2H_6SO_4$
(c) Oxygen in the mineral leadhillite, $Pb_4SO_4(CO_3)_2(OH)_2$

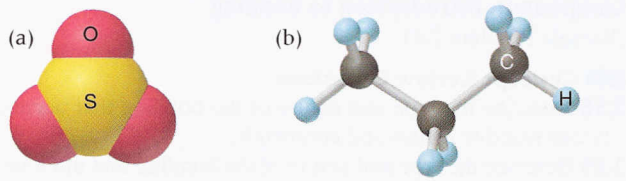
2.104 Write the formula of each compound, and determine its molecular (formula) mass: (a) ammonium sulfate; (b) sodium dihydrogen phosphate; (c) potassium bicarbonate.

2.105 Write the formula of each compound, and determine its molecular (formula) mass: (a) sodium dichromate; (b) ammonium perchlorate; (c) magnesium nitrite trihydrate.

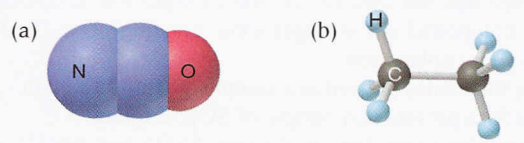
2.106 Calculate the molecular (formula) mass of each compound: (a) dinitrogen pentaoxide; (b) lead(II) nitrate; (c) calcium peroxide.

2.107 Calculate the molecular (formula) mass of each compound: (a) iron(II) acetate tetrahydrate; (b) sulfur tetrachloride; (c) potassium permanganate.

2.108 Give the formula, name, and molecular mass of the following molecules:



2.109 Give the formula, name, and molecular mass of the following molecules:



2.110 Give the name, empirical formula, and molecular mass of the molecule depicted in Figure P2.110.

2.111 Give the name, empirical formula, and molecular mass of the molecule depicted in Figure P2.111.

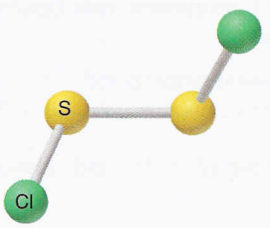


Figure P2.110

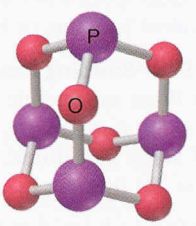

Figure P2.111

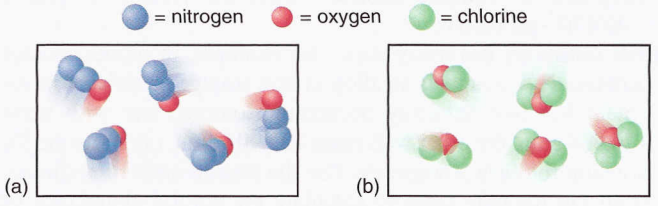
Problems in Context

2.112 Before the use of systematic names, many compounds had common names. Give the systematic name for each of the following: (a) blue vitriol, $CuSO_4 \cdot 5H_2O$; (b) slaked lime, $Ca(OH)_2$; (c) oil of vitriol, H_2SO_4; (d) washing soda, Na_2CO_3; (e) muriatic acid, HCl; (f) Epsom salts, $MgSO_4 \cdot 7H_2O$; (g) chalk, $CaCO_3$; (h) dry ice, CO_2; (i) baking soda, $NaHCO_3$; (j) lye, NaOH.

2.113 Each box contains a representation of a binary compound. Determine its name, formula, and molecular (formula) mass.



Mixtures: Classification and Separation

Concept Review Questions

2.114 In what main way is separating the components of a mixture different from separating the components of a compound?

2.115 What is the difference between a homogeneous and a heterogeneous mixture?

2.116 Is a solution a homogeneous or a heterogeneous mixture? Give an example of an aqueous solution.

Skill-Building Exercises *(grouped in similar pairs)*

2.117 Classify each of the following as a compound, a homogeneous mixture, or a heterogeneous mixture: (a) distilled water; (b) gasoline; (c) beach sand; (d) wine; (e) air.

2.118 Classify each of the following as a compound, a homogeneous mixture, or a heterogeneous mixture: (a) orange juice; (b) vegetable soup; (c) cement; (d) calcium sulfate; (e) tea.

2.119 Name the technique(s) and briefly describe the procedure you would use to separate each of the following mixtures into two components: (a) table salt and pepper; (b) table sugar and sand; (c) drinking water contaminated with fuel oil; (d) vegetable oil and vinegar.

2.120 Name the technique(s) and briefly describe the procedure you would use to separate each of the following mixtures into two components: (a) crushed ice and crushed glass; (b) table sugar dissolved in ethanol; (c) iron and sulfur; (d) two pigments (chlorophyll *a* and chlorophyll *b*) from spinach leaves.

Problems in Context

2.121 Which separation method is operating in each of the following procedures: (a) pouring a mixture of cooked pasta and boiling water into a colander; (b) removing colored impurities from raw sugar to make refined sugar; (c) preparing coffee by pouring hot water through ground coffee beans?

Comprehensive Problems

2.122 Helium is the lightest noble gas and the second most abundant element (after hydrogen) in the universe.
(a) The radius of a helium atom is 3.1×10^{-11} m; the radius of its nucleus is 2.5×10^{-15} m. What fraction of the spherical atomic volume is occupied by the nucleus (V of a sphere $=\frac{4}{3}\pi r^3$)?
(b) The mass of a helium-4 atom is 6.64648×10^{-24} g, and each of its two electrons has a mass of 9.10939×10^{-28} g. What fraction of this atom's mass is contributed by its nucleus?

2.123 From the following ions and their radii (in pm), choose a pair that gives the strongest ionic bonding and a pair that gives the weakest: Mg^{2+} 72; K^+ 138; Rb^+ 152; Ba^{2+} 135; Cl^- 181; O^{2-} 140; I^- 220.

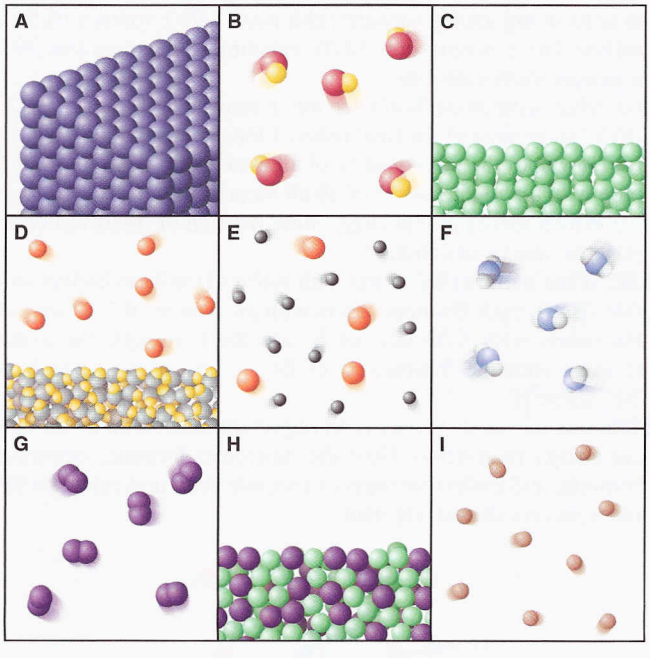
2.124 Prior to 1961, the atomic mass standard was defined as $\frac{1}{16}$ of the mass of ^{16}O. Based on that standard: (a) What was the mass of carbon-12, given the modern atomic mass of oxygen is 15.9994 amu? (b) What was the mass of potassium-39, given its modern isotopic mass is 38.9637 amu?

2.125 Transition metals, located in the center of the periodic table, have many essential uses as elements and form many important compounds as well. Calculate the molecular mass of the following transition metal compounds:
(a) $[Co(NH_3)_6]Cl_3$ (b) $[Pt(NH_3)_4BrCl]Cl_2$
(c) $K_4[V(CN)_6]$ (d) $[Ce(NH_3)_6][FeCl_4]_3$

2.126 A rock is 5.0% by mass fayalite (Fe_2SiO_4), 7.0% by mass forsterite (Mg_2SiO_4), and the remainder silicon dioxide. What is the mass percent of each element in the rock?

2.127 Polyatomic ions are named by patterns that apply to elements in a given group. Using the periodic table and Table 2.5, give the name of each of the following: (a) SeO_4^{2-}; (b) AsO_4^{3-}; (c) BrO_2^-; (d) $HSeO_4^-$; (e) TeO_3^{2-}.

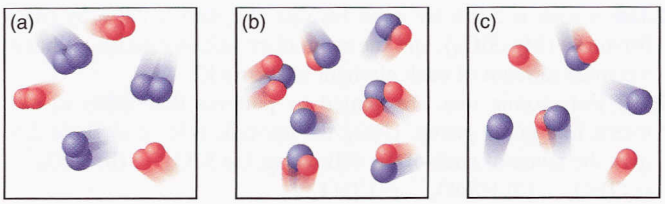
2.128 Scenes A–I depict various types of matter on the atomic scale. Choose the correct scene(s) for each of the following:
(a) A mixture that fills its container
(b) A substance that cannot be broken down into simpler ones
(c) An element with a very high resistance to flow
(d) A homogeneous mixture
(e) An element that conforms to the walls of its container and displays a surface
(f) A gas consisting of diatomic particles
(g) A gas that can be broken down into simpler substances
(h) A substance with a 2:1 number ratio of its component atoms
(i) Matter that can be separated into its component substances by physical means
(j) A heterogeneous mixture
(k) Matter that obeys the law of definite composition



2.129 Nitrogen forms more oxides than any other element. The percents by mass of N in three different nitrogen oxides are (I) 46.69%; (II) 36.85%; (III) 25.94%. (a) Determine the empirical formula of each compound. (b) How many grams of oxygen per 1.00 g of nitrogen are in each compound?

2.130 Boron has two naturally occurring isotopes, ^{10}B (19.9%) and ^{11}B (80.1%). Although the B_2 molecule does not exist naturally on Earth, it has been produced in the laboratory and been observed in stars. (a) How many different B_2 molecules are possible? (b) What are the masses and percent abundances of each?

2.131 Which of the following pictures is (are) consistent with the fact that compounds of nitrogen *(blue)* and oxygen *(red)* exhibit the law of multiple proportions? Explain.



2.132 The number of atoms in 1 dm^3 of aluminum is nearly the same as the number of atoms in 1 dm^3 of lead, but the densities of these metals are very different (see Table 1.5). Explain.

2.133 You are working in the laboratory preparing sodium chloride. Consider the following results for three preparations of the compound:

Case 1: 39.34 g Na + 60.66 g Cl_2 ⟶ 100.00 g NaCl

Case 2: 39.34 g Na + 70.00 g Cl_2 ⟶ 100.00 g NaCl + 9.34 g Cl_2

Case 3: 50.00 g Na + 50.00 g Cl_2 ⟶ 82.43 g NaCl + 17.57 g Na

Explain these results in terms of the laws of conservation of mass and definite composition.

2.134 The seven most abundant ions in seawater make up more than 99% by mass of the dissolved compounds. They are listed in units of mg ion/kg seawater: chloride 18,980; sodium 10,560; sulfate 2650; magnesium 1270; calcium 400; potassium 380; hydrogen carbonate 140.

(a) What is the mass % of each ion in seawater?

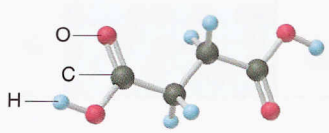
(b) What percent of the total mass of ions is sodium ion?

(c) How does the total mass % of alkaline earth metal ions compare with the total mass % of alkali metal ions?

(d) Which makes up the larger mass fraction of dissolved components, anions or cations?

2.135 When barium (Ba) reacts with sulfur (S) to form barium sulfide (BaS), each Ba atom reacts with an S atom. If 2.00 cm^3 of Ba reacts with 1.50 cm^3 of S, are there enough Ba atoms to react with the S atoms (d of Ba = 3.51 g/cm^3; d of S = 2.07 g/cm^3)?

2.136 Succinic acid *(below)* is an important metabolite in biological energy production. Give the molecular formula, empirical formula, and molecular mass of succinic acid, and calculate the mass percent of each element.



2.137 Fluoride ion is poisonous in relatively low amounts: 0.2 g of F^- per 70 kg of body weight can cause death. Nevertheless, in order to prevent tooth decay, F^- ions are added to drinking water at a concentration of 1 mg of F^- ion per L of water. How many liters of fluoridated drinking water would a 70-kg person have to consume in one day to reach this toxic level? How many kilograms of sodium fluoride would be needed to treat a 7.00×10^7-gal reservoir?

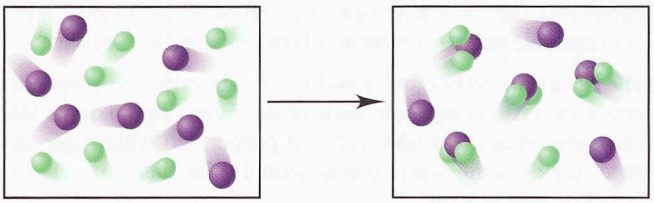
2.138 Antimony has many uses—for example, in semiconductor infrared devices and as an alloy in lead storage batteries. The element has two naturally occurring isotopes, one with mass 120.904 amu, the other with mass 122.904 amu. (a) Write the ^A_ZX notation for each isotope. (b) Use the atomic mass of antimony from the periodic table to calculate the natural abundance of each isotope.

2.139 Nitrous oxide (N_2O) is a potent greenhouse gas. It enters the atmosphere from fertilizer breakdown, car exhaust, and many other sources. Some studies have shown that the isotope ratios of ^{15}N to ^{14}N and of ^{18}O to ^{16}O in N_2O depend on the source. Thus, measuring the relative abundance of molecular masses in a sample of N_2O can help determine the source

(a) What different molecular masses are possible for N_2O?

(b) The percent abundance of ^{14}N is 99.6%, and that of ^{16}O is 99.8%. Which molecular mass of N_2O is least common, and which is most common?

2.140 The scene below represents a chemical reaction in a container. Which of the mass laws—mass conservation, definite composition, or multiple proportions—is (are) illustrated?



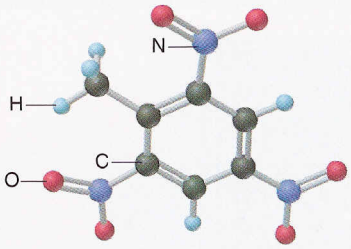
2.141 The two isotopes of potassium with significant abundance in nature are ^{39}K (isotopic mass 38.9637 amu, 93.258%) and ^{41}K (isotopic mass 40.9618 amu, 6.730%). Fluorine has only one naturally occurring isotope, ^{19}F (isotopic mass 18.9984 amu). Calculate the formula mass of potassium fluoride.

2.142 Boron trifluoride is used extensively in the synthesis of organic compounds. When it is analyzed by mass spectrometry (see Tools of the Laboratory, p. 52), several different 1+ ions form, including ions representing the whole molecule as well as molecular fragments formed by the loss of one, two, and three F atoms. Given that boron has two naturally occurring isotopes, ^{10}B and ^{11}B, and fluorine has one, ^{19}F, calculate the masses of all possible 1+ ions.

2.143 Nitrogen monoxide (NO) is a bioactive molecule in blood. Low NO concentrations cause respiratory distress and the formation of blood clots. Doctors prescribe nitroglycerin, $C_3H_5N_3O_9$, and isoamyl nitrate, $(CH_3)_2CHCH_2CH_2ONO_2$, to increase NO. If each compound releases one molecule of NO per atom of N, calculate the mass percent of NO in each medicine.

2.144 Nuclei differ in their stability, and some are so unstable that they undergo radioactive decay. The ratio of the number of neutrons to number of protons (N/Z) in a nucleus correlates with its stability. Calculate the N/Z ratio for (a) ^{144}Sm; (b) ^{56}Fe; (c) ^{20}Ne; (d) ^{107}Ag. (e) The radioactive isotope ^{238}U decays in a series of nuclear reactions that includes another uranium isotope, ^{234}U, and three lead isotopes, ^{214}Pb, ^{210}Pb, and ^{206}Pb. How many neutrons, protons, and electrons are in each of these five isotopes?

2.145 TNT (trinitrotoluene; *below*) is used as an explosive in construction. Calculate the mass of each element in 1.00 lb of TNT.



2.146 Carboxylic acids react with alcohols to form esters, which are found in all plants and animals. Some are responsible for the flavors and odors of fruits and flowers. What is the percent by mass of carbon in each of the following esters?

Name	Formula	Odor
Isoamyl isovalerate	$C_4H_9COOC_5H_{11}$	apple
Amyl butyrate	$C_3H_7COOC_5H_{11}$	apricot
Isoamyl acetate	$CH_3COOC_5H_{11}$	banana
Ethyl butyrate	$C_3H_7COOC_2H_5$	pineapple

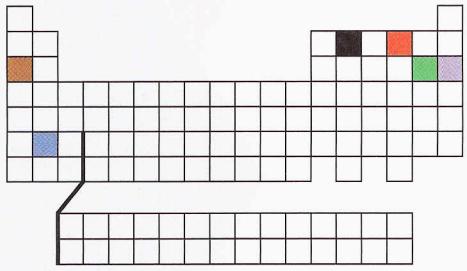
2.147 The anticancer drug Platinol (Cisplatin), $Pt(NH_3)_2Cl_2$, reacts with the cancer cell's DNA and interferes with its growth. (a) What is the mass % of platinum (Pt) in Platinol? (b) If Pt costs \$19/g, how many grams of Platinol can be made for \$1.00 million (assume that the cost of Pt determines the cost of the drug)?

2.148 Grignard reagents, which have the general formula $CH_3—(CH_2)_x—MgBr$, are essential in the synthesis of organic compounds. They contain a C—Mg bond, with the Mg so positive that the reagent exists as an ionic compound. (a) Calculate the mass percent of Mg if $x = 0$. (b) Calculate the mass percent of Mg if $x = 5$. (c) Calculate the value of x if the mass percent of Mg is 16.5%.

2.149 In a sample of any metal, spherical atoms pack closely together, but the space between them means that the density of the sample is less than that of the atoms themselves. Iridium (Ir) is one of the densest elements: 22.56 g/cm^3. The atomic mass of Ir is 192.22 amu, and the mass of the nucleus is 192.18 amu. Determine the density (in g/cm^3) of (a) an Ir atom and (b) an Ir nucleus. (c) How many Ir atoms placed in a row would extend 1.00 cm (radius of Ir atom = 1.36 Å; radius of Ir nucleus = 1.5 femtometers (fm); V of a sphere = $\frac{4}{3}\pi r^3$)?

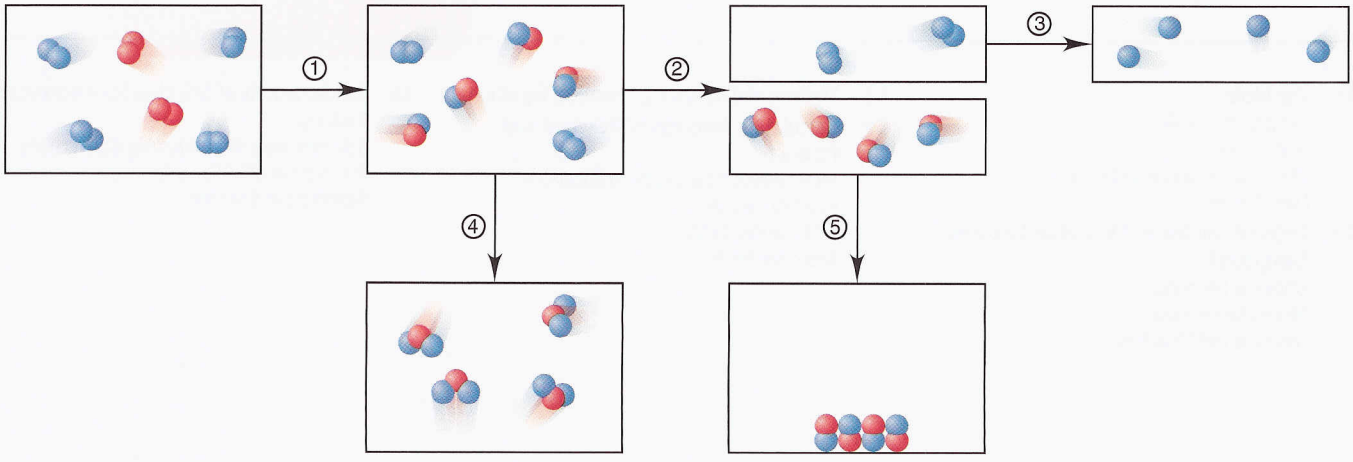
2.150 Dimercaprol ($HSCH_2CHSHCH_2OH$) is a complexing agent developed during World War I as an antidote to arsenic-based poison gas and used today to treat heavy-metal poisoning. Such an agent binds and removes the toxic element from the body.
(a) If each molecule binds one arsenic (As) atom, how many atoms of As could be removed by 250. mg of dimercaprol?
(b) If one molecule binds one metal atom, calculate the mass % of each of the following metals in a metal-dimercaprol complex: mercury, thallium, chromium.

2.151 Choose the box color(s) in the periodic table below that match(es) the following:



(a) Four elements that are nonmetals
(b) Two elements that are metals
(c) Three elements that are gases at room temperature
(d) Three elements that are solid at room temperature
(e) One pair of elements likely to form a covalent compound
(f) Another pair of elements likely to form a covalent compound
(g) One pair of elements likely to form an ionic compound with formula MX
(h) Another pair of elements likely to form an ionic compound with formula MX
(i) Two elements likely to form an ionic compound with formula M_2X
(j) Two elements likely to form an ionic compound with formula MX_2
(k) An element that forms no compounds
(l) A pair of elements whose compounds exhibit the law of multiple proportions
(m) Two elements that are building blocks in biomolecules
(n) Two elements that are macronutrients in organisms

2.152 Which of the following steps in an overall process involve(s) a physical change and which involve(s) a chemical change?



Mass and Number During any chemical reaction, such as this one between potassium and water to form hydrogen gas and a solution of potassium hydroxide, total mass is constant but individual masses change. As you'll see in this chapter, weighing provides a means for knowing not only the *mass* of each substance involved in a reaction, but also the *number* of atoms, ions, or molecules undergoing the change.

Chemistry is a practical science. Just imagine how useful it could be to determine the formula of a compound from the masses of its elements or to predict the amounts of substances consumed and produced in a reaction. Suppose you are a polymer chemist preparing a new plastic: how much of this new material will a given polymerization reaction yield? Or suppose you're a chemical engineer studying rocket engine thrust: what amount of exhaust gases will a test of this fuel mixture produce? Perhaps you are on a team of environmental chemists examining coal samples: what quantity of air pollutants will this sample release when burned? Or, maybe you're a biomedical researcher who has extracted a new cancer-preventing substance from a tropical plant: what is its formula, and what quantity of metabolic products will establish a safe dosage level? You can answer such questions and countless others like them with a knowledge of **stoichiometry** (pronounced "stoy-key-AHM-uh-tree"; from the Greek *stoicheion,* "element or part," and *metron,* "measure"), the study of the quantitative aspects of chemical formulas and reactions.

IN THIS CHAPTER . . . We relate the mass of a substance to the number of chemical entities comprising it (atoms, ions, molecules, or formula units). We convert the results of mass analysis into a chemical formula and distinguish the types of chemical formulas and their relation to molecular structures. Reading, writing, and thinking in the language of chemical equations are applied to finding the amounts of reactants and products involved in a reaction. These methods are also applied to reactions that occur in solution.

Concepts & Skills to Review

before you study this chapter

- isotopes and atomic mass (Section 2.5)
- names and formulas of compounds (Section 2.8)
- molecular mass of a compound (Section 2.8)
- empirical and molecular formulas (Section 2.8)
- mass laws in chemical reactions (Section 2.2)

3.1 THE MOLE

All the concepts and skills discussed here depend on an understanding of the *mole* concept, so let's begin with this central idea. In daily life, we typically measure things out by counting or by weighing, with the choice based on convenience. It is more convenient to weigh beans or rice than to count individual pieces, and it is more convenient to count eggs or pencils than to weigh them. To measure out such things, we use mass units (a kilogram of rice) or counting units (a dozen pencils). Similarly, daily life in the laboratory involves measuring out substances to prepare a solution or "run" a reaction. However, an obvious problem arises when we try to do this. The atoms, ions, molecules, or formula units are the entities that react with one another, so we would like to know the numbers of them that we mix together. But, how can we possibly count entities that are so small? To do this, chemists have devised a unit called the mole to *count chemical entities by weighing them.*

Defining the Mole

The **mole** (abbreviated **mol**) is the SI unit for amount of substance. It is defined as *the amount of a substance that contains the same number of entities as there are atoms in exactly 12 g of carbon-12.* This number is called **Avogadro's number,** in honor of the 19th-century Italian physicist Amedeo Avogadro, and as you can tell from the definition, it is enormous:

One mole (1 mol) contains 6.022×10^{23} entities (to four significant figures) (3.1)

Thus,

1 mol of carbon-12	contains	6.022×10^{23} carbon-12 atoms
1 mol of H_2O	contains	6.022×10^{23} H_2O molecules
1 mol of NaCl	contains	6.022×10^{23} NaCl formula units

Imagine a Mole of . . . A mole of any ordinary object is a staggering amount: a mole of periods (.) lined up side by side would equal the radius of our galaxy; a mole of marbles stacked tightly together would cover the United States 70 miles deep. However, atoms and molecules are not ordinary objects: a mole of water molecules (about 18 mL) can be swallowed in one gulp!

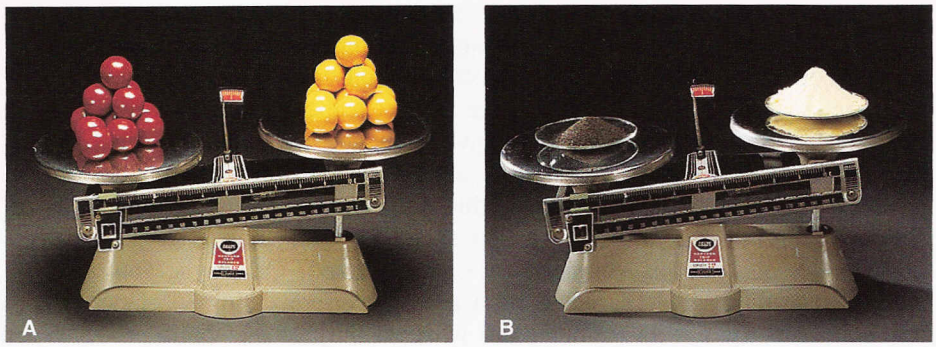

Figure 3.1 Counting objects of fixed relative mass. A, If marbles had a fixed mass, we could count them by weighing them. Each red marble weighs 7 g, and each yellow marble weighs 4 g, so 84 g of red marbles and 48 g of yellow marbles each consists of 12 marbles. Equal numbers of the two types of marbles always have a 7:4 mass ratio of red:yellow marbles. **B,** Because atoms of a substance have a fixed mass, we can weigh the substance to count the atoms; 55.85 g of Fe (left pan) and 32.07 g of S (right pan) each consists of 6.022×10^{23} atoms (1 mol of atoms). Any two samples of Fe and S that contain equal numbers of atoms have a 55.85:32.07 mass ratio of Fe:S.

However, the mole is not just a counting unit, like the dozen, which specifies only the *number* of objects. The definition of the mole specifies the number of objects in a fixed *mass* of substance. Therefore, *1 mole of a substance represents a fixed number of chemical entities* ***and*** *has a fixed mass.* To see why this is important, consider the marbles in Figure 3.1A, which we'll use as an analogy for atoms. Suppose you have large groups of red marbles and yellow marbles; each red marble weighs 7 g and each yellow marble weighs 4 g. Right away you know that there are 12 marbles in 84 g of red marbles or in 48 g of yellow marbles. Moreover, because one red marble weighs $\frac{7}{4}$ as much as one yellow marble, any given *number* of red and of yellow marbles always has this 7:4 *mass* ratio. By the same token, any given *mass* of red and of yellow marbles always has a 4:7 *number* ratio. For example, 280 g of red marbles contains 40 marbles, and 280 g of yellow marbles contains 70 marbles. As you can see, the fixed masses of the marbles allow you to count marbles by weighing them.

Atoms have fixed masses also, and the mole gives us a practical way to determine the number of atoms, molecules, or formula units in a sample by weighing it. Let's focus on elements first and recall a key point from Chapter 2: the atomic mass of an element (which appears on the periodic table) is the weighted average of the masses of its naturally occurring isotopes. For purposes of weighing, all atoms of an element are considered to have this atomic mass. That is, all iron (Fe) atoms have an atomic mass of 55.85 amu, all sulfur (S) atoms have an atomic mass of 32.07 amu, and so forth.

The central relationship between the mass of one atom and the mass of 1 mole of those atoms is that *the atomic mass of an element expressed in* ***amu*** *is numerically the same as the mass of 1 mole of atoms of the element expressed in* ***grams.*** You can see this from the definition of the mole, which referred to the number of atoms in "**12** g of carbon-**12.**" Thus,

1 Fe atom	has a mass of	55.85 amu	and	1 mol of Fe atoms	has a mass of	55.85 g
1 S atom	has a mass of	32.07 amu	and	1 mol of S atoms	has a mass of	32.07 g
1 O atom	has a mass of	16.00 amu	and	1 mol of O atoms	has a mass of	16.00 g
1 O_2 molecule	has a mass of	32.00 amu	and	1 mol of O_2 molecules	has a mass of	32.00 g

Moreover, because of their fixed atomic masses, we know that 55.85 g of Fe atoms and 32.07 g of S atoms each contains 6.022×10^{23} atoms. As with marbles of fixed mass, one Fe atom weighs $\frac{55.85}{32.07}$ as much as one S atom, and 1 mol of Fe atoms weighs $\frac{55.85}{32.07}$ as much as 1 mol of S atoms (Figure 3.1B).

A similar relationship holds for compounds: *the molecular mass (or formula mass) of a compound expressed in* ***amu*** *is numerically the same as the mass of 1 mole of the compound expressed in* ***grams.*** Thus, for example,

1 molecule of H_2O	has a mass of	18.02 amu	and	1 mol of H_2O (6.022×10^{23} molecules)	has a mass of	18.02 g
1 formula unit of NaCl	has a mass of	58.44 amu	and	1 mol of NaCl (6.022×10^{23} formula units)	has a mass of	58.44 g

To summarize the two key points about the usefulness of the mole concept:

- The mole maintains the *same mass relationship* between macroscopic samples as exists between individual chemical entities.
- The mole relates the *number* of chemical entities to the *mass* of a sample of those entities.

A grocer cannot obtain 1 dozen eggs by weighing them because eggs vary in mass. But a chemist *can* obtain 1 mol of copper atoms (6.022×10^{23} atoms) simply by weighing 63.55 g of copper. Figure 3.2 shows 1 mol of some familiar elements and compounds.

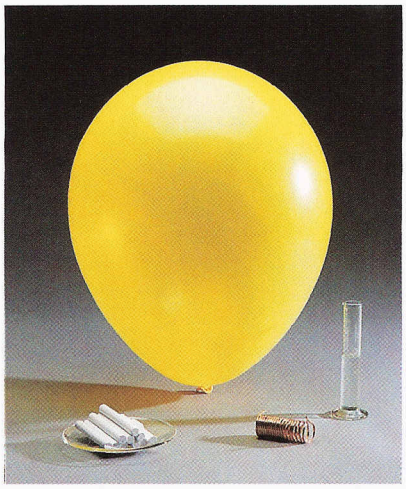

Figure 3.2 One mole of some familiar substances. One mole of a substance is the amount that contains 6.022×10^{23} atoms, molecules, or formula units. From left to right: 1 mol (172.19 g) of calcium sulfate dihydrate, 1 mol (32.00 g) of gaseous O_2, 1 mol (63.55 g) of copper, and 1 mol (18.02 g) of liquid H_2O.

Molar Mass

The **molar mass** ($\mathcal{M}$) of a substance is the mass per mole of its entities (atoms, molecules, or formula units). Thus, molar mass has units of grams per mole (g/mol). Table 3.1 summarizes the meanings of mass units used in this text.

Table 3.1 Summary of Mass Terminology*

Term	Definition	Unit
Isotopic mass	Mass of an isotope of an element	amu
Atomic mass (also called atomic weight)	Average of the masses of the naturally occurring isotopes of an element weighted according to their abundance	amu
Molecular (or formula) mass (also called molecular weight)	Sum of the atomic masses of the atoms (or ions) in a molecule (or formula unit)	amu
Molar mass ($\mathcal{M}$) (also called gram-molecular weight)	Mass of 1 mole of chemical entities (atoms, ions, molecules, formula units)	g/mol

*All terms based on the ^{12}C standard: 1 atomic mass unit = $\frac{1}{12}$ mass of one ^{12}C atom.

The periodic table is indispensable for calculating the molar mass of a substance. Here's how the calculations are done:

1. **Elements.** You find the molar mass of an element simply by looking up its atomic mass in the periodic table and then noting whether the element occurs naturally as individual atoms or as molecules.

- *Monatomic elements.* For elements that occur as collections of individual atoms, the molar mass is the numerical value from the periodic table expressed in units of grams per mole.* Thus, the molar mass of neon is 20.18 g/mol, the molar mass of iron is 55.85 g/mol, and the molar mass of gold is 197.0 g/mol.
- *Molecular elements.* For elements that occur naturally as molecules, you must know the molecular formula to determine the molar mass. For example, oxygen exists normally in air as diatomic molecules, so the molar mass of O_2 molecules is twice that of O atoms:

$$\text{Molar mass } (\mathcal{M}) \text{ of } O_2 = 2 \times \mathcal{M} \text{ of O} = 2 \times 16.00 \text{ g/mol} = 32.00 \text{ g/mol}$$

The most common form of sulfur consists of octatomic molecules, S_8:

$$\mathcal{M} \text{ of } S_8 = 8 \times \mathcal{M} \text{ of S} = 8 \times 32.07 \text{ g/mol} = 256.6 \text{ g/mol}$$

*The mass value in the periodic table is unitless because it is a *relative* atomic mass, given by the atomic mass (in amu) divided by 1 amu ($\frac{1}{12}$ mass of one ^{12}C atom in amu):

$$\text{Relative atomic mass} = \frac{\text{atomic mass (amu)}}{\frac{1}{12} \text{ mass of } ^{12}C \text{ (amu)}}$$

Therefore, you use the same number for the atomic mass (weighted average mass of one atom in amu) and the molar mass (mass of 1 mole of atoms in grams).

2. **Compounds.** *The molar mass of a compound is the sum of the molar masses of the atoms of the elements in the formula.* For example, the formula of sulfur dioxide (SO_2) tells us that 1 mol of SO_2 molecules contains 1 mol of S atoms and 2 mol of O atoms:

$$\mathcal{M} \text{ of } SO_2 = \mathcal{M} \text{ of S} + (2 \times \mathcal{M} \text{ of O}) = 32.07 \text{ g/mol} + (2 \times 16.00 \text{ g/mol}) = 64.07 \text{ g/mol}$$

Similarly, for ionic compounds, such as potassium sulfide (K_2S), we have

$$\mathcal{M} \text{ of } K_2S = (2 \times \mathcal{M} \text{ of K}) + \mathcal{M} \text{ of S} = (2 \times 39.10 \text{ g/mol}) + 32.07 \text{ g/mol} = 110.27 \text{ g/mol}$$

A key point to note is that *the subscripts in a formula refer to individual atoms (or ions), as well as to moles of atoms (or ions).* Table 3.2 presents this idea for glucose ($C_6H_{12}O_6$), the essential sugar in energy metabolism.

Table 3.2 Information Contained in the Chemical Formula of Glucose, $C_6H_{12}O_6$ ($\mathcal{M}$ = 180.16 g/mol)

	Carbon (C)	Hydrogen (H)	Oxygen (O)
Atoms/molecule of compound	6 atoms	12 atoms	6 atoms
Moles of atoms/mole of compound	6 mol of atoms	12 mol of atoms	6 mol of atoms
Atoms/mole of compound	$6(6.022\times10^{23})$ atoms	$12(6.022\times10^{23})$ atoms	$6(6.022\times10^{23})$ atoms
Mass/molecule of compound	6(12.01 amu) = 72.06 amu	12(1.008 amu) = 12.10 amu	6(16.00 amu) = 96.00 amu
Mass/mole of compound	72.06 g	12.10 g	96.00 g

Interconverting Moles, Mass, and Number of Chemical Entities

One of the reasons the mole is such a convenient unit for laboratory work is that it allows you to calculate the mass (or number of entities) of a substance in a sample if you know the amount (number of moles) of the substance. Conversely, if you know the mass (or number of entities) of a substance, you can calculate the number of moles.

The molar mass, which expresses the equivalent relationship between 1 mole of a substance and its mass in grams, can be used as a conversion factor. We multiply by the molar mass of an element or compound ($\mathcal{M}$, in g/mol) to convert a given amount (in moles) to mass (in grams):

$$\text{Mass (g)} = \text{no. of moles} \times \frac{\text{no. of grams}}{1 \text{ mol}} \tag{3.2}$$

Or, we divide by the molar mass (multiply by $1/\mathcal{M}$) to convert a given mass (in grams) to amount (in moles):

$$\text{No. of moles} = \text{mass (g)} \times \frac{1 \text{ mol}}{\text{no. of grams}} \tag{3.3}$$

In a similar way, we use Avogadro's number, which expresses the equivalent relationship between 1 mole of a substance and the number of entities it contains, as a conversion factor. We multiply by Avogadro's number to convert amount of substance (in moles) to the number of entities (atoms, molecules, or formula units):

$$\text{No. of entities} = \text{no. of moles} \times \frac{6.022\times10^{23} \text{ entities}}{1 \text{ mol}} \tag{3.4}$$

Or, we divide by Avogadro's number to do the reverse:

$$\text{No. of moles} = \text{no. of entities} \times \frac{1 \text{ mol}}{6.022\times10^{23} \text{ entities}} \tag{3.5}$$

Converting Moles of Elements For problems involving mass-mole-number relationships of elements, keep these points in mind:

- To convert between amount (mol) and mass (g), use the molar mass ($\mathcal{M}$ in g/mol).
- To convert between amount (mol) and number of entities, use Avogadro's number (6.022×10^{23} entities/mol). For elements that occur as molecules, use the molecular formula to find atoms/mol.
- Mass and number of entities relate directly to number of moles, *not* to each other. Therefore, to convert between number of entities and mass, *first convert to number of moles*. For example, to find the number of atoms in a given mass,

$$\text{No. of atoms} = \text{mass (g)} \times \frac{1 \text{ mol}}{\text{no. of grams}} \times \frac{6.022\times10^{23} \text{ atoms}}{1 \text{ mol}}$$

These relationships are summarized in Figure 3.3 and demonstrated in Sample Problem 3.1.

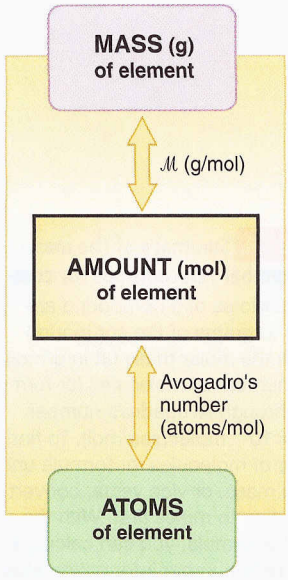

Figure 3.3 Summary of the mass-mole-number relationships for elements. The amount (mol) of an element is related to its mass (g) through the molar mass ($\mathcal{M}$ in g/mol) and to its number of atoms through Avogadro's number (6.022×10^{23} atoms/mol). For elements that occur as molecules, Avogadro's number gives *molecules* per mole.

SAMPLE PROBLEM 3.1 Calculating the Mass and Number of Atoms in a Given Number of Moles of an Element

Problem **(a)** Silver (Ag) is used in jewelry and tableware but no longer in U.S. coins. How many grams of Ag are in 0.0342 mol of Ag?
(b) Iron (Fe), the main component of steel, is the most important metal in industrial society. How many Fe atoms are in 95.8 g of Fe?

(a) Determining the mass (g) of Ag

Plan We know the number of moles of Ag (0.0342 mol) and have to find the mass (in g). To convert *moles* of Ag to *grams* of Ag, we multiply by the *molar mass* of Ag, which we find in the periodic table (see roadmap a).

Solution Converting from moles of Ag to grams:

$$\text{Mass (g) of Ag} = 0.0342 \text{ mol Ag} \times \frac{107.9 \text{ g Ag}}{1 \text{ mol Ag}} = 3.69 \text{ g Ag}$$

Check We rounded the mass to three significant figures because the number of moles has three. The units are correct. About 0.03 mol × 100 g/mol gives 3 g; the small mass makes sense because 0.0342 is a small fraction of a mole.

(b) Determining the number of Fe atoms

Plan We know the grams of Fe (95.8 g) and need the number of Fe atoms. We cannot convert directly from grams to atoms, so we first convert to moles by dividing grams of Fe by its molar mass. [This is the reverse of the step in part (a).] Then, we multiply number of moles by Avogadro's number to find number of atoms (see roadmap b).

Solution Converting from grams of Fe to moles:

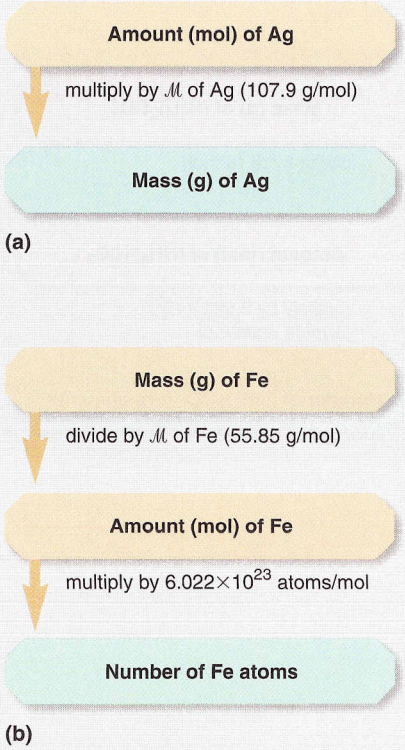
$$\text{Moles of Fe} = 95.8 \text{ g Fe} \times \frac{1 \text{ mol Fe}}{55.85 \text{ g Fe}} = 1.72 \text{ mol Fe}$$

Converting from moles of Fe to number of atoms:

$$\text{No. of Fe atoms} = 1.72 \text{ mol Fe} \times \frac{6.022\times10^{23} \text{ atoms Fe}}{1 \text{ mol Fe}}$$

$$= 10.4\times10^{23} \text{ atoms Fe} = 1.04\times10^{24} \text{ atoms Fe}$$

Check When we approximate the mass of Fe and the molar mass of Fe, we have ~100 g/(~50 g/mol) = 2 mol. Therefore, the number of atoms should be about twice Avogadro's number: $2(6\times10^{23}) = 1.2\times10^{24}$.



FOLLOW-UP PROBLEM 3.1 **(a)** Graphite is the crystalline form of carbon used in "lead" pencils. How many moles of carbon are in 315 mg of graphite?
(b) Manganese (Mn) is a transition element essential for the growth of bones. What is the mass in grams of 3.22×10^{20} Mn atoms, the number found in 1 kg of bone?

Converting Moles of Compounds Solving mass-mole-number problems involving compounds requires a very similar approach to the one for elements. We need the chemical formula to find the molar mass and to determine the moles of a given element in the compound. These relationships are shown in Figure 3.4, and an example is worked through in Sample Problem 3.2.

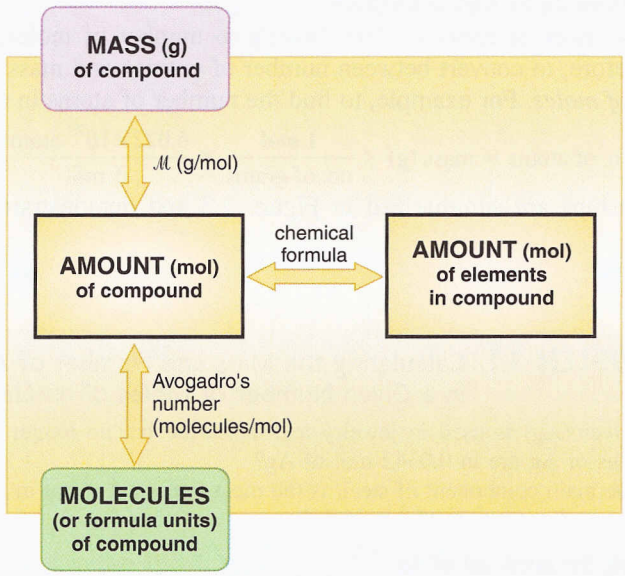


Figure 3.4 Summary of the mass-mole-number relationships for compounds. Moles of a compound are related to grams of the compound through the molar mass ($\mathcal{M}$ in g/mol) and to the number of molecules (or formula units) through Avogadro's number (6.022×10^{23} molecules/mol). To find the number of molecules (or formula units) in a given mass, or vice versa, convert the information to moles first. With the chemical formula, you can calculate mass-mole-number information about each component element.

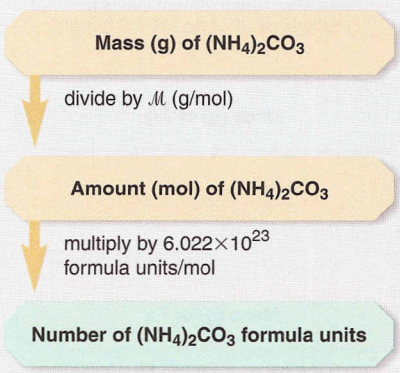
SAMPLE PROBLEM 3.2 Calculating the Moles and Number of Formula Units in a Given Mass of a Compound

Problem Ammonium carbonate is a white solid that decomposes with warming. Among its many uses, it is a component of baking powder, fire extinguishers, and smelling salts. How many formula units are in 41.6 g of ammonium carbonate?

Plan We know the mass of compound (41.6 g) and need to find the number of formula units. As we saw in Sample Problem 3.1(b), to convert grams to number of entities, we have to find number of moles first, so we must divide the grams by the molar mass ($\mathcal{M}$). For this, we need $\mathcal{M}$, so we determine the formula (see Table 2.5) and take the sum of the elements' molar masses. Once we have the number of moles, we multiply by Avogadro's number to find the number of formula units.



Solution The formula is $(NH_4)_2CO_3$. Calculating molar mass:

$$\begin{aligned}\mathcal{M} &= (2 \times \mathcal{M} \text{ of N}) + (8 \times \mathcal{M} \text{ of H}) + (1 \times \mathcal{M} \text{ of C}) + (3 \times \mathcal{M} \text{ of O})\\ &= (2 \times 14.01 \text{ g/mol}) + (8 \times 1.008 \text{ g/mol}) + 12.01 \text{ g/mol} + (3 \times 16.00 \text{ g/mol})\\ &= 96.09 \text{ g/mol}\end{aligned}$$

Converting from grams to moles:

$$\text{Moles of } (NH_4)_2CO_3 = 41.6 \text{ g } \cancel{(NH_4)_2CO_3} \times \frac{1 \text{ mol } (NH_4)_2CO_3}{96.09 \text{ g } \cancel{(NH_4)_2CO_3}} = 0.433 \text{ mol } (NH_4)_2CO_3$$

Converting from moles to formula units:

$$\begin{aligned}\text{Formula units of } (NH_4)_2CO_3 &= 0.433 \cancel{\text{ mol } (NH_4)_2CO_3}\\ &\quad \times \frac{6.022\times10^{23} \text{ formula units } (NH_4)_2CO_3}{1 \cancel{\text{ mol } (NH_4)_2CO_3}}\\ &= 2.61\times10^{23} \text{ formula units } (NH_4)_2CO_3\end{aligned}$$

Check The units are correct. Since the mass is less than half the molar mass ($\sim42/96 < 0.5$), the number of formula units should be less than half Avogadro's number ($\sim2.6\times10^{23}/6.0\times10^{23} < 0.5$).

Comment A *common mistake* is to forget the subscript 2 outside the parentheses in $(NH_4)_2CO_3$, which would give a much lower molar mass.

FOLLOW-UP PROBLEM 3.2 Tetraphosphorus decaoxide reacts with water to form phosphoric acid, a major industrial acid. In the laboratory, the oxide is used as a drying agent.
(a) What is the mass (in g) of 4.65×10^{22} molecules of tetraphosphorus decaoxide?
(b) How many P atoms are present in this sample?

Mass Percent from the Chemical Formula

Each element in a compound constitutes its own particular portion of the compound's mass. For an individual molecule (or formula unit), we use the molecular (or formula) mass and chemical formula to find the mass percent of any element X in the compound:

$$\text{Mass \% of element X} = \frac{\text{atoms of X in formula} \times \text{atomic mass of X (amu)}}{\text{molecular (or formula) mass of compound (amu)}} \times 100$$

Since the formula also tells the number of *moles* of each element in the compound, we use the molar mass to find the mass percent of each element on a mole basis:

$$\text{Mass \% of element X} = \frac{\text{moles of X in formula} \times \text{molar mass of X (g/mol)}}{\text{mass (g) of 1 mol of compound}} \times 100 \quad (3.6)$$

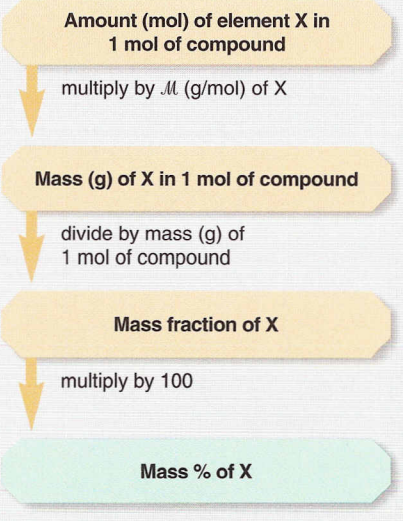
As always, the individual mass percents of the elements in the compound must add up to 100% (within rounding). As Sample Problem 3.3 demonstrates, an important practical use of mass percent is to determine the amount of an element in any size sample of a compound.

SAMPLE PROBLEM 3.3 Calculating Mass Percents and Masses of Elements in a Sample of a Compound

Problem In mammals, lactose (milk sugar) is broken down to glucose ($C_6H_{12}O_6$), the key nutrient for generating chemical potential energy.
(a) What is the mass percent of each element in glucose?
(b) How many grams of carbon are in 16.55 g of glucose?

(a) Determining the mass percent of each element

Plan We know the relative numbers of moles of the elements in glucose from the formula (6 C, 12 H, 6 O). We multiply the number of moles of each element by its molar mass to find grams. Dividing each element's mass by the mass of 1 mol of glucose gives the mass fraction of each element, and multiplying each fraction by 100 gives the mass percent. The calculation steps for any element X are shown in the roadmap.



Solution Calculating the mass of 1 mol of $C_6H_{12}O_6$:

$$\begin{aligned}\mathcal{M} &= (6 \times \mathcal{M} \text{ of C}) + (12 \times \mathcal{M} \text{ of H}) + (6 \times \mathcal{M} \text{ of O})\\ &= (6 \times 12.01 \text{ g/mol}) + (12 \times 1.008 \text{ g/mol}) + (6 \times 16.00 \text{ g/mol})\\ &= 180.16 \text{ g/mol}\end{aligned}$$

Converting moles of C to grams: There are 6 mol of C in 1 mol of glucose, so

$$\text{Mass (g) of C} = 6 \text{ mol C} \times \frac{12.01 \text{ g C}}{1 \text{ mol C}} = 72.06 \text{ g C}$$

Finding the mass fraction of C in glucose:

$$\text{Mass fraction of C} = \frac{\text{total mass C}}{\text{mass of 1 mol glucose}} = \frac{72.06 \text{ g}}{180.16 \text{ g}} = 0.4000$$

Finding the mass percent of C:

$$\text{Mass \% of C} = \text{mass fraction of C} \times 100 = 0.4000 \times 100 = 40.00 \text{ mass \% C}$$

Combining the steps for each of the other two elements in glucose:

$$\text{Mass \% of H} = \frac{\text{mol H} \times \mathcal{M} \text{ of H}}{\text{mass of 1 mol glucose}} \times 100 = \frac{12 \text{ mol H} \times \dfrac{1.008 \text{ g H}}{1 \text{ mol H}}}{180.16 \text{ g}} \times 100$$

$$= 6.714 \text{ mass \% H}$$

$$\text{Mass \% of O} = \frac{\text{mol O} \times \mathcal{M} \text{ of O}}{\text{mass of 1 mol glucose}} \times 100 = \frac{6 \text{ mol O} \times \dfrac{16.00 \text{ g O}}{1 \text{ mol O}}}{180.16 \text{ g}} \times 100$$

$$= 53.29 \text{ mass \% O}$$

Check The answers make sense: the mass % of O is greater than the mass % of C because, even though there are equal numbers of moles of each in the compound, the molar mass of O is greater than the molar mass of C. The mass % of H is small because the molar mass of H is small. The total of the mass percents is 100.00%.

(b) Determining the mass (g) of carbon

Plan To find the mass of C in the glucose sample, we multiply the mass of the sample by the mass fraction of C from part (a).

Solution Finding the mass of C in a given mass of glucose (with units for mass fraction):

$$\text{Mass (g) of C} = \text{mass of glucose} \times \text{mass fraction of C} = 16.55 \text{ g glucose} \times \frac{0.4000 \text{ g C}}{1 \text{ g glucose}}$$

$$= 6.620 \text{ g C}$$

Check Rounding shows that the answer is "in the right ballpark": 16 g times less than 0.5 parts by mass should be less than 8 g.

Comment 1. A *more direct approach* to finding the mass of element in any mass of compound is similar to the approach we used in Sample Problem 2.1 (p. 43) and eliminates the need to calculate the mass fraction. Just multiply the given mass of compound by the ratio of the total mass of element to the mass of 1 mol of compound:

$$\text{Mass (g) of C} = 16.55 \text{ g glucose} \times \frac{72.06 \text{ g C}}{180.16 \text{ g glucose}} = 6.620 \text{ g C}$$

2. From here on, you should be able to determine the molar mass of a compound, so that calculation will no longer be shown.

FOLLOW-UP PROBLEM 3.3 Ammonium nitrate is a common fertilizer. Agronomists base the effectiveness of fertilizers on their nitrogen content.

(a) Calculate the mass percent of N in ammonium nitrate.

(b) How many grams of N are in 35.8 kg of ammonium nitrate?

SECTION SUMMARY

A mole of substance is the amount that contains Avogadro's number (6.022×10^{23}) of chemical entities (atoms, molecules, or formula units). The mass (in grams) of a mole has the same numerical value as the mass (in amu) of the entity. Thus, the mole allows us to count entities by weighing them. Using the molar mass ($\mathcal{M}$, g/mol) of an element (or compound) and Avogadro's number as conversion factors, we can convert among amount (mol), mass (g), and number of entities. The mass fraction of element X in a compound is used to find the mass of X in any amount of the compound.

3.2 DETERMINING THE FORMULA OF AN UNKNOWN COMPOUND

In Sample Problem 3.3, we knew the formula and used it to find the mass percent (or mass fraction) of an element in a compound *and* the mass of the element in a given mass of the compound. In this section, we do the reverse: use the masses of elements in a compound to find its formula. We'll present the mass data in several ways and then look briefly at molecular structures.

Empirical Formulas

An analytical chemist investigating a compound decomposes it into simpler substances, finds the mass of each component element, converts these masses to numbers of moles, and then arithmetically converts the moles to whole-number (integer) subscripts. This procedure yields the empirical formula, the *simplest whole-number ratio* of moles of each element in the compound (see Section 2.8, p. 62). Let's see how to obtain the subscripts from the moles of each element.

Analysis of an unknown compound shows that the sample contains 0.21 mol of zinc, 0.14 mol of phosphorus, and 0.56 mol of oxygen. Because the subscripts in a formula represent individual atoms or moles of atoms, we write a preliminary formula that contains fractional subscripts: $Zn_{0.21}P_{0.14}O_{0.56}$. Next, we convert these fractional subscripts to whole numbers using one or two simple arithmetic steps (rounding when needed):

1. Divide each subscript by the smallest subscript:

$$Zn_{\frac{0.21}{0.14}}P_{\frac{0.14}{0.14}}O_{\frac{0.56}{0.14}} \longrightarrow Zn_{1.5}P_{1.0}O_{4.0}$$

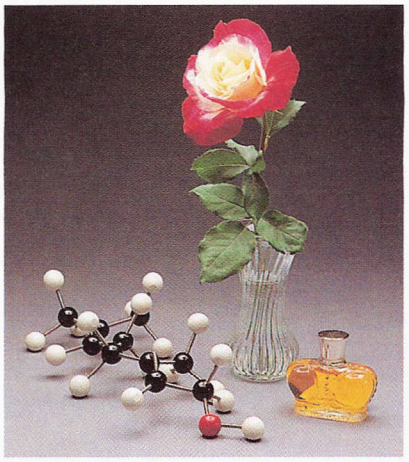
   This step alone often gives integer subscripts.
2. If any of the subscripts is still not an integer, multiply through by the *smallest integer* that will turn all subscripts into integers. Here, we multiply by 2, the smallest integer that will make 1.5 (the subscript for Zn) into an integer:

$$Zn_{(1.5\times2)}P_{(1.0\times2)}O_{(4.0\times2)} \longrightarrow Zn_{3.0}P_{2.0}O_{8.0}, \text{ or } Zn_3P_2O_8$$

   Notice that the *relative* number of moles has not changed because we multiplied *all* the subscripts by 2.

Always check that the subscripts are the smallest set of integers with the same ratio as the original numbers of moles; that is, 3:2:8 is *in the same ratio* as 0.21:0.14:0.56. A more conventional way to write this formula is $Zn_3(PO_4)_2$; the compound is zinc phosphate, a dental cement.

The following three sample problems (3.4, 3.5, and 3.6) demonstrate how other types of compositional data are used to determine chemical formulas. In the first problem, the empirical formula is found from data given as grams of each element rather than as moles.



A Rose by Any Other Name . . . Chemists studying natural substances obtained from animals and plants isolate compounds and determine their formulas. Geraniol ($C_{10}H_{18}O$), the main compound that gives a rose its odor, is used in many perfumes and cosmetics. Geraniol is also in citronella and lemongrass oils and is part of a larger compound in geranium leaves, from which its name is derived.

SAMPLE PROBLEM 3.4 Determining an Empirical Formula from Masses of Elements

Problem Elemental analysis of a sample of an ionic compound showed 2.82 g of Na, 4.35 g of Cl, and 7.83 g of O. What is the empirical formula and name of the compound?

Plan This problem is similar to the one we just discussed, except that we are given element *masses*, so we must convert the masses into integer subscripts. We first divide each mass by the element's molar mass to find *number of moles*. Then we construct a preliminary formula and convert the numbers of moles to integers.

Solution Finding moles of elements:

$$\text{Moles of Na} = 2.82 \text{ g-Na} \times \frac{1 \text{ mol Na}}{22.99 \text{ g-Na}} = 0.123 \text{ mol Na}$$

$$\text{Moles of Cl} = 4.35 \text{ g-Cl} \times \frac{1 \text{ mol Cl}}{35.45 \text{ g-Cl}} = 0.123 \text{ mol Cl}$$

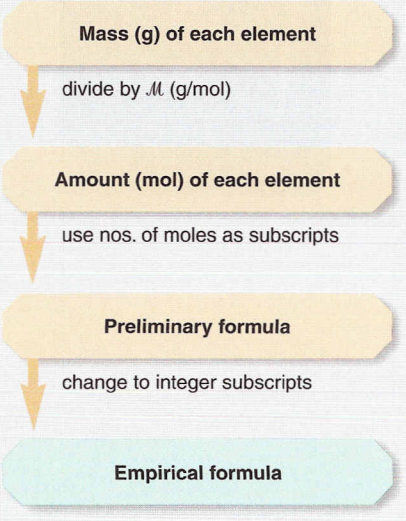
$$\text{Moles of O} = 7.83 \text{ g-O} \times \frac{1 \text{ mol O}}{16.00 \text{ g-O}} = 0.489 \text{ mol O}$$

Constructing a preliminary formula: $Na_{0.123}Cl_{0.123}O_{0.489}$

Converting to integer subscripts (dividing all by the smallest subscript):

$$Na_{\frac{0.123}{0.123}}Cl_{\frac{0.123}{0.123}}O_{\frac{0.489}{0.123}} \longrightarrow Na_{1.00}Cl_{1.00}O_{3.98} \approx Na_1Cl_1O_4, \text{ or } NaClO_4$$

We rounded the subscript of O from 3.98 to 4. The empirical formula is $NaClO_4$; the name is sodium perchlorate.



Check The moles seem correct because the masses of Na and Cl are slightly more than 0.1 of their molar masses. The mass of O is greatest and its molar mass is smallest, so it should have the greatest number of moles. The ratio of subscripts, 1:1:4, is the same as the ratio of moles, 0.123:0.123:0.489 (within rounding).

FOLLOW-UP PROBLEM 3.4 An unknown metal M reacts with sulfur to form a compound with the formula M_2S_3. If 3.12 g of M reacts with 2.88 g of S, what are the names of M and M_2S_3? (*Hint:* Determine the number of moles of S and use the formula to find the number of moles of M.)

Molecular Formulas

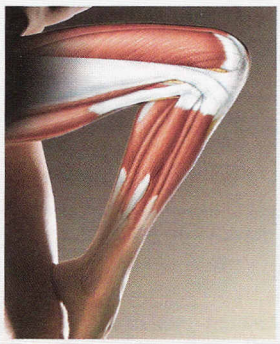
If we know the molar mass of a compound, we can use the empirical formula to obtain the molecular formula, the *actual* number of moles of each element in 1 mol of compound. In some cases, such as water (H_2O), ammonia (NH_3), and methane (CH_4), the empirical and molecular formulas are identical, but in many others the molecular formula is a *whole-number multiple* of the empirical formula. Hydrogen peroxide, for example, has the empirical formula HO and the molecular formula H_2O_2. Dividing the molar mass of H_2O_2 (34.02 g/mol) by the empirical formula mass (17.01 g/mol) gives the whole-number multiple:

$$\text{Whole-number multiple} = \frac{\text{molar mass (g/mol)}}{\text{empirical formula mass (g/mol)}}$$

$$= \frac{34.02\ \cancel{\text{g/mol}}}{17.01\ \cancel{\text{g/mol}}} = 2.000 = 2$$

Instead of giving compositional data in terms of masses of each element, analytical laboratories provide it as mass percents. From this, we determine the empirical formula by (1) assuming 100.0 g of compound, which allows us to express mass percent directly as mass, (2) converting the mass to number of moles, and (3) constructing the empirical formula. With the molar mass, we can also find the whole-number multiple and then the molecular formula.

SAMPLE PROBLEM 3.5 Determining a Molecular Formula from Elemental Analysis and Molar Mass



Problem During physical activity, lactic acid ($\mathcal{M}$ = 90.08 g/mol) forms in muscle tissue and is responsible for muscle soreness. Elemental analysis shows that this compound contains 40.0 mass % C, 6.71 mass % H, and 53.3 mass % O.

(a) Determine the empirical formula of lactic acid.

(b) Determine the molecular formula.

(a) Determining the empirical formula

Plan We know the mass % of each element and must convert each to an integer subscript. The mass of lactic acid is not given but, since mass % is the same for any mass of compound, we assume 100.0 g of lactic acid and express each mass % directly as grams. Then, we convert grams to moles and construct the empirical formula as we did in Sample Problem 3.4.

Solution Expressing mass % as grams, assuming 100.0 g of lactic acid:

$$\text{Mass (g) of C} = \frac{40.0 \text{ parts C by mass}}{100 \text{ parts by mass}} \times 100.0 \text{ g} = 40.0 \text{ g C}$$

Similarly, we have 6.71 g of H and 53.3 g of O.

Converting from grams of each element to moles:

$$\text{Moles of C} = \text{mass of C} \times \frac{1}{\mathcal{M} \text{ of C}} = 40.0\ \cancel{\text{g C}} \times \frac{1 \text{ mol C}}{12.01\ \cancel{\text{g C}}} = 3.33 \text{ mol C}$$

Similarly, we have 6.66 mol of H and 3.33 mol of O.

Constructing the preliminary formula: $C_{3.33}H_{6.66}O_{3.33}$
Converting to integer subscripts:

$$\frac{C_{3.33}}{3.33}\frac{H_{6.66}}{3.33}\frac{O_{3.33}}{3.33} \longrightarrow C_{1.00}H_{2.00}O_{1.00} \approx C_1H_2O_1; \text{ the empirical formula is } CH_2O$$

Check The numbers of moles seem correct: the masses of C and O are each slightly more than 3 times their molar masses (e.g., for C, 40 g/(12 g/mol) > 3 mol), and the mass of H is over 6 times its molar mass.

(b) Determining the molecular formula

Plan The molecular formula subscripts are whole-number multiples of the empirical formula subscripts. To find this whole number, we divide the given molar mass (90.08 g/mol) by the empirical formula mass, which we find from the sum of the elements' molar masses. Then we multiply the whole number by each subscript in the empirical formula.

Solution The empirical-formula molar mass is 30.03 g/mol. Finding the whole-number multiple:

$$\text{Whole-number multiple} = \frac{\mathcal{M} \text{ of lactic acid}}{\mathcal{M} \text{ of empirical formula}} = \frac{90.08 \text{ g/mol}}{30.03 \text{ g/mol}} = 3.000 = 3$$

Determining the molecular formula:

$$C_{(1\times3)}H_{(2\times3)}O_{(1\times3)} = C_3H_6O_3$$

Check The calculated molecular formula has the same ratio of moles of elements (3:6:3) as the empirical formula (1:2:1) and corresponds to the given molar mass:

$$\mathcal{M} \text{ of lactic acid} = (3 \times \mathcal{M} \text{ of C}) + (6 \times \mathcal{M} \text{ of H}) + (3 \times \mathcal{M} \text{ of O})$$
$$= (3 \times 12.01) + (6 \times 1.008) + (3 \times 16.00) = 90.08 \text{ g/mol}$$

FOLLOW-UP PROBLEM 3.5 One of the most widespread environmental carcinogens (cancer-causing agents) is benzo[*a*]pyrene ($\mathcal{M}$ = 252.30 g/mol). It is found in coal dust, in cigarette smoke, and even in charcoal-grilled meat. Analysis of this hydrocarbon shows 95.21 mass % C and 4.79 mass % H. What is the molecular formula of benzo[*a*]pyrene?

Combustion Analysis of Organic Compounds Still another type of compositional data is obtained through **combustion analysis,** a method used to measure the amounts of carbon and hydrogen in a combustible organic compound. The unknown is burned in pure O_2 in an apparatus that consists of a combustion chamber and chambers containing compounds that absorb either H_2O or CO_2 (Figure 3.5). All the H in the compound is converted to H_2O, which is absorbed in the first chamber, and all the C is converted to CO_2, which is absorbed in the second. By weighing the contents of the chambers before and after combustion, we find the masses of CO_2 and H_2O and use them to calculate the masses of C and H in the compound, from which we find the empirical formula. As you've seen, many organic compounds also contain oxygen, nitrogen, or halogen. As long as the third element doesn't interfere with the absorption of CO_2 and H_2O, we calculate its mass by subtracting the masses of C and H from the original mass of the compound.

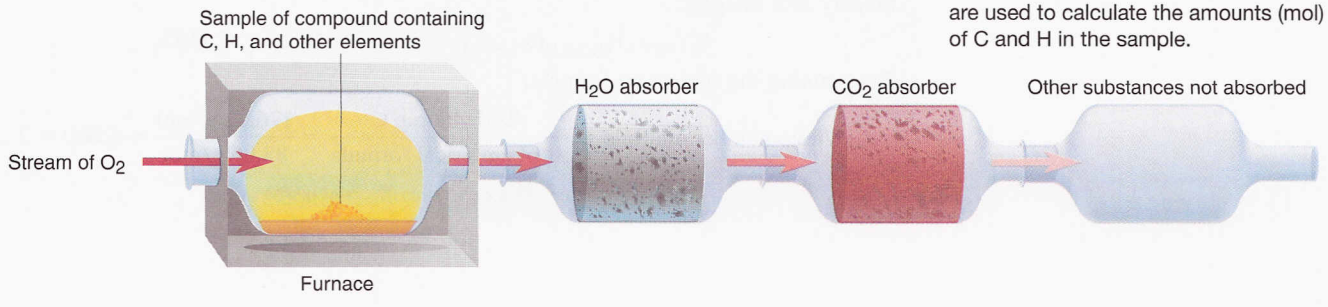


Figure 3.5 Combustion apparatus for determining formulas of organic compounds. A sample of compound that contains C and H (and perhaps other elements) is burned in a stream of O_2 gas. The CO_2 and H_2O formed are absorbed separately, while any other element oxides are carried through by the O_2 gas stream. H_2O is absorbed by $Mg(ClO_4)_2$; CO_2 is absorbed by NaOH on asbestos. The increases in mass of the absorbers are used to calculate the amounts (mol) of C and H in the sample.

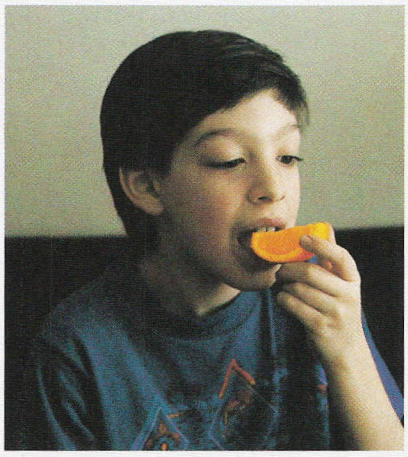


SAMPLE PROBLEM 3.6 Determining a Molecular Formula from Combustion Analysis

Problem Vitamin C ($\mathcal{M}$ = 176.12 g/mol) is a compound of C, H, and O found in many natural sources, especially citrus fruits. When a 1.000-g sample of vitamin C is placed in a combustion chamber and burned, the following data are obtained:

Mass of CO_2 absorber after combustion = 85.35 g
Mass of CO_2 absorber before combustion = 83.85 g
Mass of H_2O absorber after combustion = 37.96 g
Mass of H_2O absorber before combustion = 37.55 g

What is the molecular formula of vitamin C?

Plan We find the masses of CO_2 and H_2O by subtracting the masses of the absorbers before the reaction from the masses after. From the mass of CO_2, we use the mass fraction of C in CO_2 to find the mass of C (see Comment in Sample Problem 3.3). Similarly, we find the mass of H from the mass of H_2O. The mass of vitamin C (1.000 g) minus the sum of the C and H masses gives the mass of O, the third element present. Then, we proceed as in Sample Problem 3.5: calculate numbers of moles using the elements' molar masses, construct the empirical formula, determine the whole-number multiple from the given molar mass, and construct the molecular formula.

Solution Finding the masses of combustion products:

$$\begin{aligned}\text{Mass (g) of } CO_2 &= \text{mass of } CO_2 \text{ absorber after} - \text{mass before}\\ &= 85.35\text{ g} - 83.85\text{ g} = 1.50\text{ g } CO_2\\ \text{Mass (g) of } H_2O &= \text{mass of } H_2O \text{ absorber after} - \text{mass before}\\ &= 37.96\text{ g} - 37.55\text{ g} = 0.41\text{ g } H_2O\end{aligned}$$

Calculating masses of C and H using their mass fractions:

$$\text{Mass of element} = \text{mass of compound} \times \frac{\text{mass of element in compound}}{\text{mass of 1 mol of compound}}$$

$$\text{Mass (g) of C} = \text{mass of } CO_2 \times \frac{1\text{ mol C} \times \mathcal{M}\text{ of C}}{\text{mass of 1 mol } CO_2} = 1.50\text{ g } \cancel{CO_2} \times \frac{12.01\text{ g C}}{44.01\text{ g } \cancel{CO_2}}$$

$$= 0.409\text{ g C}$$

$$\text{Mass (g) of H} = \text{mass of } H_2O \times \frac{2\text{ mol H} \times \mathcal{M}\text{ of H}}{\text{mass of 1 mol } H_2O} = 0.41\text{ g } \cancel{H_2O} \times \frac{2.016\text{ g H}}{18.02\text{ g } \cancel{H_2O}}$$

$$= 0.046\text{ g H}$$

Calculating the mass of O:

$$\begin{aligned}\text{Mass (g) of O} &= \text{mass of vitamin C sample} - (\text{mass of C} + \text{mass of H})\\ &= 1.000\text{ g} - (0.409\text{ g} + 0.046\text{ g}) = 0.545\text{ g O}\end{aligned}$$

Finding the amounts (mol) of elements: Dividing the mass in grams of each element by its molar mass gives 0.0341 mol of C, 0.046 mol of H, and 0.0341 mol of O.

Constructing the preliminary formula: $C_{0.0341}H_{0.046}O_{0.0341}$

Determining the empirical formula: Dividing through by the smallest subscript gives

$$C_{\frac{0.0341}{0.0341}}H_{\frac{0.046}{0.0341}}O_{\frac{0.0341}{0.0341}} = C_{1.00}H_{1.3}O_{1.00}$$

By trial and error, we find that 3 is the smallest integer that will make all subscripts approximately into integers:

$$C_{(1.00\times3)}H_{(1.3\times3)}O_{(1.00\times3)} = C_{3.00}H_{3.9}O_{3.00} \approx C_3H_4O_3$$

Determining the molecular formula:

$$\text{Whole-number multiple} = \frac{\mathcal{M}\text{ of vitamin C}}{\mathcal{M}\text{ of empirical formula}} = \frac{176.12\text{ g/mol}}{88.06\text{ g/mol}} = 2.000 = 2$$

$$C_{(3\times2)}H_{(4\times2)}O_{(3\times2)} = C_6H_8O_6$$

Check The element masses seem correct: carbon makes up slightly more than 0.25 of the mass of CO_2 (12 g/44 g > 0.25), as do the masses in the problem (0.409 g/1.50 g > 0.25). Hydrogen makes up slightly more than 0.10 of the mass of H_2O (2 g/18 g > 0.10), as do the masses in the problem (0.046 g/0.41 g > 0.10). The molecular formula has the same ratio of subscripts (6:8:6) as the empirical formula (3:4:3) and adds up to the given molar mass:

$$(6 \times \mathcal{M} \text{ of C}) + (8 \times \mathcal{M} \text{ of H}) + (6 \times \mathcal{M} \text{ of O}) = \mathcal{M} \text{ of vitamin C}$$
$$(6 \times 12.01) + (8 \times 1.008) + (6 \times 16.00) = 176.12 \text{ g/mol}$$

Comment In determining the subscript for H, if we string the calculation steps together, we obtain the subscript 4.0, rather than 3.9, and don't need to round:

$$\text{Subscript of H} = 0.41 \text{ g } H_2O \times \frac{2.016 \text{ g H}}{18.02 \text{ g } H_2O} \times \frac{1 \text{ mol H}}{1.008 \text{ g H}} \times \frac{1}{0.0341 \text{ mol}} \times 3 = 4.0$$

FOLLOW-UP PROBLEM 3.6 A dry-cleaning solvent ($\mathcal{M}$ = 146.99 g/mol) that contains C, H, and Cl is suspected to be a cancer-causing agent. When a 0.250-g sample was studied by combustion analysis, 0.451 g of CO_2 and 0.0617 g of H_2O formed. Find the molecular formula.

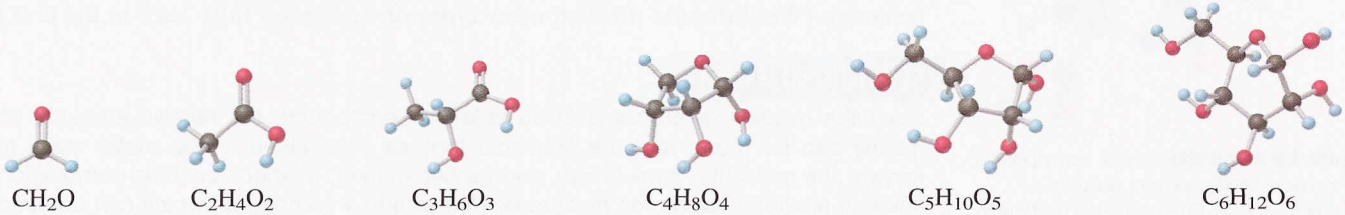
Chemical Formulas and Molecular Structures

Let's take a short break from calculations to recall that *a formula represents a real three-dimensional object*. How much structural information is contained in the different types of chemical formulas?

1. *Different compounds with the same empirical formula.* The empirical formula tells the *relative* number of each type of atom, but it tells nothing about molecular structure. In fact, *different compounds can have the* ***same*** *empirical formula*. The oxides NO_2 and N_2O_4 are examples among inorganic compounds, but this phenomenon is especially common among organic compounds. While there is no stable hydrocarbon with the formula CH_2, compounds with the general formula C_nH_{2n} are well known, such as ethylene (C_2H_4) and propylene (C_3H_6), starting material for two very common plastics. Table 3.3 shows a few biologically important compounds with a given empirical formula.

Table 3.3 Some Compounds with Empirical Formula CH_2O (Composition by Mass: 40.0% C, 6.71% H, 53.3% O)

Name	Molecular Formula	Whole-Number Multiple	$\mathcal{M}$ (g/mol)	Use or Function
Formaldehyde	CH_2O	1	30.03	Disinfectant; biological preservative
Acetic acid	$C_2H_4O_2$	2	60.05	Acetate polymers; vinegar (5% solution)
Lactic acid	$C_3H_6O_3$	3	90.08	Causes milk to sour; forms in muscle during exercise
Erythrose	$C_4H_8O_4$	4	120.10	Forms during sugar metabolism
Ribose	$C_5H_{10}O_5$	5	150.13	Component of many nucleic acids and vitamin B_2
Glucose	$C_6H_{12}O_6$	6	180.16	Major nutrient for energy in cells



CH_2O $C_2H_4O_2$ $C_3H_6O_3$ $C_4H_8O_4$ $C_5H_{10}O_5$ $C_6H_{12}O_6$

2. *Isomers: different compounds with the same molecular formula.* A molecular formula tells the *actual* number of each type of atom, providing as much information as possible from mass analysis. Yet *different compounds can have the* ***same*** *molecular formula* because the atoms can bond to each other in different arrangements to give more than one *structural formula.* **Isomers** are compounds with the same molecular formula but different properties. The simplest type of isomerism, called *constitutional,* or *structural, isomerism,* occurs when the atoms link together in different arrangements. Table 3.4 shows two pairs of examples.

Table 3.4 Two Pairs of Constitutional Isomers

	C_4H_{10}		C_2H_6O	
Property	**Butane**	**2-Methylpropane**	**Ethanol**	**Dimethyl Ether**
$\mathcal{M}$ (g/mol)	58.12	58.12	46.07	46.07
Boiling point	−0.5°C	−11.6°C	78.5°C	−25°C
Density (at 20°C)	0.579 g/mL (gas)	0.549 g/mL (gas)	0.789 g/mL (liquid)	0.00195 g/mL (gas)
Structural formula				Space-filling model				
The left pair is two compounds with the molecular formula C_4H_{10}, butane and 2-methylpropane. One has a four-C chain, and the other has a one-C branch attached to the second C of a three-C chain. Both are small alkanes, so their properties are similar, if not identical. The right pair of constitutional isomers share the molecular formula C_2H_6O but have very different properties because they are different types of compounds—one is an alcohol, and the other is an ether.

As the number and kinds of atoms increase, the number of isomers—that is, the number of structural formulas that can be written for a given molecular formula—also increases: C_2H_6O has two structural formulas, as you've seen, C_3H_8O three, and $C_4H_{10}O$, seven. Imagine how many there are for $C_{16}H_{19}N_3O_4S$! Of all the possible isomers with this formula, only one is the antibiotic ampicillin (Figure 3.6). Only by knowing a molecule's structure—the relative placement of atoms and the distances and angles separating them—can we begin to predict its behavior. (We'll discuss this and other types of isomerism fully later in the text.)

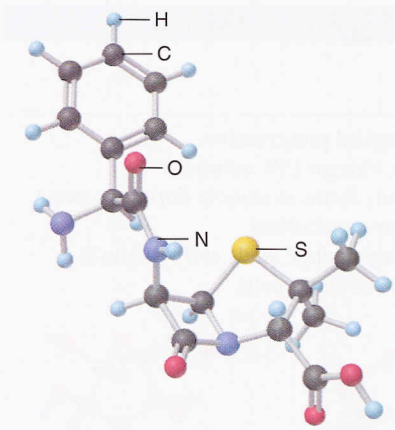

Figure 3.6 Ampicillin. Of the many possible constitutional isomers with the formula $C_{16}H_{19}N_3O_4S$, only this particular arrangement of the atoms is the widely used antibiotic ampicillin.

SECTION SUMMARY

From the masses of elements in an unknown compound, the relative amounts (in moles) can be found and the empirical formula determined. If the molar mass is known, the molecular formula can also be determined. Methods such as combustion analysis provide data on the masses of elements in a compound, which can be used to obtain the formula. Because atoms can bond in different arrangements, more than one compound may have the same molecular formula (constitutional isomers).

3.3 WRITING AND BALANCING CHEMICAL EQUATIONS

Perhaps the most important reason for thinking in terms of moles is because it greatly clarifies the amounts of substances taking part in a reaction. Comparing masses doesn't tell the ratio of substances reacting but comparing numbers of moles does. It allows us to view substances as large populations of interacting particles rather than as grams of material. To clarify this idea, consider the formation of hydrogen fluoride gas from H_2 and F_2, a reaction that occurs explosively at room temperature. If we weigh the gases, we find that

2.016 g of H_2 and 38.00 g of F_2 react to form 40.02 g of HF

This information tells us little except that mass is conserved. However, if we convert these masses (in grams) to amounts (in moles), we find that

1 mol of H_2 and 1 mol of F_2 react to form 2 mol of HF

This information reveals that equal-size populations of H_2 and F_2 molecules combine to form twice as large a population of HF molecules. Dividing through by Avogadro's number shows us the chemical event that occurs between individual molecules:

1 H_2 molecule and 1 F_2 molecule react to form 2 HF molecules

Figure 3.7 shows that when we express the reaction in terms of moles, *the macroscopic (molar) change corresponds to the submicroscopic (molecular) change*. As you'll see, a balanced chemical equation shows both changes.

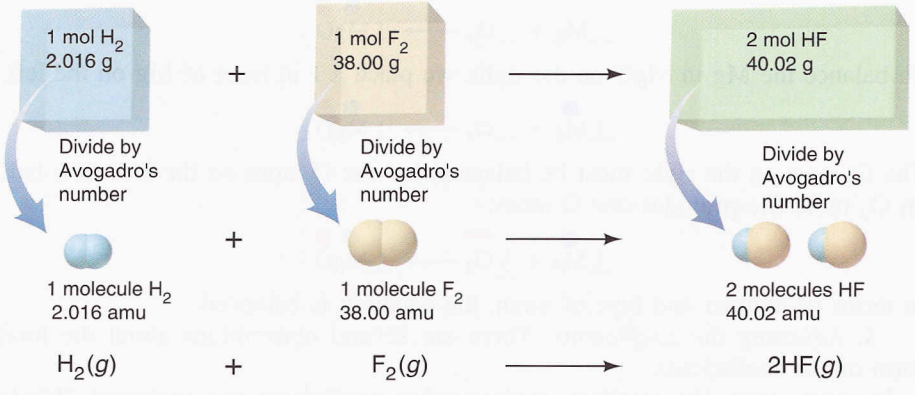

Figure 3.7 The formation of HF gas on the macroscopic and molecular levels. When 1 mol of H_2 (2.016 g) and 1 mol of F_2 (38.00 g) react, 2 mol of HF (40.02 g) forms. Dividing by Avogadro's number shows the change at the molecular level.

A **chemical equation** is a statement in formulas that expresses the identities and quantities of the substances involved in a chemical or physical change. Equations are the "sentences" of chemistry, just as chemical formulas are the "words" and atomic symbols the "letters." The left side of an equation shows the amount of each substance present before the change, and the right side shows the amounts present afterward. *For an equation to depict these amounts accurately, it must be balanced; that is, the same number of each type of atom must appear on both sides of the equation.* This requirement follows directly from the mass laws and the atomic theory:

- In a chemical process, atoms cannot be created, destroyed, or changed, only rearranged into different combinations.
- A formula represents a fixed ratio of the elements in a compound, so a different ratio represents a different compound.

Consider the chemical change that occurs in an old-fashioned photographic flashbulb: magnesium wire and oxygen gas yield powdery magnesium oxide. (Light and heat are produced as well, but here we're concerned only with the substances involved.) Let's convert this chemical statement into a balanced equation through the following steps:

1. *Translating the statement.* We first translate the chemical statement into a "skeleton" equation: chemical formulas arranged in an equation format. All the substances that react during the change, called **reactants,** are placed to the left of a "yield" arrow, which points to all the substances produced, called **products:**

reactants yield product

$$_\text{Mg} + _\text{O}_2 \longrightarrow _\text{MgO}$$

magnesium and oxygen yield magnesium oxide

At the beginning of the balancing process, we put a blank in front of each substance to remind us that we have to account for its atoms.

2. *Balancing the atoms.* The next step involves shifting our attention back and forth from right to left in order to *match the number of each type of atom on each side.* At the end of this step, each blank will contain a **balancing (stoichiometric) coefficient,** a numerical multiplier of *all the atoms* in the formula that follows it. In general, balancing is easiest when we

- Start with the most complex substance, the one with the largest number of atoms or different types of atoms.
- End with the least complex substance, such as an element by itself.

In this case, MgO is the most complex, so we place a coefficient 1 *in front of* the compound:

$$_\text{Mg} + _\text{O}_2 \longrightarrow \underline{1}\,\text{MgO}$$

To balance the Mg in MgO on the right, we place a 1 in front of Mg on the left:

$$\underline{1}\,\text{Mg} + _\text{O}_2 \longrightarrow \underline{1}\,\text{MgO}$$

The O atom on the right must be balanced by one O atom on the left. One-half an O_2 molecule provides one O atom:

$$\underline{1}\,\text{Mg} + \underline{\tfrac{1}{2}}\,\text{O}_2 \longrightarrow \underline{1}\,\text{MgO}$$

In terms of number and type of atom, the equation is balanced.

3. *Adjusting the coefficients.* There are several conventions about the final form of the coefficients:

- In most cases, *the smallest whole-number coefficients are preferred.* Whole numbers allow entities such as O_2 molecules to be treated as intact particles. One-half of an O_2 molecule cannot exist, so we multiply the equation by 2:

$$2\text{Mg} + 1\text{O}_2 \longrightarrow 2\text{MgO}$$

- We used the coefficient 1 to remind us to balance each substance. In the final form, a coefficient of 1 is implied just by the presence of the formula of the substance, so we don't need to write it:

$$2\text{Mg} + \text{O}_2 \longrightarrow 2\text{MgO}$$

(This convention is similar to that of not writing a subscript 1 in a formula.)

4. *Checking.* After balancing and adjusting the coefficients, always check that the equation is balanced:

Reactants (2 Mg, 2 O) $\longrightarrow$ products (2 Mg, 2 O)

5. *Specifying the states of matter.* The final equation also indicates the physical state of each substance or whether it is dissolved in water. The abbreviations that are used for these states are solid (*s*), liquid (*l*), gas (*g*), and aqueous solution (*aq*). From the original statement, we know that the Mg "wire" is solid, the O_2 is a gas, and the "powdery" MgO is also solid. The balanced equation, therefore, is

$$2Mg(s) + O_2(g) \longrightarrow 2MgO(s)$$

Of course, the key point to realize is, as was pointed out in Figure 3.7, *the balancing coefficients refer to both individual chemical entities and moles of chemical entities*. Thus, 2 mol of Mg and 1 mol of O_2 yield 2 mol of MgO. Figure 3.8 shows this reaction from three points of view—as you see it on the macroscopic level, as chemists (and you!) can imagine it on the atomic level (darker colored atoms represent the stoichiometry), and on the symbolic level of the chemical equation.

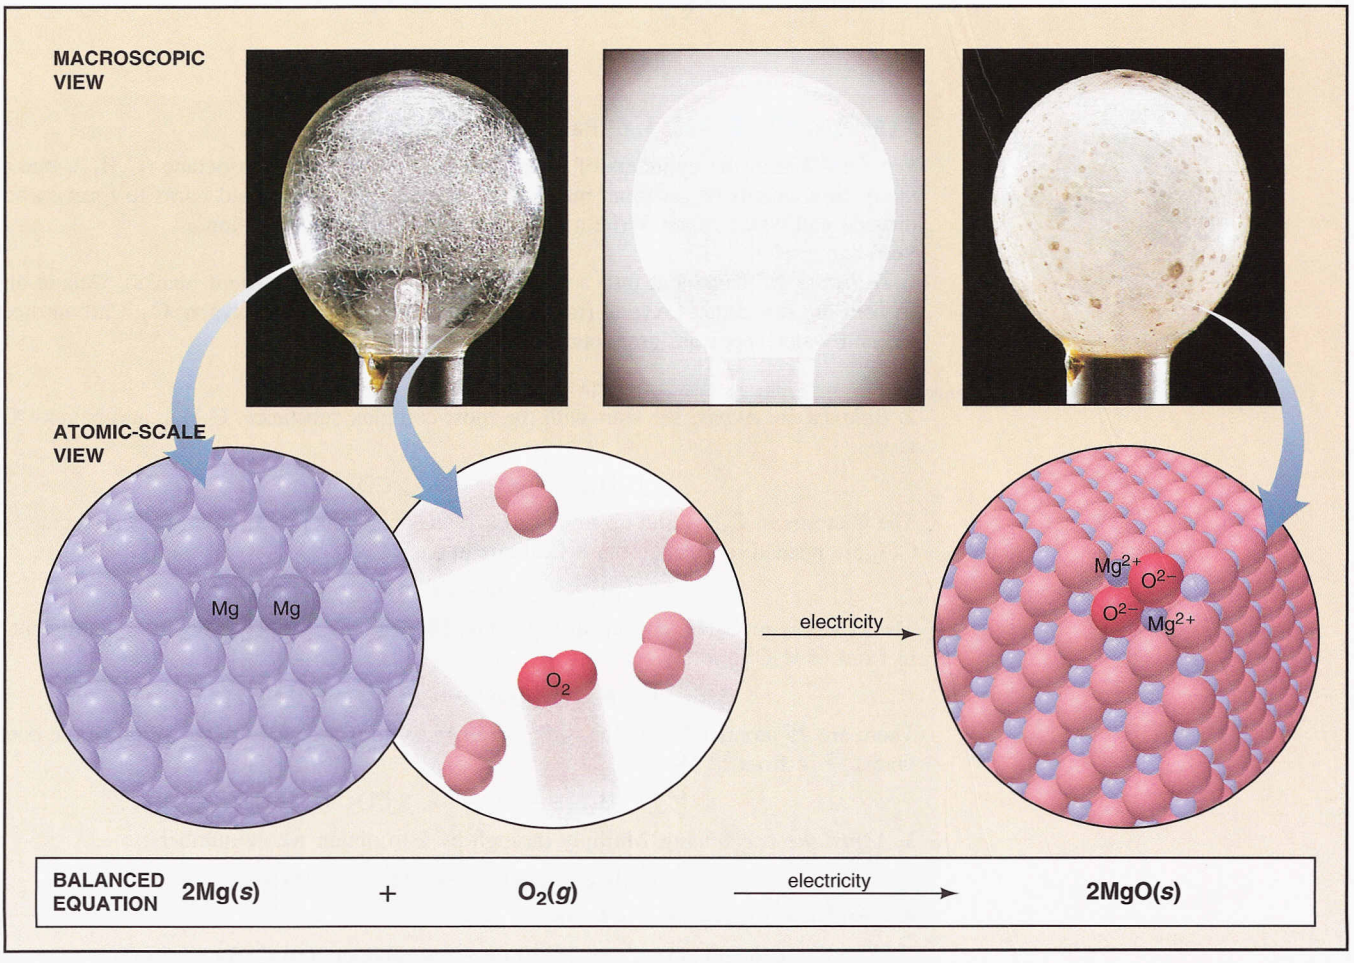

Figure 3.8 A three-level view of the chemical reaction in a flashbulb. The photos present the macroscopic view that you see. Before the reaction occurs, a fine magnesium filament is surrounded by oxygen (*left*). After the reaction, white, powdery magnesium oxide coats the bulb's inner surface (*right*). The blow-up arrows lead to an atomic-scale view, a representation of the chemist's mental picture of the reaction. The darker colored spheres show the stoichiometry. By knowing the substances before and after a reaction, we can write a balanced equation (*bottom*), the chemist's symbolic shorthand for the change.

Keep in mind these other key points about the balancing process:

- A coefficient operates on *all the atoms in the formula* that follows it: 2MgO means 2 × (MgO), or 2 Mg atoms and 2 O atoms; $2Ca(NO_3)_2$ means 2 × $[Ca(NO_3)_2]$, or 2 Ca atoms, 4 N atoms, and 12 O atoms.
- In balancing an equation, *chemical formulas cannot be altered.* In step 2 of the example, we *cannot* balance the O atoms by changing MgO to MgO_2 because MgO_2 has a different elemental composition and thus is a different compound.
- We *cannot add other reactants or products* to balance the equation because this would represent a different chemical reaction. For example, we *cannot* balance the O atoms by changing O_2 to O or by adding one O atom to the products, because the chemical statement does not say that the reaction involves O atoms.
- A balanced equation remains balanced even if you multiply all the coefficients by the same number. For example,

$$4Mg(s) + 2O_2(g) \longrightarrow 4MgO(s)$$

is also balanced: it is just the balanced equation we obtained above multiplied by 2. However, we balance an equation with the *smallest* whole-number coefficients.

SAMPLE PROBLEM 3.7 Balancing Chemical Equations

Problem Within the cylinders of a car's engine, the hydrocarbon octane (C_8H_{18}), one of many components of gasoline, mixes with oxygen from the air and burns to form carbon dioxide and water vapor. Write a balanced equation for this reaction.

Solution

1. *Translate* the statement into a skeleton equation (with coefficient blanks). Octane and oxygen are reactants; "oxygen from the air" implies molecular oxygen, O_2. Carbon dioxide and water vapor are products:

$$_C_8H_{18} + _O_2 \longrightarrow _CO_2 + _H_2O$$

2. *Balance the atoms.* We start with the most complex substance, C_8H_{18}, and balance O_2 last:

$$\underline{1}\,C_8H_{18} + _O_2 \longrightarrow _CO_2 + _H_2O$$

The C atoms in C_8H_{18} end up in CO_2. Each CO_2 contains one C atom, so 8 molecules of CO_2 are needed to balance the 8 C atoms in each C_8H_{18}:

$$\underline{1}\,C_8H_{18} + _O_2 \longrightarrow \underline{8}\,CO_2 + _H_2O$$

The H atoms in C_8H_{18} end up in H_2O. The 18 H atoms in C_8H_{18} require a coefficient 9 in front of H_2O:

$$\underline{1}\,C_8H_{18} + _O_2 \longrightarrow \underline{8}\,CO_2 + \underline{9}\,H_2O$$

There are 25 atoms of O on the right (16 in $8CO_2$ plus 9 in $9H_2O$), so we place the coefficient $\frac{25}{2}$ in front of O_2:

$$\underline{1}\,C_8H_{18} + \underline{\tfrac{25}{2}}\,O_2 \longrightarrow \underline{8}\,CO_2 + \underline{9}\,H_2O$$

3. *Adjust the coefficients.* Multiply through by 2 to obtain whole numbers:

$$2C_8H_{18} + 25O_2 \longrightarrow 16CO_2 + 18H_2O$$

4. *Check* that the equation is balanced:

Reactants (16 C, 36 H, 50 O) ⟶ products (16 C, 36 H, 50 O)

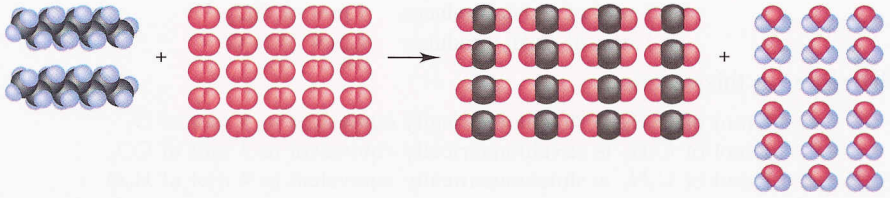
5. *Specify* states of matter. C_8H_{18} is liquid; O_2, CO_2, and H_2O vapor are gases:

$$2C_8H_{18}(l) + 25O_2(g) \longrightarrow 16CO_2(g) + 18H_2O(g)$$

Comment This is an example of a combustion reaction. *Any* compound containing C and H that burns in an excess of air produces CO_2 and H_2O.

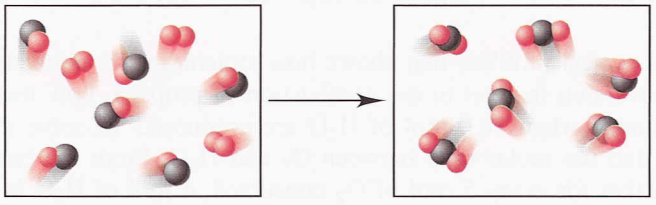
FOLLOW-UP PROBLEM 3.7 Write a balanced equation for each chemical statement:
(a) A characteristic reaction of Group 1A(1) elements: chunks of sodium react violently with water to form hydrogen gas and sodium hydroxide solution.
(b) The destruction of marble statuary by acid rain: aqueous nitric acid reacts with calcium carbonate to form carbon dioxide, water, and aqueous calcium nitrate.
(c) Halogen compounds exchanging bonding partners: phosphorus trifluoride is prepared by the reaction of phosphorus trichloride and hydrogen fluoride; hydrogen chloride is the other product. The reaction involves gases only.
(d) Explosive decomposition of dynamite: liquid nitroglycerine ($C_3H_5N_3O_9$) explodes to produce a mixture of gases—carbon dioxide, water vapor, nitrogen, and oxygen.

Viewing an equation in a schematic molecular scene is a great way to focus on the essence of the change—the rearrangement of the atoms from reactants to products. Here's a simple schematic for the combustion of octane:



$$2C_8H_{18}(l) + 25O_2(g) \longrightarrow 16CO_2(g) + 18H_2O(g)$$

We can also derive a balanced equation from a molecular scene. Let's do this for the following change (black = carbon, red = oxygen):



We can see from the colors that the reactant box includes carbon monoxide (CO) and oxygen (O_2) molecules, and the product box contains carbon dioxide (CO_2). Once we identify the substances with formulas, we count the number of each kind of molecule and put the numbers and formulas in equation format. There are six CO, three O_2, and six CO_2, that is, twice as many CO as O_2 and the same number as CO_2. So, given that they are all gases, we adjust the coefficients and have

$$2CO(g) + O_2(g) \longrightarrow 2CO_2(g)$$

SECTION SUMMARY

To conserve mass and maintain the fixed composition of compounds, a chemical equation must be balanced in terms of number and type of each atom. A balanced equation has reactant formulas on the left of a yield arrow and product formulas on the right. Balancing coefficients are integer multipliers for *all* the atoms in a formula and apply to the individual entity or to moles of entities.

3.4 CALCULATING AMOUNTS OF REACTANT AND PRODUCT

A balanced equation contains a wealth of quantitative information relating individual chemical entities, amounts of chemical entities, and masses of substances. A balanced equation is essential for all calculations involving amounts of reactants and products: *if you know the number of moles of one substance, the balanced equation tells you the number of moles of all the others in the reaction.*

Stoichiometrically Equivalent Molar Ratios from the Balanced Equation

In a balanced equation, *the number of moles of one substance is stoichiometrically equivalent to the number of moles of any other substance*. The term *stoichiometrically equivalent* means that a definite amount of one substance is formed from, produces, or reacts with a definite amount of the other. These quantitative relationships are expressed as *stoichiometrically equivalent molar ratios* that we use as conversion factors to calculate these amounts. Table 3.5 presents the quantitative information contained in the equation for the combustion of propane, a hydrocarbon fuel used in cooking and water heating:

$$C_3H_8(g) + 5O_2(g) \longrightarrow 3CO_2(g) + 4H_2O(g)$$

If we view the reaction quantitatively in terms of C_3H_8, we see that

1 mol of C_3H_8 reacts with 5 mol of O_2
1 mol of C_3H_8 produces 3 mol of CO_2
1 mol of C_3H_8 produces 4 mol of H_2O

Therefore, in this reaction,

1 mol of C_3H_8 is stoichiometrically equivalent to 5 mol of O_2
1 mol of C_3H_8 is stoichiometrically equivalent to 3 mol of CO_2
1 mol of C_3H_8 is stoichiometrically equivalent to 4 mol of H_2O

We chose to look at C_3H_8, but any two of the substances are stoichiometrically equivalent to each other. Thus,

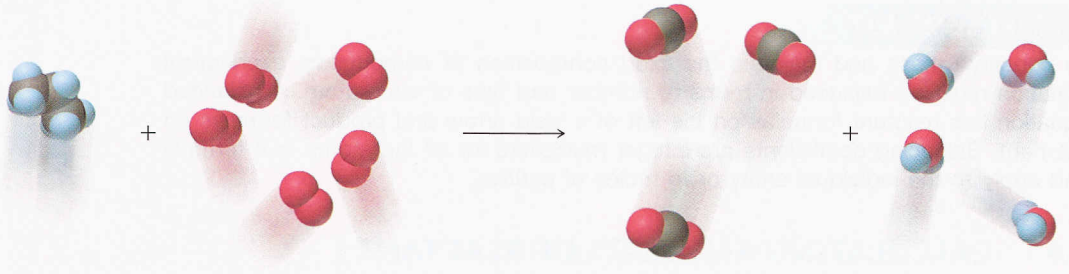
3 mol of CO_2 is stoichiometrically equivalent to 4 mol of H_2O
5 mol of O_2 is stoichiometrically equivalent to 3 mol of CO_2

and so on.

Here's a typical problem that shows how stoichiometric equivalence is used to create conversion factors: in the combustion of propane, how many moles of O_2 are consumed when 10.0 mol of H_2O are produced? To solve this problem, we have to find the molar ratio between O_2 and H_2O. From the balanced equation, we see that for every 5 mol of O_2 consumed, 4 mol of H_2O is formed:

5 mol of O_2 is stoichiometrically equivalent to 4 mol of H_2O

Table 3.5 Information Contained in a Balanced Equation

Viewed in Terms of	Reactants $C_3H_8(g) + 5O_2(g)$		Products $3CO_2(g) + 4H_2O(g)$
Molecules	1 molecule C_3H_8 + 5 molecules O_2	⟶	3 molecules CO_2 + 4 molecules H_2O
			


Amount (mol)	1 mol C_3H_8 + 5 mol O_2	⟶	3 mol CO_2 + 4 mol H_2O
Mass (amu)	44.09 amu C_3H_8 + 160.00 amu O_2	⟶	132.03 amu CO_2 + 72.06 amu H_2O
Mass (g)	44.09 g C_3H_8 + 160.00 g O_2	⟶	132.03 g CO_2 + 72.06 g H_2O
Total mass (g)	204.09 g	⟶	204.09 g

We can construct two conversion factors from this equivalence, depending on the quantity we want to find:

$$\frac{5 \text{ mol } O_2}{4 \text{ mol } H_2O} \quad \text{or} \quad \frac{4 \text{ mol } H_2O}{5 \text{ mol } O_2}$$

Since we want to find moles of O_2 and we know moles of H_2O, we choose "5 mol O_2/4 mol H_2O" to cancel "mol H_2O":

$$\text{Moles of } O_2 \text{ consumed} = 10.0 \text{ mol } \cancel{H_2O} \times \frac{5 \text{ mol } O_2}{4 \text{ mol } \cancel{H_2O}} = 12.5 \text{ mol } O_2$$

mol H_2O $\xrightarrow[\text{conversion factor}]{\text{molar ratio as}}$ mol O_2

Obviously, we could not have solved this problem without the balanced equation. Here is a general approach for solving *any* stoichiometry problem that involves a chemical reaction:

1. Write a balanced equation for the reaction.
2. Convert the given mass (or number of entities) of the first substance to amount (mol).
3. Use the appropriate molar ratio from the balanced equation to calculate the amount (mol) of the second substance.
4. Convert the amount of the second substance to the desired mass (or number of entities).

This approach is shown in Figure 3.9 and demonstrated in the following sample problem.

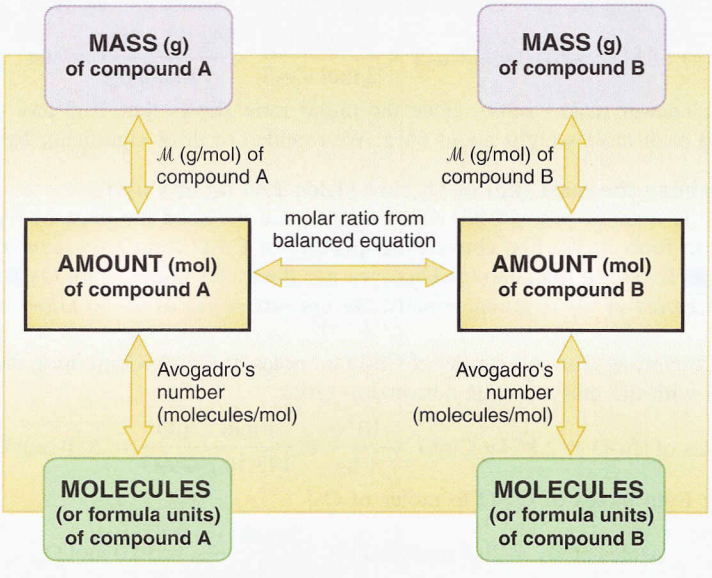


Figure 3.9 Summary of the mass-mole-number relationships in a chemical reaction. The amount of one substance in a reaction is related to that of any other. Quantities are expressed in terms of grams, moles, or number of entities (atoms, molecules, or formula units). Start at any box in the diagram (known) and move to any other box (unknown) by using the information on the arrows as conversion factors. As an example, if you know the mass (in g) of A and want to know the number of molecules of B, the path involves three calculation steps:
1. Grams of A to moles of A, using the molar mass ($\mathcal{M}$) of A
2. Moles of A to moles of B, using the molar ratio from the balanced equation
3. Moles of B to molecules of B, using Avogadro's number

Steps 1 and 3 refer to calculations discussed in Section 3.1 (see Figure 3.4).

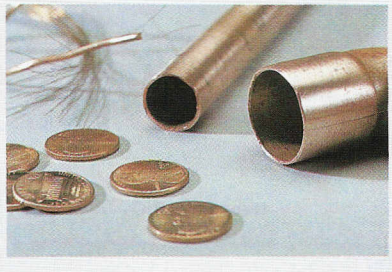
SAMPLE PROBLEM 3.8 Calculating Amounts of Reactants and Products

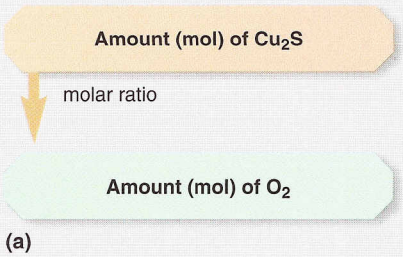
Problem In a lifetime, the average American uses 1750 lb (794 kg) of copper in coins, plumbing, and wiring. Copper is obtained from sulfide ores, such as chalcocite, or copper(I) sulfide, by a multistep process. After an initial grinding, the first step is to "roast" the ore (heat it strongly with oxygen gas) to form powdered copper(I) oxide and gaseous sulfur dioxide.

(a) How many moles of oxygen are required to roast 10.0 mol of copper(I) sulfide?

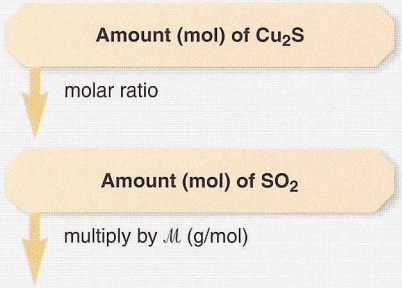
(b) How many grams of sulfur dioxide are formed when 10.0 mol of copper(I) sulfide is roasted?

(c) How many kilograms of oxygen are required to form 2.86 kg of copper(I) oxide?

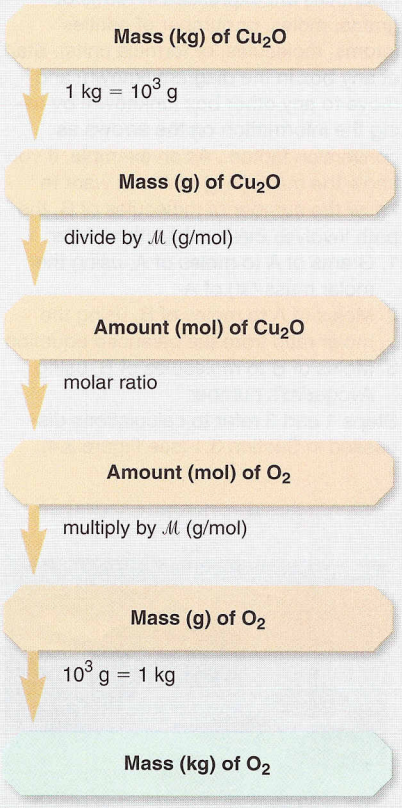




(a)



(b)



(c)

(a) Determining the moles of O_2 needed to roast 10.0 mol of Cu_2S

Plan We *always* write the balanced equation first. The formulas of the reactants are Cu_2S and O_2, and the formulas of the products are Cu_2O and SO_2:

$$2Cu_2S(s) + 3O_2(g) \longrightarrow 2Cu_2O(s) + 2SO_2(g)$$

We are given the *moles* of Cu_2S and need to find the *moles* of O_2. The balanced equation shows that 3 mol of O_2 is needed for every 2 mol of Cu_2S consumed, so the conversion factor is "3 mol O_2/2 mol Cu_2S" (see roadmap a).

Solution Calculating number of moles of O_2:

$$\text{Moles of } O_2 = 10.0 \text{ mol } Cu_2S \times \frac{3 \text{ mol } O_2}{2 \text{ mol } Cu_2S} = 15.0 \text{ mol } O_2$$

Check The units are correct, and the answer is reasonable because this O_2/Cu_2S molar ratio (15:10) is equivalent to the ratio in the balanced equation (3:2).

Comment A *common mistake* is to use the incorrect conversion factor; the calculation would then be

$$\text{Moles of } O_2 = 10.0 \text{ mol } Cu_2S \times \frac{2 \text{ mol } Cu_2S}{3 \text{ mol } O_2} = \frac{6.67 \text{ mol}^2 Cu_2S}{1 \text{ mol } O_2}$$

Such strange units should signal that you made an error in setting up the conversion factor. In addition, the answer, 6.67, is *less* than 10.0, whereas the balanced equation shows that *more* moles of O_2 than of Cu_2S are needed. Be sure to think through the calculation when setting up the conversion factor and canceling units.

(b) Determining the mass (g) of SO_2 formed from 10.0 mol of Cu_2S

Plan Here we need the *grams* of product (SO_2) that form from the given *moles* of reactant (Cu_2S). We first find the moles of SO_2 using the molar ratio from the balanced equation (2 mol SO_2/2 mol Cu_2S) and then multiply by its molar mass (64.07 g/mol) to find grams of SO_2. The steps appear in roadmap b.

Solution Combining the two conversion steps into one calculation, we have

$$\text{Mass (g) of } SO_2 = 10.0 \text{ mol } Cu_2S \times \frac{2 \text{ mol } SO_2}{2 \text{ mol } Cu_2S} \times \frac{64.07 \text{ g } SO_2}{1 \text{ mol } SO_2} = 641 \text{ g } SO_2$$

Check The answer makes sense, since the molar ratio shows that 10.0 mol of SO_2 are formed and each mole weighs about 64 g. We rounded to three significant figures.

(c) Determining the mass (kg) of O_2 that yields 2.86 kg of Cu_2O

Plan Here the mass of product (Cu_2O) is known, and we need the mass of reactant (O_2) that reacts to form it. We first convert the quantity of Cu_2O from *kilograms* to *moles* (in two steps, as shown in roadmap c). Then, we use the molar ratio (3 mol O_2/2 mol Cu_2O) to find the *moles* of O_2 required. Finally, we convert *moles* of O_2 to *kilograms* (in two steps).

Solution Converting from kilograms of Cu_2O to moles of Cu_2O: Combining the mass unit conversion with the mass-to-mole conversion gives

$$\text{Moles of } Cu_2O = 2.86 \text{ kg } Cu_2O \times \frac{10^3 \text{ g}}{1 \text{ kg}} \times \frac{1 \text{ mol } Cu_2O}{143.10 \text{ g } Cu_2O} = 20.0 \text{ mol } Cu_2O$$

Converting from moles of Cu_2O to moles of O_2:

$$\text{Moles of } O_2 = 20.0 \text{ mol } Cu_2O \times \frac{3 \text{ mol } O_2}{2 \text{ mol } Cu_2O} = 30.0 \text{ mol } O_2$$

Converting from moles of O_2 to kilograms of O_2: Combining the mole-to-mass conversion with the mass unit conversion gives

$$\text{Mass (kg) of } O_2 = 30.0 \text{ mol } O_2 \times \frac{32.00 \text{ g } O_2}{1 \text{ mol } O_2} \times \frac{1 \text{ kg}}{10^3 \text{ g}} = 0.960 \text{ kg } O_2$$

Check The units are correct. Round off to check the math: for example, in the final step, ~30 mol × 30 g/mol × 1 kg/10^3 g = 0.90 kg. The answer seems reasonable: even though the amount (mol) of O_2 is greater than the amount (mol) of Cu_2O, the mass of O_2 is less than the mass of Cu_2O because $\mathcal{M}$ of O_2 is less than $\mathcal{M}$ of Cu_2O.

Comment This problem highlights a key point for solving stoichiometry problems: *convert the information given into moles*. Then, use the appropriate molar ratio and any other conversion factors to complete the solution.

FOLLOW-UP PROBLEM 3.8 Thermite is a mixture of iron(III) oxide and aluminum powders that was once used to weld railroad tracks. It undergoes a spectacular reaction to yield solid aluminum oxide and molten iron.
(a) How many grams of iron form when 135 g of aluminum reacts?
(b) How many atoms of aluminum react for every 1.00 g of aluminum oxide formed?

Chemical Reactions That Occur in a Sequence

In many situations, a product of one reaction becomes a reactant for the next reaction in a sequence of reactions. For stoichiometric purposes, when the same substance forms in one reaction and is used up in the next, we eliminate this common substance in an **overall (net) equation:**

1. Write the sequence of balanced equations.
2. Adjust the equations arithmetically to cancel out the common substance.
3. Add the adjusted equations together to obtain the overall balanced equation.

Sample Problem 3.9 shows the approach by continuing with the copper recovery process that was begun in Sample Problem 3.8.

SAMPLE PROBLEM 3.9 Writing an Overall Equation for a Reaction Sequence

Problem Roasting is the first step in extracting copper from chalcocite (Sample Problem 3.8). In the next step, copper(I) oxide reacts with powdered carbon to yield copper metal and carbon monoxide gas. Write a balanced overall equation for the two-step sequence.
Plan To obtain the overall equation, we write the individual equations in sequence, adjust coefficients to cancel the common substance (or substances), and add the equations together. In this case, only Cu_2O appears as a product in one equation and as a reactant in the other, so it is the common substance.
Solution Writing the individual balanced equations:

$$2Cu_2S(s) + 3O_2(g) \longrightarrow 2Cu_2O(s) + 2SO_2(g) \quad \text{[equation 1; see Sample Problem 3.8(a)]}$$
$$Cu_2O(s) + C(s) \longrightarrow 2Cu(s) + CO(g) \quad \text{[equation 2]}$$

Adjusting the coefficients: Since 2 mol of Cu_2O is produced in equation 1 but only 1 mol of Cu_2O reacts in equation 2, we double *all* the coefficients in equation 2. Thus, the amount of Cu_2O formed in equation 1 is used up in equation 2:

$$2Cu_2S(s) + 3O_2(g) \longrightarrow 2Cu_2O(s) + 2SO_2(g) \quad \text{[equation 1]}$$
$$2Cu_2O(s) + 2C(s) \longrightarrow 4Cu(s) + 2CO(g) \quad \text{[equation 2, doubled]}$$

Adding the two equations and canceling the common substance: We keep the reactants of both equations on the left and the products of both equations on the right:

$$2Cu_2S(s) + 3O_2(g) + \cancel{2Cu_2O(s)} + 2C(s) \longrightarrow \cancel{2Cu_2O(s)} + 2SO_2(g) + 4Cu(s) + 2CO(g)$$

Or,
$$2Cu_2S(s) + 3O_2(g) + 2C(s) \longrightarrow 2SO_2(g) + 4Cu(s) + 2CO(g)$$

Check Reactants (4 Cu, 2 S, 6 O, 2 C) $\longrightarrow$ products (4 Cu, 2 S, 6 O, 2 C)
Comment 1. Even though Cu_2O *does* participate in the chemical change, it is not involved in the reaction stoichiometry. An overall equation *may not* show which substances actually react; for example, $C(s)$ and $Cu_2S(s)$ do not interact directly here, even though both are shown as reactants.
2. The SO_2 formed in metal extraction contributes to acid rain (see the follow-up problem). To help control the problem, chemists have devised microbial and electrochemical methods to extract metals without roasting sulfide ores. Such methods are among many examples of *green chemistry;* we'll discuss another later in the chapter.
3. These reactions were shown to explain how to obtain an overall equation. The actual extraction of copper is more complex and will be discussed in Chapter 22.

FOLLOW-UP PROBLEM 3.9 The SO_2 produced in copper recovery reacts in air with oxygen and forms sulfur trioxide. This gas, in turn, reacts with water to form a sulfuric acid solution that falls as rain or snow. Write a balanced overall equation for this process.

Reaction Sequences in Organisms Multistep reaction sequences called *metabolic pathways* occur throughout biological systems. In fact, in many cases, nearly every one of an organism's biomolecules is made within it from ingested nutrients. For example, in most cells, the chemical energy in glucose is released through a sequence of about 30 individual reactions. The product of each reaction step is the reactant of the next, so that all the common substances cancel. The overall equation is

$$C_6H_{12}O_6(aq) + 6O_2(g) \longrightarrow 6CO_2(g) + 6H_2O(l)$$

We eat food that contains glucose, inhale O_2, and excrete CO_2 and H_2O. In our cells, these reactants and products are many steps apart: O_2 never reacts *directly* with glucose, and CO_2 and H_2O are formed at various, often distant, steps along the sequence of reactions. Nevertheless, the molar ratios are the same as if the glucose burned in a combustion apparatus filled with pure O_2 and formed CO_2 and H_2O directly.

Chemical Reactions That Involve a Limiting Reactant

In the problems we've considered up to now, the amount of *one* reactant was given, and we assumed there was enough of any other reactant for the first reactant to be completely used up. For example, to find the amount of SO_2 that forms when 100 g of Cu_2S reacts, we convert the grams of Cu_2S to moles and assume that the Cu_2S reacts with as much O_2 as needed. Because all the Cu_2S is used up, its initial amount determines, or limits, how much SO_2 can form. We call Cu_2S the **limiting reactant** (or *limiting reagent*) because the reaction stops once the Cu_2S is gone, no matter how much O_2 is present.

Animation: Limiting Reagent
Online Learning Center

Suppose, however, that the amounts of both Cu_2S *and* O_2 are given in the problem, and we need to find out how much SO_2 forms. We first have to determine whether Cu_2S *or* O_2 is the limiting reactant (that is, which one is completely used up) because the amount of that reactant limits how much SO_2 can form. The other reactant is present *in excess,* and whatever amount of it is not used is left over.

To clarify the idea of limiting reactant, let's consider a much more appetizing situation. Suppose you have a job making sundaes in an ice cream parlor. Each sundae requires two scoops (12 oz) of ice cream, one cherry, and 50 mL of chocolate syrup:

$$2 \text{ scoops (12 oz)} + 1 \text{ cherry} + 50 \text{ mL syrup} \longrightarrow 1 \text{ sundae}$$

A mob of 25 ravenous school kids enters, and every one wants a vanilla sundae. Can you feed them all? You have 300 oz of vanilla ice cream, 30 cherries, and 1 L of syrup, so a quick calculation shows the number of sundaes you can make from each ingredient:

$$\text{Ice cream: No. of sundaes} = 300 \cancel{\text{oz}} \times \frac{2 \cancel{\text{scoops}}}{12 \cancel{\text{oz}}} \times \frac{1 \text{ sundae}}{2 \cancel{\text{scoops}}}$$

$$= 25 \text{ sundaes}$$

$$\text{Cherries: No. of sundaes} = 30 \cancel{\text{cherries}} \times \frac{1 \text{ sundae}}{1 \cancel{\text{cherry}}}$$

$$= 30 \text{ sundaes}$$

$$\text{Syrup: No. of sundaes} = 1000 \cancel{\text{mL syrup}} \times \frac{1 \text{ sundae}}{50 \cancel{\text{mL syrup}}}$$

$$= 20 \text{ sundaes}$$

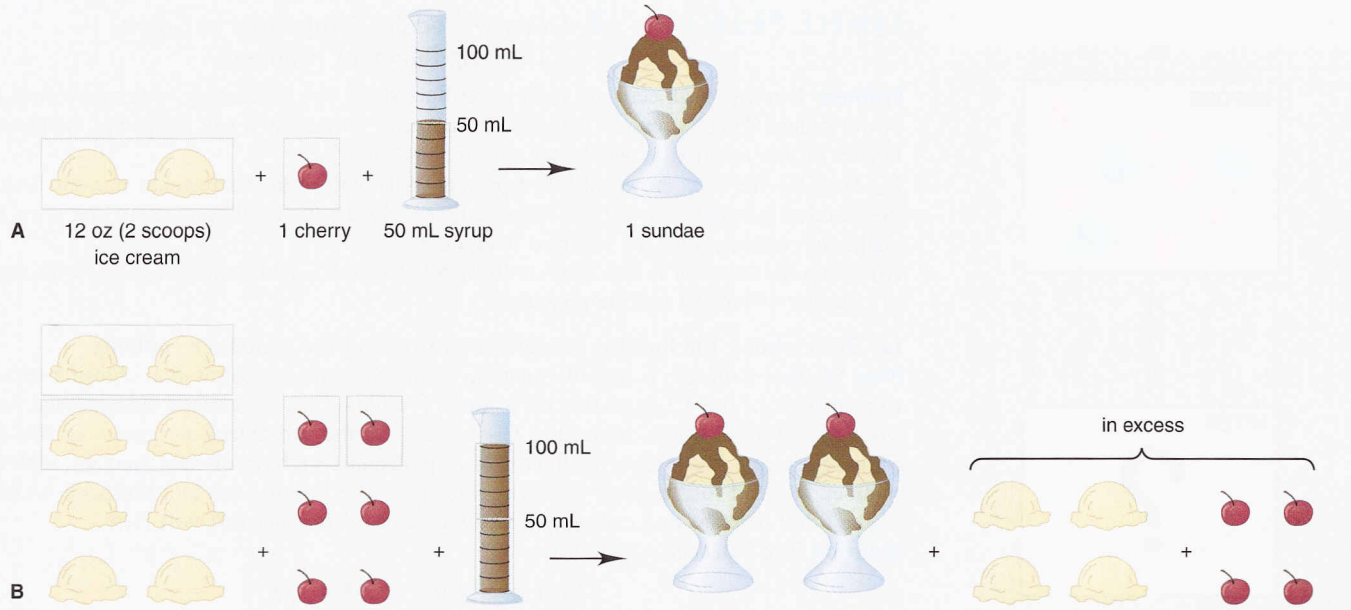


Figure 3.10 An ice cream sundae analogy for limiting reactants. A, The "components" combine in specific amounts to form a sundae. **B,** In this example, the number of sundaes possible is limited by the amount of syrup, the limiting "reactant." Here, only two sundaes can be made. Four scoops of ice cream and four cherries remain "in excess." See the text for another situation involving these components.

The syrup is the limiting "reactant" in this case because it limits the total amount of "product" (sundaes) that can "form": of the three ingredients, the syrup allows the *fewest* sundaes to be made. (Also see the example in Figure 3.10.) Some ice cream and cherries are still left "unreacted" when all the syrup has been used up, so they are present in excess:

300 oz (50 scoops) + 30 cherries + 1 L syrup ⟶
20 sundaes + 60 oz (10 scoops) + 10 cherries

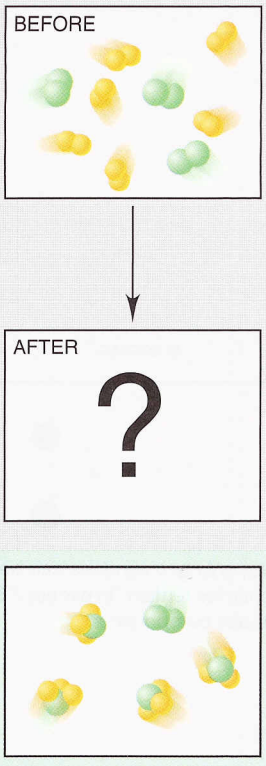
Now let's apply these ideas to solving chemical problems. In limiting-reactant problems, the amounts of two (or more) reactants are given, and we must first determine which is limiting. To do this, just as we did with the ice-cream sundaes, we first note how much of each reactant *should* be present to completely use up the other, and then we compare it with the amount that is *actually* present. Simply put, the limiting reactant is the one there is not enough of, that is, *it is the one that limits the amount of the other reactant that can react, and thus the amount of product that can form.* In mathematical terms, *the limiting reactant is the one that yields the* ***lower*** *amount of product.*

We'll examine limiting reactants in the following two sample problems. Sample Problem 3.10 has two parts, and in both we have to identify the limiting reactant. In the first part, we'll look at a simple molecular view of a reaction and compare the number of molecules to find the limiting reactant; in the second part, we start with the amounts (mol) of two reactants and perform two calculations, each of which assumes an excess of one of the reactants, to see which reactant forms less product. Then, in Sample Problem 3.11, we go through a similar process but start with the masses of the two reactants.

Limiting "Reactants" in Everyday Life

Limiting-"reactant" situations arise in business all the time. A car assembly-plant manager must order more tires if there are 1500 car bodies and only 4000 tires, and a clothes manufacturer must cut more sleeves if there are 320 sleeves for 170 shirt bodies. You've probably faced such situations in daily life as well. A muffin recipe calls for 2 cups of flour and 1 cup of sugar, but you have 3 cups of flour and only $\frac{3}{4}$ cup of sugar. Clearly, the flour is in excess and the sugar limits the number of muffins you can make. Or, you're in charge of making cheeseburgers for a picnic, and you have 10 buns, 12 meat patties, and 15 slices of cheese. Here, the number of buns limits the cheeseburgers you can make. Or, there are 26 students and only 23 microscopes in a cell biology lab. You'll find that limiting-reactant situations are almost limitless.

SAMPLE PROBLEM 3.10 Using Molecular Depictions to Solve a Limiting-Reactant Problem



Problem Nuclear engineers use chlorine trifluoride in the processing of uranium fuel for power plants. This extremely reactive substance is formed as a gas in special metal containers by the reaction of elemental chlorine and fluorine.

(a) Suppose the box shown at left represents a container of the reactant mixture before the reaction occurs (with chlorine colored green). Name the limiting reactant and draw the container contents after the reaction is complete.

(b) When the reaction is run again with 0.750 mol of Cl_2 and 3.00 mol of F_2, what mass of chlorine trifluoride will be prepared?

(a) Determining the limiting reactant and drawing the container contents

Plan We first write the balanced equation. From its name, we know that chlorine trifluoride consists of one Cl atom bonded to three F atoms, ClF_3. Elemental chlorine and fluorine refer to the diatomic molecules Cl_2 and F_2. All the substances are gases. To find the limiting reactant, we compare the number of molecules we have of each reactant, with the number we need for the other to react completely. The limiting reactant limits the amount of the other reactant that can react and the amount of product that will form.

Solution The balanced equation is

$$Cl_2(g) + 3F_2(g) \longrightarrow 2ClF_3(g)$$

The equation shows that two ClF_3 molecules are formed for every one Cl_2 molecule and three F_2 molecules that react. Before the reaction, there are three Cl_2 molecules (six Cl atoms). For all the Cl_2 to react, we need three times three, or nine, F_2 molecules (18 F atoms). But there are only six F_2 molecules (12 F atoms). Therefore, F_2 is the limiting reactant because it limits the amount of Cl_2 that can react, and thus the amount of ClF_3 that can form. After the reaction, as the box at left depicts, all 12 F atoms and four of the six Cl atoms make four ClF_3 molecules, and one Cl_2 molecule remains in excess.

Check The equation is balanced: reactants (2 Cl, 6 F) $\longrightarrow$ products (2 Cl, 6 F), and, in the boxes, the number of each type of atom before the reaction equals the number after the reaction. You can check the choice of limiting reactant by examining the reaction from the perspective of Cl_2: Two Cl_2 molecules are enough to react with the six F_2 molecules in the container. But there are three Cl_2 molecules, so there is not enough F_2.

(b) Calculating the mass of ClF_3 formed

Plan We first determine the limiting reactant by using the molar ratios from the balanced equation to convert the moles of each reactant to moles of ClF_3 formed, assuming an excess of the other reactant. Whichever reactant forms fewer moles of ClF_3 is limiting. Then we use the molar mass of ClF_3 to convert this lower number of moles to grams.

Solution Determining the limiting reactant:

Finding moles of ClF_3 from moles of Cl_2 (assuming F_2 is in excess):

$$\text{Moles of } ClF_3 = 0.750 \text{ mol } Cl_2 \times \frac{2 \text{ mol } ClF_3}{1 \text{ mol } Cl_2} = 1.50 \text{ mol } ClF_3$$

Finding moles of ClF_3 from moles of F_2 (assuming Cl_2 is in excess):

$$\text{Moles of } ClF_3 = 3.00 \text{ mol } F_2 \times \frac{2 \text{ mol } ClF_3}{3 \text{ mol } F_2} = 2.00 \text{ mol } ClF_3$$

In this experiment, Cl_2 is limiting because it forms fewer moles of ClF_3.

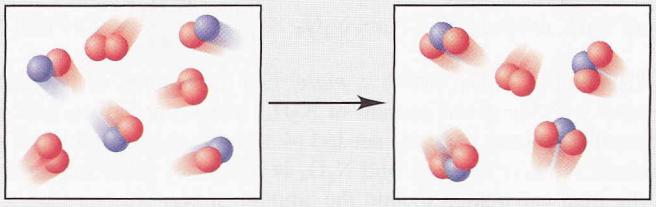
Calculating grams of ClF_3 formed:

$$\text{Mass (g) of } ClF_3 = 1.50 \text{ mol } ClF_3 \times \frac{92.45 \text{ g } ClF_3}{1 \text{ mol } ClF_3} = 139 \text{ g } ClF_3$$

Check Let's check our reasoning that Cl_2 is the limiting reactant by assuming, for the moment, that F_2 is limiting. In that case, all 3.00 mol of F_2 would react to form 2.00 mol of ClF_3. Based on the balanced equation, however, that amount would require that 1.00 mol of Cl_2 reacted. But that result is impossible because only 0.750 mol of Cl_2 is present.

Comment Note that a reactant can be limiting even though it is present in the greater amount. It is the *reactant molar ratio in the balanced equation* that is the determining factor. In both parts (a) and (b), F_2 is present in greater amount than Cl_2. However, in (a), the F_2/Cl_2 ratio is 6/3, or 2/1, which is less than the required molar ratio of 3/1, so F_2 is limiting; in (b), the F_2/Cl_2 ratio is 3.00/0.750, greater than the required 3/1, so F_2 is in excess.

FOLLOW-UP PROBLEM 3.10 B_2 (red spheres) reacts with AB as shown below:

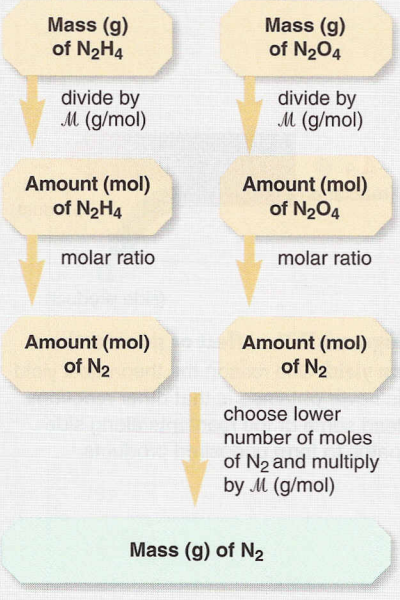


(a) Write a balanced equation for the reaction, and determine the limiting reactant.
(b) How many moles of product can form from the reaction of 1.5 mol of each reactant?

SAMPLE PROBLEM 3.11 Calculating Amounts of Reactant and Product in a Limiting-Reactant Problem

Problem A fuel mixture used in the early days of rocketry is composed of two liquids, hydrazine (N_2H_4) and dinitrogen tetraoxide (N_2O_4), which ignite on contact to form nitrogen gas and water vapor. How many grams of nitrogen gas form when 1.00×10^2 g of N_2H_4 and 2.00×10^2 g of N_2O_4 are mixed?

Plan We first write the balanced equation. *Because the amounts of two reactants are given, we know this is a limiting-reactant problem.* To determine which reactant is limiting, we calculate the mass of N_2 formed from each reactant *assuming an excess of the other.* We convert the grams of each reactant to moles and use the appropriate molar ratio to find the moles of N_2 each forms. Whichever yields *less* N_2 is the limiting reactant. Then, we convert this lower number of moles of N_2 to mass. The roadmap shows the steps.



Solution Writing the balanced equation:

$$2N_2H_4(l) + N_2O_4(l) \longrightarrow 3N_2(g) + 4H_2O(g)$$

Finding the moles of N_2 from the moles of N_2H_4 (if N_2H_4 is limiting):

$$\text{Moles of } N_2H_4 = 1.00\times10^2 \text{ g } \cancel{N_2H_4} \times \frac{1 \text{ mol } N_2H_4}{32.05 \text{ g } \cancel{N_2H_4}} = 3.12 \text{ mol } N_2H_4$$

$$\text{Moles of } N_2 = 3.12 \text{ } \cancel{\text{mol } N_2H_4} \times \frac{3 \text{ mol } N_2}{2 \text{ } \cancel{\text{mol } N_2H_4}} = \mathbf{4.68 \text{ mol } N_2}$$

Finding the moles of N_2 from the moles of N_2O_4 (if N_2O_4 is limiting):

$$\text{Moles of } N_2O_4 = 2.00\times10^2 \text{ g } \cancel{N_2O_4} \times \frac{1 \text{ mol } N_2O_4}{92.02 \text{ g } \cancel{N_2O_4}} = 2.17 \text{ mol } N_2O_4$$

$$\text{Moles of } N_2 = 2.17 \text{ } \cancel{\text{mol } N_2O_4} \times \frac{3 \text{ mol } N_2}{1 \text{ } \cancel{\text{mol } N_2O_4}} = \mathbf{6.51 \text{ mol } N_2}$$

Thus, N_2H_4 is the limiting reactant because it yields fewer moles of N_2.
Converting from moles of N_2 to grams:

$$\text{Mass (g) of } N_2 = 4.68 \text{ } \cancel{\text{mol } N_2} \times \frac{28.02 \text{ g } N_2}{1 \text{ } \cancel{\text{mol } N_2}} = 131 \text{ g } N_2$$

Check The mass of N_2O_4 is greater than that of N_2H_4, but there are fewer moles of N_2O_4 because its $\mathcal{M}$ is much higher. Round off to check the math: for N_2H_4, 100 g N_2H_4 × 1 mol/32 g ≈ 3 mol; ~3 mol × $\frac{3}{2}$ ≈ 4.5 mol N_2; ~4.5 mol × 30 g/mol ≈ 135 g N_2.

Comment **1.** Here are two *common mistakes* in solving limiting-reactant problems:

- The limiting reactant is not the *reactant* present in fewer moles (2.17 mol of N_2O_4 vs. 3.12 mol of N_2H_4). Rather, it is the reactant that forms fewer moles of *product*.
- Similarly, the limiting reactant is not the *reactant* present in lower mass. Rather, it is the reactant that forms the lower mass of *product*.

2. Here is an *alternative approach* to finding the limiting reactant. Find the moles of each reactant that would be needed to react with the other reactant. Then see which amount actually given in the problem is sufficient. That substance is in excess, and the other substance is limiting. For example, the balanced equation shows 2 mol of N_2H_4 reacts with 1 mol of N_2O_4. The moles of N_2O_4 needed to react with the given moles of N_2H_4 are

$$\text{Moles of } N_2O_4 \text{ needed} = 3.12 \text{ } \cancel{\text{mol } N_2H_4} \times \frac{1 \text{ mol } N_2O_4}{2 \text{ } \cancel{\text{mol } N_2H_4}} = 1.56 \text{ mol } N_2O_4$$

The moles of N_2H_4 needed to react with the given moles of N_2O_4 are

$$\text{Moles of } N_2H_4 \text{ needed} = 2.17 \text{ mol } N_2O_4 \times \frac{2 \text{ mol } N_2H_4}{1 \text{ mol } N_2O_4} = 4.34 \text{ mol } N_2H_4$$

We are given 2.17 mol of N_2O_4, which is *more* than the amount of N_2O_4 that is needed (1.56 mol) to react with the given amount of N_2H_4, and we are given 3.12 mol of N_2H_4, which is *less* than the amount of N_2H_4 needed (4.34 mol) to react with the given amount of N_2O_4. Therefore, N_2H_4 is limiting, and N_2O_4 is in excess. Once we determine this, we continue with the final calculation to find the amount of N_2.

FOLLOW-UP PROBLEM 3.11 How many grams of solid aluminum sulfide can be prepared by the reaction of 10.0 g of aluminum and 15.0 g of sulfur? How much of the nonlimiting reactant is in excess?

Chemical Reactions in Practice: Theoretical, Actual, and Percent Yields

Up until now, we've been optimistic about the amount of product obtained from a reaction. We have assumed that 100% of the limiting reactant becomes product, that ideal separation and purification methods exist for isolating the product, and that we use perfect lab technique to collect all the product formed. In other words, we have assumed that we obtain the **theoretical yield,** the amount indicated by the stoichiometrically equivalent molar ratio in the balanced equation.

It's time to face reality. The theoretical yield is *never* obtained, for reasons that are largely uncontrollable. For one thing, although the major reaction predominates, many reactant mixtures also proceed through one or more **side reactions** that form smaller amounts of different products, as shown in Figure 3.11. In the rocket fuel reaction in Sample Problem 3.11, for example, the reactants might form some NO in the following side reaction:

$$2N_2O_4(l) + N_2H_4(l) \longrightarrow 6NO(g) + 2H_2O(g)$$

This reaction decreases the amounts of reactants available for N_2 production (see Problem 3.116 at the end of the chapter). Even more important, as we'll discuss in Chapter 4, many reactions seem to stop before they are complete, which leaves some limiting reactant unused. But, even when a reaction does go completely to product, losses occur in virtually every step of a separation procedure (see Tools of the Laboratory, Section 2.9): a tiny amount of product clings to filter paper, some distillate evaporates, a small amount of extract remains in the separatory funnel, and so forth. With careful technique, you can minimize these losses but never eliminate them. The amount of product that you actually obtain is the **actual yield.** The **percent yield (% yield)** is the actual yield expressed as a percentage of the theoretical yield:

$$\% \text{ yield} = \frac{\text{actual yield}}{\text{theoretical yield}} \times 100 \qquad (3.7)$$

Since the actual yield must be less than the theoretical yield, the percent yield is always less than 100%. Theoretical and actual yields are expressed in units of amount (moles) or mass (grams).

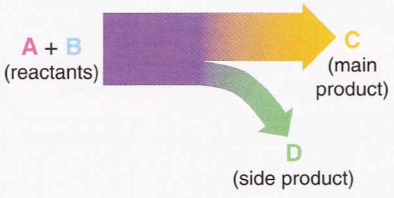


Figure 3.11 The effect of side reactions on yield. One reason the theoretical yield is never obtained is that other reactions lead some of the reactants along side paths to form undesired products.

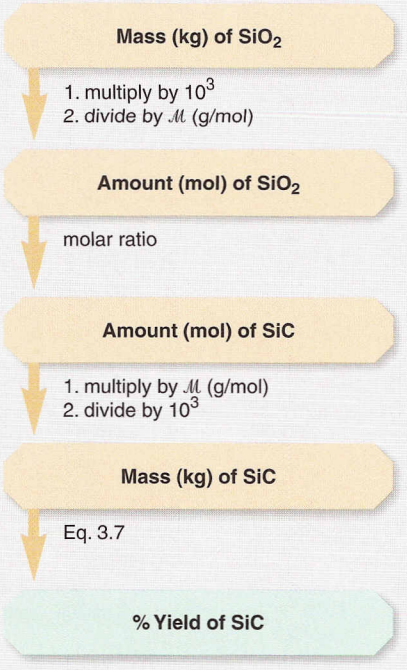
SAMPLE PROBLEM 3.12 Calculating Percent Yield

Problem Silicon carbide (SiC) is an important ceramic material that is made by allowing sand (silicon dioxide, SiO_2) to react with powdered carbon at high temperature. Carbon monoxide is also formed. When 100.0 kg of sand is processed, 51.4 kg of SiC is recovered. What is the percent yield of SiC from this process?

Plan We are given the actual yield of SiC (51.4 kg), so we need the theoretical yield to calculate the percent yield. After writing the balanced equation, we convert the given mass

of SiO_2 (100.0 kg) to amount (mol). We use the molar ratio to find the amount of SiC formed and convert that amount to mass (kg) to obtain the theoretical yield [see Sample Problem 3.8(c)]. Then, we use Equation 3.7 to find the percent yield (see the roadmap).



Solution Writing the balanced equation:

$$SiO_2(s) + 3C(s) \longrightarrow SiC(s) + 2CO(g)$$

Converting from kilograms of SiO_2 to moles:

$$\text{Moles of } SiO_2 = 100.0 \text{ kg } SiO_2 \times \frac{1000 \text{ g}}{1 \text{ kg}} \times \frac{1 \text{ mol } SiO_2}{60.09 \text{ g } SiO_2} = 1664 \text{ mol } SiO_2$$

Converting from moles of SiO_2 to moles of SiC: The molar ratio is 1 mol SiC/1 mol SiO_2, so

$$\text{Moles of } SiO_2 = \text{moles of SiC} = 1664 \text{ mol SiC}$$

Converting from moles of SiC to kilograms:

$$\text{Mass (kg) of SiC} = 1664 \text{ mol SiC} \times \frac{40.10 \text{ g SiC}}{1 \text{ mol SiC}} \times \frac{1 \text{ kg}}{1000 \text{ g}} = 66.73 \text{ kg SiC}$$

Calculating the percent yield:

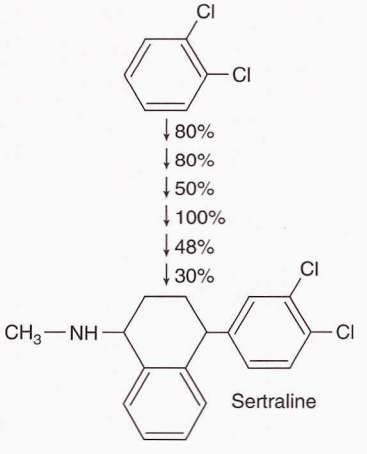
$$\%\text{ yield of SiC} = \frac{\text{actual yield}}{\text{theoretical yield}} \times 100 = \frac{51.4 \text{ kg}}{66.73 \text{ kg}} \times 100 = 77.0\%$$

Check Rounding shows that the mass of SiC seems correct: ~1500 mol × 40 g/mol × 1 kg/1000 g = 60 kg. The molar ratio of SiC:SiO_2 is 1:1, and the $\mathcal{M}$ of SiC is about two-thirds ($\sim\frac{40}{60}$) the $\mathcal{M}$ of SiO_2, so 100 kg of SiO_2 should form about 66 kg of SiC.

FOLLOW-UP PROBLEM 3.12 Marble (calcium carbonate) reacts with hydrochloric acid solution to form calcium chloride solution, water, and carbon dioxide. What is the percent yield of carbon dioxide if 3.65 g of the gas is collected when 10.0 g of marble reacts?

Yields in Multistep Syntheses In the multistep laboratory synthesis of a complex compound, *the percent yield of each step is expressed as a fraction and multiplied by the others to find the overall yield.* Even when the yield of each step is high, the final result can be surprisingly low. For example, suppose a six-step reaction sequence has a 90.0% yield for each step; that is, you are able to recover 90.0% of the theoretical yield of product in each step. Even so, overall recovery is only slightly more than 50%:

$$\text{Overall \% yield} = (0.900 \times 0.900 \times 0.900 \times 0.900 \times 0.900 \times 0.900) \times 100 = 53.1\%$$



Such multistep sequences are common in the laboratory synthesis of medicines, dyes, pesticides, and many other organic compounds. For example, the antidepressant Sertraline is prepared from a simple starting compound in six steps with yields of 80%, 80%, 50%, 100%, 48%, and 30% respectively. Multiplying these together as fractions gives an overall yield of only 4.6%. Because a typical synthesis begins with large amounts of inexpensive, simple reactants and ends with small amounts of expensive, complex products, the overall yield greatly influences the commercial potential of a product.

A Green Chemistry Perspective on Yield: Atom Economy Reactants are wasted by undesirable side reactions during each step in a synthesis, drastically lowering the overall yield. Moreover, many by-products may be harmful. This fact is one of several concerns addressed by **green chemistry**. A major focus of the academic, industrial, and government chemists who work in this new field is to develop methods that reduce or prevent the release of harmful substances into the environment.

To fully evaluate alternative methods, several green chemistry principles are taken into account, including the quantity of energy needed and the nature of the solvents required. When these factors are similar, the *atom economy,* the proportion of reactant atoms that end up in the desired product, is a useful criterion for

choosing the more efficient synthetic route. The efficiency of a synthesis is quantified in terms of the *percent atom economy:*

$$\%\ \text{atom economy} = \frac{\text{no. of moles} \times \text{molar mass of desired product}}{\text{sum of no. of moles} \times \text{molar mass for all products}} \times 100$$

Consider two synthetic routes—one starting with benzene (C_6H_6), the other with butane (C_4H_{10})—for the production of maleic anhydride ($C_4H_2O_3$), a key industrial chemical used in the manufacture of polymers, dyes, medicines, pesticides, and other important products:

Route 1. $2C_6H_6(l) + 9O_2(g) \rightarrow \cdots \rightarrow 2C_4H_2O_3(l) + 4H_2O(l) + 4CO_2(g)$

Route 2. $2C_4H_{10}(g) + 7O_2(g) \rightarrow \cdots \rightarrow 2C_4H_2O_3(l) + 8H_2O(l)$

Let's compare the efficiency of these routes in terms of percent atom economy:

Route 1.

$$\%\ \text{atom economy} = \frac{2 \times \mathcal{M}\ \text{of}\ C_4H_2O_3}{(2 \times \mathcal{M}\ \text{of}\ C_4H_2O_3) + (4 \times \mathcal{M}\ \text{of}\ H_2O) + (4 \times \mathcal{M}\ \text{of}\ CO_2)} \times 100$$

$$= \frac{2 \times 98.06\ \text{g}}{(2 \times 98.06\ \text{g}) + (4 \times 18.02\ \text{g}) + (4 \times 44.01\ \text{g})} \times 100 = 44.15\%$$

Route 2.

$$\%\ \text{atom economy} = \frac{2 \times \mathcal{M}\ \text{of}\ C_4H_2O_3}{(2 \times \mathcal{M}\ \text{of}\ C_4H_2O_3) + (8 \times \mathcal{M}\ \text{of}\ H_2O)} \times 100$$

$$= \frac{2 \times 98.06\ \text{g}}{(2 \times 98.06\ \text{g}) + (8 \times 18.02\ \text{g})} \times 100 = 57.63\%$$

Clearly, from the perspective of atom economy, route 2 is preferable because a larger percentage of reactant atoms end up in the desired product. It is also a "greener" approach than route 1 because it avoids the use of the toxic reactant benzene and does not produce CO_2, a gas that contributes to global warming.

SECTION SUMMARY

The substances in a balanced equation are related to each other by stoichiometrically equivalent molar ratios, which can be used as conversion factors to find the moles of one substance given the moles of another. In limiting-reactant problems, the amounts of two (or more) reactants are given, and one of them limits the amount of product that forms. The limiting reactant is the one that forms the lower amount of product. In practice, side reactions, incomplete reactions, and physical losses result in an actual yield of product that is less than the theoretical yield, the amount based solely on the molar ratio. In multistep reactions, the overall yield is found by multiplying the yields for each step. Atom economy, or the proportion of reactant atoms found in the desired product, is one criterion for choosing a "greener" reaction.

3.5 FUNDAMENTALS OF SOLUTION STOICHIOMETRY

In the popular media, you may have seen a chemist portrayed as a person in a white lab coat, surrounded by odd-shaped glassware, pouring one colored solution into another, which produces frothing bubbles and billowing fumes. Although most reactions in solution are not this dramatic and good technique usually requires safer mixing procedures, the image is true to the extent that aqueous solution chemistry is a central part of laboratory activity. Liquid solutions are more convenient to store and mix than solids or gases, and the amounts of substances in solution can be measured very precisely. Since many environmental reactions and almost all biochemical reactions occur in solution, an understanding of reactions in solution is extremely important in chemistry and related sciences.

We'll discuss solution chemistry at many places in the text, but here we focus on solution stoichiometry. Only one aspect of the stoichiometry of dissolved substances is different from what we've seen so far. We know the amounts of pure substances by converting their masses directly into moles. For dissolved sub-

stances, we must know the *concentration*—the number of moles present in a certain volume of solution—to find the volume that contains a given number of moles. Of the various ways to express concentration, the most important is *molarity,* so we discuss it here (and wait until Chapter 13 to discuss the other ways). Then, we see how to prepare a solution of a specific molarity and how to use solutions in stoichiometric calculations.

Expressing Concentration in Terms of Molarity

A typical solution consists of a smaller amount of one substance, the **solute,** dissolved in a larger amount of another substance, the **solvent.** When a solution forms, the solute's individual chemical entities become evenly dispersed throughout the available volume and surrounded by solvent molecules. The **concentration** of a solution is usually expressed as *the amount of solute dissolved in a given amount of solution.* Concentration is an *intensive* quantity (like density or temperature) and thus independent of the volume of solution: a 50-L tank of a given solution has the *same concentration* (solute amount/solution amount) as a 50-mL beaker of the solution. **Molarity** ***(M)*** expresses the concentration in units of *moles of solute per liter of solution:*

$$\text{Molarity} = \frac{\text{moles of solute}}{\text{liters of solution}} \quad \text{or} \quad M = \frac{\text{mol solute}}{\text{L soln}} \tag{3.8}$$

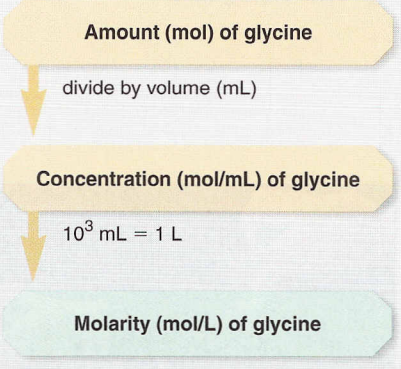
SAMPLE PROBLEM 3.13 Calculating the Molarity of a Solution

Problem Glycine (H_2NCH_2COOH) is the simplest amino acid. What is the molarity of an aqueous solution that contains 0.715 mol of glycine in 495 mL?

Plan The molarity is the number of moles of solute in each liter of solution. We are given the number of moles (0.715 mol) and the volume (495 mL), so we divide moles by volume and convert the volume to liters to find the molarity.

Solution

$$\text{Molarity} = \frac{0.715 \text{ mol glycine}}{495 \cancel{\text{mL soln}}} \times \frac{1000 \cancel{\text{mL}}}{1 \text{ L}} = 1.44 \ M \text{ glycine}$$



Check A quick look at the math shows about 0.7 mol of glycine in about 0.5 L of solution, so the concentration should be about 1.4 mol/L, or 1.4 *M*.

FOLLOW-UP PROBLEM 3.13 How many moles of KI are in 84 mL of 0.50 *M* KI?

Mole-Mass-Number Conversions Involving Solutions

Molarity can be thought of as a conversion factor used to convert between volume of solution and amount (mol) of solute, from which we then find the mass or the number of entities of solute. Figure 3.12 shows this new stoichiometric relationship, and Sample Problem 3.14 applies it.

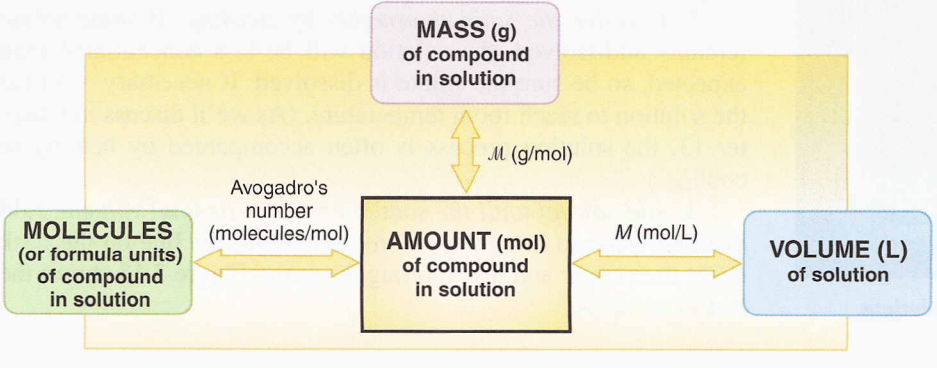


Figure 3.12 Summary of mass-mole-number-volume relationships in solution. The amount (in moles) of a compound in solution is related to the volume of solution in liters through the molarity (*M*) in moles per liter. The other relationships shown are identical to those in Figure 3.4, except that here they refer to the quantities *in solution*. As in previous cases, to find the quantity of substance expressed in one form or another, convert the given information to moles first.

SAMPLE PROBLEM 3.14 Calculating Mass of Solute in a Given Volume of Solution

Problem A *buffered* solution maintains acidity as a reaction occurs. In living cells, phosphate ions play a key buffering role, so biochemists often study reactions in such solutions. How many grams of solute are in 1.75 L of 0.460 *M* sodium monohydrogen phosphate?

Plan We know the solution volume (1.75 L) and molarity (0.460 *M*), and we need the mass of solute. We use the known quantities to find the amount (mol) of solute and then convert moles to grams with the solute molar mass.

Volume (L) of solution
↓ multiply by *M* (mol/L)
Amount (mol) of solute
↓ multiply by $\mathcal{M}$ (g/mol)
Mass (g) of solute

Solution Calculating moles of solute in solution:

$$\text{Moles of } Na_2HPO_4 = 1.75 \cancel{\text{ L soln}} \times \frac{0.460 \text{ mol } Na_2HPO_4}{1 \cancel{\text{ L soln}}} = 0.805 \text{ mol } Na_2HPO_4$$

Converting from moles of solute to grams:

$$\text{Mass (g) } Na_2HPO_4 = 0.805 \cancel{\text{ mol } Na_2HPO_4} \times \frac{141.96 \text{ g } Na_2HPO_4}{1 \cancel{\text{ mol } Na_2HPO_4}} = 114 \text{ g } Na_2HPO_4$$

Check The answer seems to be correct: ~1.8 L of 0.5 mol/L contains 0.9 mol, and 150 g/mol × 0.9 mol = 135 g, which is close to 114 g of solute.

FOLLOW-UP PROBLEM 3.14 In biochemistry laboratories, solutions of sucrose (table sugar, $C_{12}H_{22}O_{11}$) are used in high-speed centrifuges to separate the parts of a biological cell. How many liters of 3.30 *M* sucrose contain 135 g of solute?

Preparing and Diluting Molar Solutions

Whenever you prepare a solution of specific molarity, remember that the volume term in the denominator of the molarity expression is the *solution* volume, **not** the *solvent* volume. The solution volume includes contributions from solute *and* solvent, so you cannot simply dissolve 1 mol of solute in 1 L of solvent and expect a 1 *M* solution. The solute would increase the solution volume above 1 L, resulting in a lower-than-expected concentration. The correct preparation of a solution containing a solid solute consists of four steps. Let's go through them to prepare 0.500 L of 0.350 *M* nickel(II) nitrate hexahydrate [$Ni(NO_3)_2 \cdot 6H_2O$]:

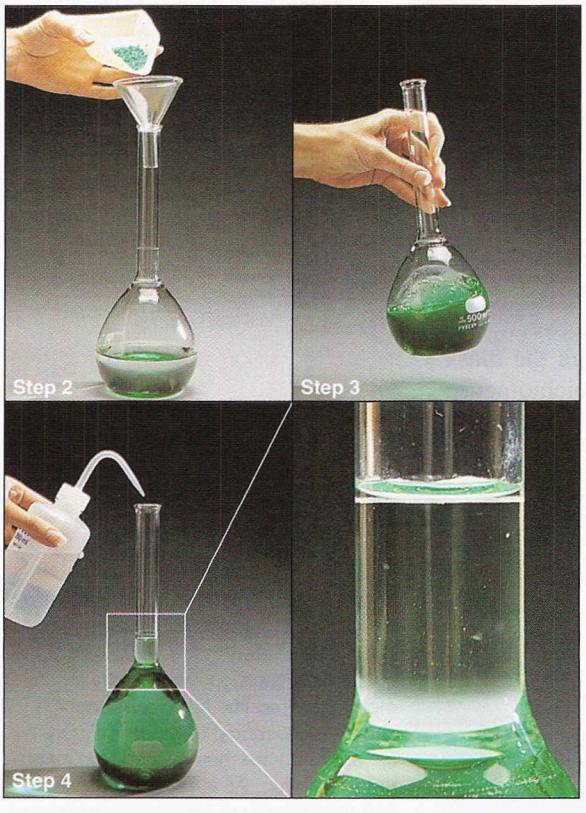

Figure 3.13 Laboratory preparation of molar solutions.

1. *Weigh the solid needed.* Calculate the mass of solid needed by converting from liters to moles and from moles to grams:

$$\text{Mass (g) of solute} = 0.500 \cancel{\text{ L soln}} \times \frac{0.350 \cancel{\text{ mol } Ni(NO_3)_2 \cdot 6H_2O}}{1 \cancel{\text{ L soln}}} \times \frac{290.82 \text{ g } Ni(NO_3)_2 \cdot 6H_2O}{1 \cancel{\text{ mol } Ni(NO_3)_2 \cdot 6H_2O}} = 50.9 \text{ g } Ni(NO_3)_2 \cdot 6H_2O$$

2. *Carefully transfer the solid to a volumetric flask that contains about half the final volume of solvent.* Since we need 0.500 L of solution, we choose a 500-mL volumetric flask. Add about 250 mL of distilled water and then transfer the solid. Wash down any solid clinging to the neck with a small amount of solvent.

3. *Dissolve the solid thoroughly by swirling.* If some solute remains undissolved, the solution will be less concentrated than expected, so be sure the solute is dissolved. If necessary, wait for the solution to reach room temperature. (As we'll discuss in Chapter 13, the solution process is often accompanied by heating or cooling.)

4. *Add solvent until the solution reaches its final volume.* Add distilled water to bring the volume exactly to the line on the flask neck, then cover and mix thoroughly again. Figure 3.13 shows the last three steps.

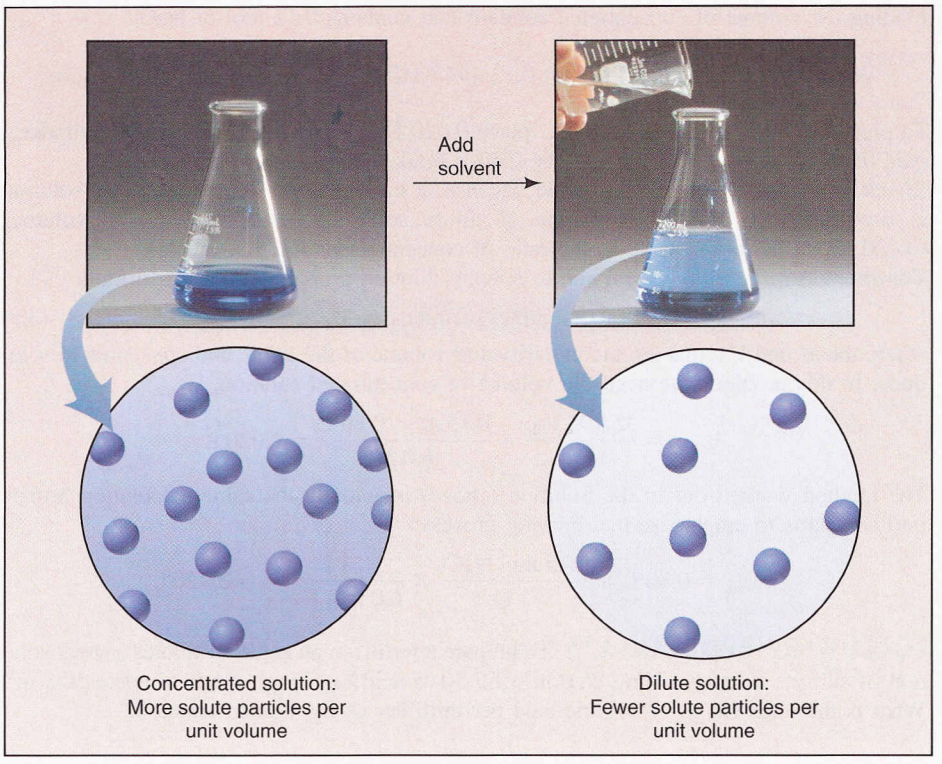

Figure 3.14 Converting a concentrated solution to a dilute solution. When a solution is diluted, only solvent is added. The solution volume increases while the total number of moles of solute remains the same. Therefore, as shown in the blow-up views, a unit volume of concentrated solution contains more solute particles than the same unit volume of dilute solution.

Animation: Preparing a Solution by Dilution
Online Learning Center

As Figure 3.14 shows, *only solvent is added when a solution is diluted,* so the solute is dispersed in a larger final volume. Thus, a given volume of the final solution contains fewer solute particles and has a lower concentration. If various low concentrations of a solution are used frequently, it is common practice to prepare a more concentrated solution (called a *stock solution*), which is stored and diluted as needed.

SAMPLE PROBLEM 3.15 Preparing a Dilute Solution from a Concentrated Solution

Problem Isotonic saline is a 0.15 *M* aqueous solution of NaCl that simulates the total concentration of ions found in many cellular fluids. Its uses range from a cleansing rinse for contact lenses to a washing medium for red blood cells. How would you prepare 0.80 L of isotonic saline from a 6.0 *M* stock solution?

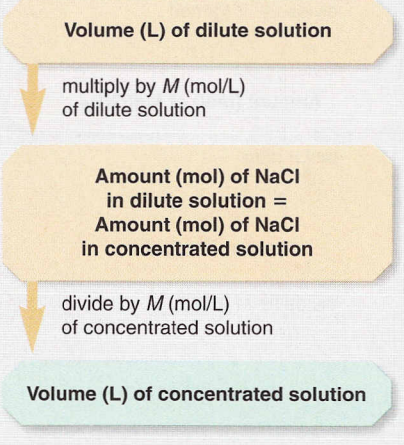
Plan To dilute a concentrated solution, we add only solvent, so the *moles of solute are the same in both solutions*. We know the volume (0.80 L) and molarity (0.15 *M*) of the dilute (dil) NaCl solution we need, so we find the moles of NaCl it contains and then find the volume of concentrated (conc; 6.0 *M*) NaCl solution that contains the same number of moles. Then, we dilute this volume with solvent *up to* the final volume.

Solution Finding moles of solute in dilute solution:

$$\text{Moles of NaCl in dil soln} = 0.80 \cancel{\text{L soln}} \times \frac{0.15 \text{ mol NaCl}}{1 \cancel{\text{L soln}}} = 0.12 \text{ mol NaCl}$$

Finding moles of solute in concentrated solution: Since we add only solvent to dilute the solution,

$$\text{Moles of NaCl in dil soln} = \text{moles of NaCl in conc soln} = 0.12 \text{ mol NaCl}$$



Finding the volume of concentrated solution that contains 0.12 mol of NaCl:

$$\text{Volume (L) of conc NaCl soln} = 0.12 \text{ mol NaCl} \times \frac{1 \text{ L soln}}{6.0 \text{ mol NaCl}} = 0.020 \text{ L soln}$$

To prepare 0.80 L of dilute solution, place 0.020 L of 6.0 *M* NaCl in a 1.0-L cylinder, add distilled water (~780 mL) to the 0.80-L mark, and stir thoroughly.

Check The answer seems reasonable because a small volume of concentrated solution is used to prepare a large volume of dilute solution. Also, the ratio of volumes (0.020 L:0.80 L) is the same as the ratio of concentrations (0.15 *M*:6.0 *M*).

Comment An *alternative approach* to solving dilution problems uses the formula

$$M_{dil} \times V_{dil} = \text{number of moles} = M_{conc} \times V_{conc} \qquad (3.9)$$

where the *M* and *V* terms are the molarity and volume of the *dil*ute and *conc*entrated solutions. In this problem, we need the volume of concentrated solution, V_{conc}:

$$V_{conc} = \frac{M_{dil} \times V_{dil}}{M_{conc}} = \frac{0.15 \text{ M} \times 0.80 \text{ L}}{6.0 \text{ M}} = 0.020 \text{ L}$$

The method worked out in the Solution (above) is actually the same calculation broken into two parts to emphasize the thinking process:

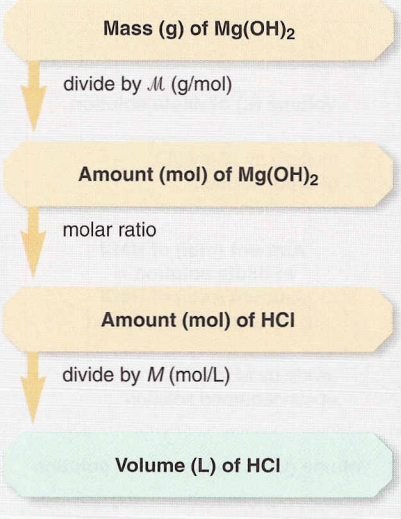
$$V_{conc} = 0.80 \text{ L} \times \frac{0.15 \text{ mol NaCl}}{1 \text{ L}} \times \frac{1 \text{ L}}{6.0 \text{ mol NaCl}} = 0.020 \text{ L}$$

FOLLOW-UP PROBLEM 3.15 To prepare a fertilizer, an engineer dilutes a stock solution of sulfuric acid by adding 25.0 m^3 of 7.50 *M* acid to enough water to make 500. m^3. What is the mass (in g) of sulfuric acid per milliliter of the diluted solution?

Stoichiometry of Chemical Reactions in Solution

Solving stoichiometry problems for reactions in solution requires the same approach as before, with the additional step of converting the volume of reactant or product to moles: (1) balance the equation, (2) find the number of moles of one substance, (3) relate it to the stoichiometrically equivalent number of moles of another substance, and (4) convert to the desired units.

SAMPLE PROBLEM 3.16 Calculating Amounts of Reactants and Products for a Reaction in Solution



Problem Specialized cells in the stomach release HCl to aid digestion. If they release too much, the excess can be neutralized with an antacid. A common antacid contains magnesium hydroxide, $Mg(OH)_2$, which reacts with the acid to form water and magnesium chloride solution. As a government chemist testing commercial antacids, you use 0.10 *M* HCl to simulate the acid concentration in the stomach. How many liters of "stomach acid" react with a tablet containing 0.10 g of $Mg(OH)_2$?

Plan We know the mass of $Mg(OH)_2$ (0.10 g) that reacts and the acid concentration (0.10 *M*), and we must find the acid volume. After writing the balanced equation, we convert the grams of $Mg(OH)_2$ to moles, use the molar ratio to find the moles of HCl that react with these moles of $Mg(OH)_2$, and then use the molarity of HCl to find the volume that contains this number of moles. The steps appear in the roadmap.

Solution Writing the balanced equation:

$$Mg(OH)_2(s) + 2HCl(aq) \longrightarrow MgCl_2(aq) + 2H_2O(l)$$

Converting from grams of $Mg(OH)_2$ to moles:

$$\text{Moles of } Mg(OH)_2 = 0.10 \text{ g } \cancel{Mg(OH)_2} \times \frac{1 \text{ mol } Mg(OH)_2}{58.33 \text{ g } \cancel{Mg(OH)_2}} = 1.7\times10^{-3} \text{ mol } Mg(OH)_2$$

Converting from moles of $Mg(OH)_2$ to moles of HCl:

$$\text{Moles of HCl} = 1.7\times10^{-3} \text{ mol } \cancel{Mg(OH)_2} \times \frac{2 \text{ mol HCl}}{1 \text{ mol } \cancel{Mg(OH)_2}} = 3.4\times10^{-3} \text{ mol HCl}$$

Converting from moles of HCl to liters:

$$\text{Volume (L) of HCl} = 3.4\times10^{-3}\ \text{mol HCl} \times \frac{1\ \text{L}}{0.10\ \text{mol HCl}}$$
$$= 3.4\times10^{-2}\ \text{L}$$

Check The size of the answer seems reasonable: a small volume of dilute acid (0.034 L of 0.10 *M*) reacts with a small amount of antacid (0.0017 mol).

Comment The reaction as written is an oversimplification; in reality, HCl and $MgCl_2$ exist as separated ions in solution. This point will be covered in great detail in Chapters 4 and 18.

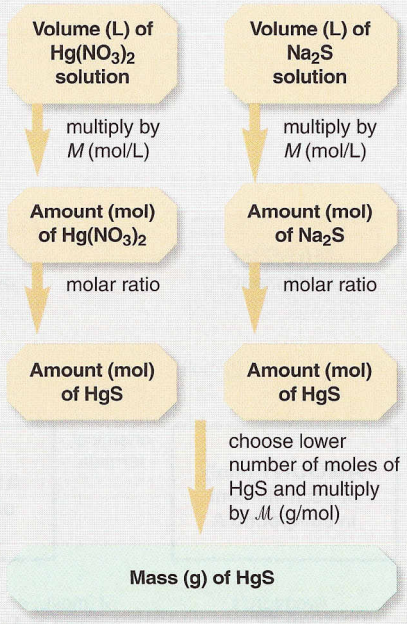
FOLLOW-UP PROBLEM 3.16 Another active ingredient found in some antacids is aluminum hydroxide. Which is more effective at neutralizing stomach acid, magnesium hydroxide or aluminum hydroxide? [*Hint:* Effectiveness refers to the amount of acid that reacts with a given mass of antacid. You already know the effectiveness of 0.10 g of $Mg(OH)_2$.]

In limiting-reactant problems for reactions in solution, we first determine which reactant is limiting and then determine the yield, as demonstrated in the next sample problem.

SAMPLE PROBLEM 3.17 Solving Limiting-Reactant Problems for Reactions in Solution

Problem Mercury and its compounds have many uses, from fillings for teeth (as an alloy with silver, copper, and tin) to the industrial production of chlorine. Because of their toxicity, however, soluble mercury compounds, such as mercury(II) nitrate, must be removed from industrial wastewater. One removal method reacts the wastewater with sodium sulfide solution to produce solid mercury(II) sulfide and sodium nitrate solution. In a laboratory simulation, 0.050 L of 0.010 *M* mercury(II) nitrate reacts with 0.020 L of 0.10 *M* sodium sulfide. How many grams of mercury(II) sulfide form?

Plan This is a limiting-reactant problem because *the amounts of two reactants are given.* After balancing the equation, we must determine the limiting reactant. The molarity (0.010 *M*) and volume (0.050 L) of the mercury(II) nitrate solution tell us the moles of one reactant, and the molarity (0.10 *M*) and volume (0.020 L) of the sodium sulfide solution tell us the moles of the other. Then, we use the molar ratio to find the moles of HgS that form from each reactant, *assuming the other reactant is present in excess.* The limiting reactant is the one that forms fewer moles of HgS, which we convert to mass using the HgS molar mass. The roadmap shows the process.



Solution Writing the balanced equation:

$$Hg(NO_3)_2(aq) + Na_2S(aq) \longrightarrow HgS(s) + 2NaNO_3(aq)$$

Finding moles of HgS assuming $Hg(NO_3)_2$ is limiting: Combining the steps gives

$$\text{Moles of HgS} = 0.050\ \text{L soln} \times \frac{0.010\ \text{mol Hg(NO}_3\text{)}_2}{1\ \text{L soln}} \times \frac{1\ \text{mol HgS}}{1\ \text{mol Hg(NO}_3\text{)}_2}$$
$$= \mathbf{5.0\times10^{-4}\ mol\ HgS}$$

Finding moles of HgS assuming Na_2S is limiting: Combining the steps gives

$$\text{Moles of HgS} = 0.020\ \text{L soln} \times \frac{0.10\ \text{mol Na}_2\text{S}}{1\ \text{L soln}} \times \frac{1\ \text{mol HgS}}{1\ \text{mol Na}_2\text{S}}$$
$$= \mathbf{2.0\times10^{-3}\ mol\ HgS}$$

$Hg(NO_3)_2$ is the limiting reactant because it forms fewer moles of HgS. Converting the moles of HgS formed from $Hg(NO_3)_2$ to grams:

$$\text{Mass (g) of HgS} = 5.0\times10^{-4}\ \text{mol HgS} \times \frac{232.7\ \text{g HgS}}{1\ \text{mol HgS}}$$
$$= 0.12\ \text{g HgS}$$

Check As a check, let's use the alternative method for finding the limiting reactant (see Comment in Sample Problem 3.11, p. 113). Finding moles of reactants available:

$$\text{Moles of } Hg(NO_3)_2 = 0.050 \cancel{\text{ L soln}} \times \frac{0.010 \text{ mol } Hg(NO_3)_2}{1 \cancel{\text{ L soln}}} = 5.0\times10^{-4} \text{ mol } Hg(NO_3)_2$$

$$\text{Moles of } Na_2S = 0.020 \cancel{\text{ L soln}} \times \frac{0.10 \text{ mol } Na_2S}{1 \cancel{\text{ L soln}}} = 2.0\times10^{-3} \text{ mol } Na_2S$$

The molar ratio of the reactants is 1 $Hg(NO_3)_2$/1 Na_2S. Therefore, $Hg(NO_3)_2$ is limiting because there are fewer moles of it than are needed to react with the moles of Na_2S. Finding grams of product from moles of limiting reactant and the molar ratio:

$$\text{Mass (g) of HgS} = 5.0\times10^{-4} \cancel{\text{ mol } Hg(NO_3)_2} \times \frac{1 \cancel{\text{ mol HgS}}}{1 \cancel{\text{ mol } Hg(NO_3)_2}} \times \frac{232.7 \text{ g HgS}}{1 \cancel{\text{ mol HgS}}}$$

$$= 0.12 \text{ g HgS}$$

FOLLOW-UP PROBLEM 3.17 Even though gasoline sold in the United States no longer contains lead, this metal persists in the environment as a poison. Despite their toxicity, many compounds of lead are still used to make pigments.

(a) What volume of 1.50 *M* lead(II) acetate contains 0.400 mol of Pb^{2+} ions?

(b) When this volume reacts with 125 mL of 3.40 *M* sodium chloride, how many grams of solid lead(II) chloride can form? (Sodium acetate solution also forms.)

SECTION SUMMARY

When reactions occur in solution, reactant and product amounts are given in terms of concentration and volume. Molarity is the number of moles of solute dissolved in one liter of solution. Using molarity as a conversion factor, we apply the principles of stoichiometry to all aspects of reactions in solution.

Chapter Perspective

You apply the mole concept every time you weigh a substance, dissolve it, or think about how much of it will react. Figure 3.15 combines the individual stoichiometry summary diagrams into one overall review diagram. Use it for homework, to study for exams, or to obtain an overview of the various ways that the amounts involved in a reaction are interrelated. We apply stoichiometry next to some of the most important types of chemical reactions (Chapter 4), to systems of reacting gases (Chapter 5), and to the heat involved in a reaction (Chapter 6). These concepts and skills appear at many places later in the text as well.

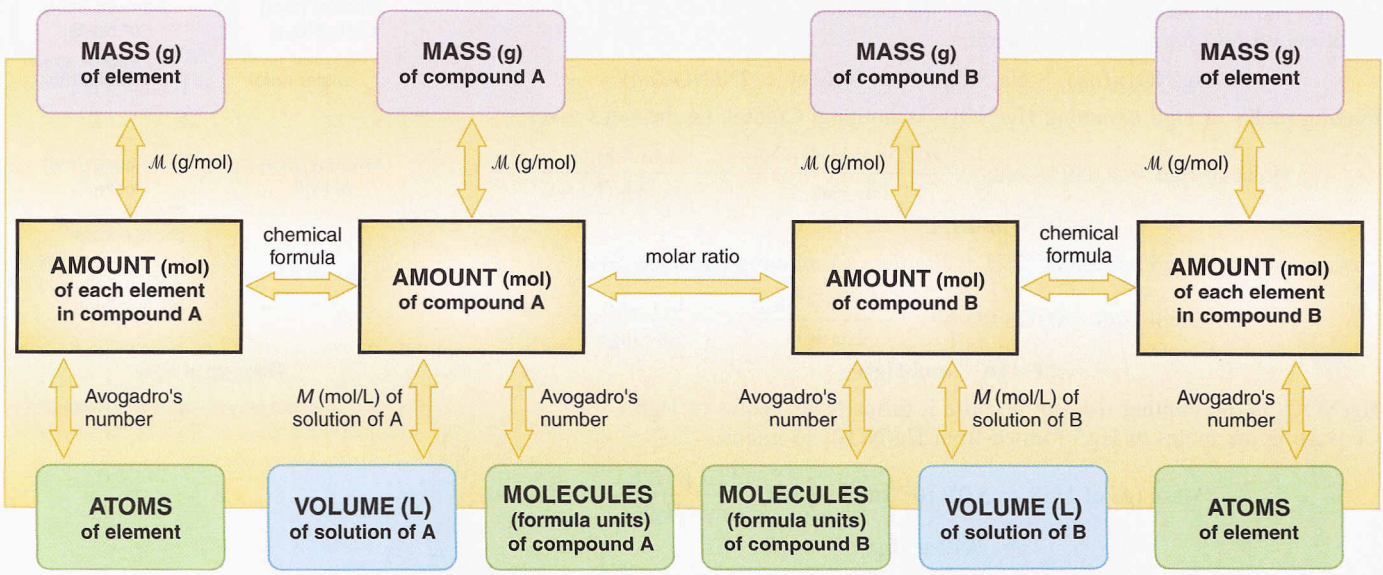


Figure 3.15 **An overview of the key mass-mole-number stoichiometric relationships.**

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The meaning and usefulness of the mole (3.1)
2. The relation between molecular (or formula) mass and molar mass (3.1)
3. The relations among amount of substance (in moles), mass (in grams), and number of chemical entities (3.1)
4. The information in a chemical formula (3.1)
5. The procedure for finding the empirical and molecular formulas of a compound (3.2)
6. How more than one substance can have the same empirical formula and the same molecular formula (isomers) (3.2)
7. The importance of balancing equations for the quantitative study of chemical reactions (3.3)
8. The mole-mass-number information in a balanced equation (3.4)
9. The relation between amounts of reactants and products (3.4)
10. Why one reactant limits the yield of product (3.4)
11. The causes of lower-than-expected yields and the distinction between theoretical and actual yields (3.4)
12. The meanings of concentration and molarity (3.5)
13. The effect of dilution on the concentration of solute (3.5)
14. How reactions in solution differ from those of pure reactants (3.5)

Master These Skills

1. Calculating the molar mass of any substance (3.1; also SPs 3.2, 3.3)
2. Converting between amount of substance (in moles), mass (in grams), and number of chemical entities (SPs 3.1, 3.2)
3. Using mass percent to find the mass of element in a given mass of compound (SP 3.3)
4. Determining empirical and molecular formulas of a compound from mass percent and molar mass of elements (SPs 3.4, 3.5)
5. Determining a molecular formula from combustion analysis (SP 3.6)
6. Converting a chemical statement into a balanced equation (SP 3.7)
7. Using stoichiometrically equivalent molar ratios to calculate amounts of reactants and products in reactions of pure and dissolved substances (SPs 3.8, 3.16)
8. Writing an overall equation from a series of equations (SP 3.9)
9. Solving limiting-reactant problems from molecular depictions and for reactions of pure and dissolved substances (SPs 3.10, 3.11, 3.17)
10. Calculating percent yield (SP 3.12)
11. Calculating molarity and the mass of solute in solution (SPs 3.13, 3.14)
12. Preparing a dilute solution from a concentrated one (SP 3.15)

Key Equations and Relationships

3.1 Number of entities in one mole (87):

$$1 \text{ mole contains } 6.022\times10^{23} \text{ entities (to 4 sf)}$$

3.2 Converting amount (mol) to mass using $\mathcal{M}$ (90):

$$\text{Mass (g)} = \text{no. of moles} \times \frac{\text{no. of grams}}{1 \text{ mol}}$$

3.3 Converting mass to amount (mol) using $1/\mathcal{M}$ (90):

$$\text{No. of moles} = \text{mass (g)} \times \frac{1 \text{ mol}}{\text{no. of grams}}$$

3.4 Converting amount (mol) to number of entities (90):

$$\text{No. of entities} = \text{no. of moles} \times \frac{6.022\times10^{23} \text{ entities}}{1 \text{ mol}}$$

3.5 Converting number of entities to amount (mol) (90):

$$\text{No. of moles} = \text{no. of entities} \times \frac{1 \text{ mol}}{6.022\times10^{23} \text{ entities}}$$

3.6 Calculating mass % (93):

$$\text{Mass \% of element X} = \frac{\text{moles of X in formula} \times \text{molar mass of X (g/mol)}}{\text{mass (g) of 1 mol of compound}} \times 100$$

3.7 Calculating percent yield (114):

$$\text{\% yield} = \frac{\text{actual yield}}{\text{theoretical yield}} \times 100$$

3.8 Defining molarity (117):

$$\text{Molarity} = \frac{\text{moles of solute}}{\text{liters of solution}} \quad \text{or} \quad M = \frac{\text{mol solute}}{\text{L soln}}$$

3.9 Diluting a concentrated solution (120):

$$M_{dil} \times V_{dil} = \text{number of moles} = M_{conc} \times V_{conc}$$

Highlighted Figures and Tables

F3.12 Mass-mole-number-volume relationships in solution (117)
F3.15 Overview of mass-mole-number relationships (122)

Brief Solutions to Follow-up Problems

3.1 (a) Moles of C $= 315\ \cancel{\text{mg C}} \times \dfrac{1\ \text{g}}{10^3\ \cancel{\text{mg}}} \times \dfrac{1\ \text{mol C}}{12.01\ \cancel{\text{g C}}}$
$= 2.62\times10^{-2}$ mol C

(b) Mass (g) of Mn $= 3.22\times10^{20}\ \cancel{\text{Mn atoms}} \times \dfrac{1\ \cancel{\text{mol Mn}}}{6.022\times10^{23}\ \cancel{\text{Mn atoms}}} \times \dfrac{54.94\ \text{g Mn}}{1\ \cancel{\text{mol Mn}}}$
$= 2.94\times10^{-2}$ g Mn

3.2 (a) Mass (g) of P_4O_{10}
$= 4.65\times10^{22}\ \cancel{\text{molecules } P_4O_{10}} \times \dfrac{1\ \cancel{\text{mol } P_4O_{10}}}{6.022\times10^{23}\ \cancel{\text{molecules } P_4O_{10}}} \times \dfrac{283.88\ \text{g } P_4O_{10}}{1\ \cancel{\text{mol } P_4O_{10}}}$
$= 21.9$ g P_4O_{10}

(b) No. of P atoms $= 4.65\times10^{22}\ \cancel{\text{molecules } P_4O_{10}} \times \dfrac{4\ \text{atoms P}}{1\ \cancel{\text{molecule } P_4O_{10}}}$
$= 1.86\times10^{23}$ P atoms

3.3 (a) Mass % of N $= \dfrac{2\ \cancel{\text{mol N}} \times \dfrac{14.01\ \cancel{\text{g N}}}{1\ \cancel{\text{mol N}}}}{80.05\ \cancel{\text{g } NH_4NO_3}} \times 100$
$= 35.00$ mass % N

(b) Mass (g) of N $= 35.8\ \cancel{\text{kg } NH_4NO_3} \times \dfrac{10^3\ \text{g}}{1\ \cancel{\text{kg}}} \times \dfrac{0.3500\ \text{g N}}{1\ \cancel{\text{g } NH_4NO_3}}$
$= 1.25\times10^4$ g N

3.4 Moles of S $= 2.88\ \cancel{\text{g S}} \times \dfrac{1\ \text{mol S}}{32.07\ \cancel{\text{g S}}} = 0.0898$ mol S

Moles of M $= 0.0898\ \cancel{\text{mol S}} \times \dfrac{2\ \text{mol M}}{3\ \cancel{\text{mol S}}} = 0.0599$ mol M

Molar mass of M $= \dfrac{3.12\ \text{g M}}{0.0599\ \text{mol M}} = 52.1$ g/mol

M is chromium, and M_2S_3 is chromium(III) sulfide.

3.5 Assuming 100.00 g of compound, we have 95.21 g of C and 4.79 g of H:

Moles of C $= 95.21\ \cancel{\text{g C}} \times \dfrac{1\ \text{mol C}}{12.01\ \cancel{\text{g C}}}$
$= 7.928$ mol C

Also, 4.75 mol H

Preliminary formula $= C_{7.928}H_{4.75} \approx C_{1.67}H_{1.00}$

Empirical formula $= C_5H_3$

Whole-number multiple $= \dfrac{252.30\ \cancel{\text{g/mol}}}{63.07\ \cancel{\text{g/mol}}} = 4$

Molecular formula $= C_{20}H_{12}$

3.6 Mass (g) of C $= 0.451\ \cancel{\text{g } CO_2} \times \dfrac{12.01\ \text{g C}}{44.01\ \cancel{\text{g } CO_2}}$
$= 0.123$ g C

Also, 0.00690 g H

Mass (g) of Cl $= 0.250\ \text{g} - (0.123\ \text{g} + 0.00690\ \text{g}) = 0.120$ g Cl

Moles of elements
$= 0.0102$ mol C; 0.00685 mol H; 0.00339 mol Cl

Empirical formula $= C_3H_2Cl$; multiple $= 2$

Molecular formula $= C_6H_4Cl_2$

3.7 (a) $2Na(s) + 2H_2O(l) \longrightarrow H_2(g) + 2NaOH(aq)$

(b) $2HNO_3(aq) + CaCO_3(s) \longrightarrow H_2O(l) + CO_2(g) + Ca(NO_3)_2(aq)$

(c) $PCl_3(g) + 3HF(g) \longrightarrow PF_3(g) + 3HCl(g)$

(d) $4C_3H_5N_3O_9(l) \longrightarrow 12CO_2(g) + 10H_2O(g) + 6N_2(g) + O_2(g)$

3.8 $Fe_2O_3(s) + 2Al(s) \longrightarrow Al_2O_3(s) + 2Fe(l)$

(a) Mass (g) of Fe
$= 135\ \cancel{\text{g Al}} \times \dfrac{1\ \cancel{\text{mol Al}}}{26.98\ \cancel{\text{g Al}}} \times \dfrac{2\ \cancel{\text{mol Fe}}}{2\ \cancel{\text{mol Al}}} \times \dfrac{55.85\ \text{g Fe}}{1\ \cancel{\text{mol Fe}}}$
$= 279$ g Fe

(b) No. of Al atoms $= 1.00\ \cancel{\text{g } Al_2O_3} \times \dfrac{1\ \cancel{\text{mol } Al_2O_3}}{101.96\ \cancel{\text{g } Al_2O_3}} \times \dfrac{2\ \cancel{\text{mol Al}}}{1\ \cancel{\text{mol } Al_2O_3}} \times \dfrac{6.022\times10^{23}\ \text{Al atoms}}{1\ \cancel{\text{mol Al}}}$
$= 1.18\times10^{22}$ Al atoms

3.9
$$2SO_2(g) + O_2(g) \longrightarrow \cancel{2SO_3(g)}$$
$$\cancel{2SO_3(g)} + 2H_2O(l) \longrightarrow 2H_2SO_4(aq)$$
$$2SO_2(g) + O_2(g) + 2H_2O(l) \longrightarrow 2H_2SO_4(aq)$$

3.10 (a) $2AB + B_2 \longrightarrow 2AB_2$

In the boxes, the AB/B_2 ratio is 4/3, which is less than the 2/1 ratio in the equation, so there is not enough AB and it is the limiting reactant; note that one B_2 is in excess.

(b) Moles of $AB_2 = 1.5\ \cancel{\text{mol AB}} \times \dfrac{2\ \text{mol } AB_2}{2\ \cancel{\text{mol AB}}} = 1.5$ mol AB_2

Moles of $AB_2 = 1.5\ \cancel{\text{mol } B_2} \times \dfrac{2\ \text{mol } AB_2}{1\ \cancel{\text{mol } B_2}} = 3.0$ mol AB_2

3.11 $2Al(s) + 3S(s) \longrightarrow Al_2S_3(s)$

Mass (g) of Al_2S_3 formed from Al
$= 10.0\ \cancel{\text{g Al}} \times \dfrac{1\ \cancel{\text{mol Al}}}{26.98\ \cancel{\text{g Al}}} \times \dfrac{1\ \cancel{\text{mol } Al_2S_3}}{2\ \cancel{\text{mol Al}}} \times \dfrac{150.17\ \text{g } Al_2S_3}{1\ \cancel{\text{mol } Al_2S_3}}$
$= 27.8$ g Al_2S_3

Similarly, mass (g) of Al_2S_3 formed from S $= 23.4$ g Al_2S_3.

Therefore, S is limiting reactant, and 23.4 g of Al_2S_3 can form.

Mass (g) of Al in excess
= total mass of Al − mass of Al used
= 10.0 g Al
$$- \left(15.0 \text{ g S} \times \frac{1 \text{ mol S}}{32.07 \text{ g S}} \times \frac{2 \text{ mol Al}}{3 \text{ mol S}} \times \frac{26.98 \text{ g Al}}{1 \text{ mol Al}}\right)$$
= 1.6 g Al

(We would obtain the same answer if sulfur were shown more correctly as S_8.)

3.12 $CaCO_3(s) + 2HCl(aq) \longrightarrow CaCl_2(aq) + H_2O(l) + CO_2(g)$
Theoretical yield (g) of CO_2
$$= 10.0 \text{ g } CaCO_3 \times \frac{1 \text{ mol } CaCO_3}{100.09 \text{ g } CaCO_3} \times \frac{1 \text{ mol } CO_2}{1 \text{ mol } CaCO_3} \times \frac{44.01 \text{ g } CO_2}{1 \text{ mol } CO_2} = 4.40 \text{ g } CO_2$$
$$\% \text{ yield} = \frac{3.65 \text{ g } CO_2}{4.40 \text{ g } CO_2} \times 100 = 83.0\%$$

3.13 $$\text{Moles of KI} = 84 \text{ mL soln} \times \frac{1 \text{ L}}{10^3 \text{ mL}} \times \frac{0.50 \text{ mol KI}}{1 \text{ L soln}}$$
= 0.042 mol KI

3.14 Volume (L) of soln
$$= 135 \text{ g sucrose} \times \frac{1 \text{ mol sucrose}}{342.30 \text{ g sucrose}} \times \frac{1 \text{ L soln}}{3.30 \text{ mol sucrose}}$$
= 0.120 L soln

3.15 $$M_{dil} \text{ of } H_2SO_4 = \frac{7.50\ M \times 25.0 \text{ m}^3}{500. \text{ m}^3} = 0.375\ M\ H_2SO_4$$
Mass (g) of H_2SO_4/mL soln
$$= \frac{0.375 \text{ mol } H_2SO_4}{1 \text{ L soln}} \times \frac{1 \text{ L}}{10^3 \text{ mL}} \times \frac{98.09 \text{ g } H_2SO_4}{1 \text{ mol } H_2SO_4}$$
$= 3.68 \times 10^{-2}$ g/mL soln

3.16 $Al(OH)_3(s) + 3HCl(aq) \longrightarrow AlCl_3(aq) + 3H_2O(l)$
Volume (L) of HCl consumed
$$= 0.10 \text{ g } Al(OH)_3 \times \frac{1 \text{ mol } Al(OH)_3}{78.00 \text{ g } Al(OH)_3} \times \frac{3 \text{ mol HCl}}{1 \text{ mol } Al(OH)_3} \times \frac{1 \text{ L soln}}{0.10 \text{ mol HCl}}$$
$= 3.8 \times 10^{-2}$ L soln

Therefore, $Al(OH)_3$ is more effective than $Mg(OH)_2$.

3.17 (a) Volume (L) of soln
$$= 0.400 \text{ mol } Pb^{2+} \times \frac{1 \text{ mol } Pb(C_2H_3O_2)_2}{1 \text{ mol } Pb^{2+}} \times \frac{1 \text{ L soln}}{1.50 \text{ mol } Pb(C_2H_3O_2)_2}$$
= 0.267 L soln

(b) $Pb(C_2H_3O_2)_2(aq) + 2NaCl(aq) \longrightarrow PbCl_2(s) + 2NaC_2H_3O_2(aq)$
Mass (g) of $PbCl_2$ from $Pb(C_2H_3O_2)_2$ soln = 111 g $PbCl_2$
Mass (g) of $PbCl_2$ from NaCl soln = 59.1 g $PbCl_2$
Thus, NaCl is the limiting reactant, and 59.1 g of $PbCl_2$ can form.

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

The Mole

(Sample Problems 3.1 to 3.3)

Concept Review Questions

3.1 The atomic mass of Cl is 35.45 amu, and the atomic mass of Al is 26.98 amu. What are the masses in grams of 2 mol of Al atoms and of 3 mol of Cl atoms?

3.2 (a) How many moles of C atoms are in 1 mol of sucrose ($C_{12}H_{22}O_{11}$)?
(b) How many C atoms are in 1 mol of sucrose?

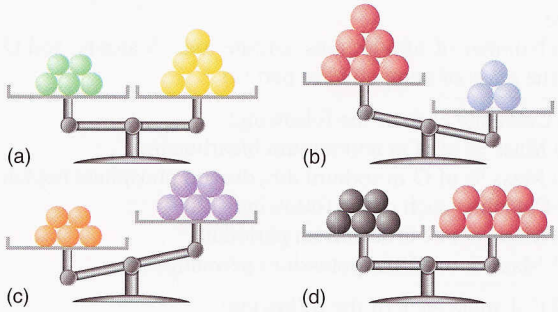
3.3 Why might the expression "1 mol of nitrogen" be confusing? What change would remove any uncertainty? For what other elements might a similar confusion exist? Why?

3.4 How is the molecular mass of a compound the same as the molar mass, and how is it different?

3.5 What advantage is there to using a counting unit (the mole) in chemistry rather than a mass unit?

3.6 You need to calculate the number of P_4 molecules that can form from 2.5 g of $Ca_3(PO_4)_2$. Explain how you would proceed. (That is, write a solution "Plan," without actually doing any calculations.)

3.7 Each of the following balances weighs the indicated numbers of atoms of two elements:



Which element—left, right, or neither,
(a) Has the higher molar mass?
(b) Has more atoms per gram?
(c) Has fewer atoms per gram?
(d) Has more atoms per mole?

Skill-Building Exercises *(grouped in similar pairs)*

3.8 Calculate the molar mass of each of the following:
(a) $Sr(OH)_2$ (b) N_2O (c) $NaClO_3$ (d) Cr_2O_3

3.9 Calculate the molar mass of each of the following:
(a) $(NH_4)_3PO_4$ (b) CH_2Cl_2 (c) $CuSO_4 \cdot 5H_2O$ (d) BrF_5

3.10 Calculate the molar mass of each of the following:
(a) SnO_2 (b) BaF_2 (c) $Al_2(SO_4)_3$ (d) $MnCl_2$

3.11 Calculate the molar mass of each of the following:
(a) N_2O_4 (b) C_8H_{10} (c) $MgSO_4 \cdot 7H_2O$ (d) $Ca(C_2H_3O_2)_2$

3.12 Calculate each of the following quantities:
(a) Mass in grams of 0.57 mol of $KMnO_4$
(b) Moles of O atoms in 8.18 g of $Mg(NO_3)_2$
(c) Number of O atoms in 8.1×10^{-3} g of $CuSO_4\cdot5H_2O$

3.13 Calculate each of the following quantities:
(a) Mass in kilograms of 3.8×10^{20} molecules of NO_2
(b) Moles of Cl atoms in 0.0425 g of $C_2H_4Cl_2$
(c) Number of H^- ions in 4.92 g of SrH_2

3.14 Calculate each of the following quantities:
(a) Mass in grams of 0.64 mol of $MnSO_4$
(b) Moles of compound in 15.8 g of $Fe(ClO_4)_3$
(c) Number of N atoms in 92.6 g of NH_4NO_2

3.15 Calculate each of the following quantities:
(a) Total number of ions in 38.1 g of CaF_2
(b) Mass in milligrams of 3.58 mol of $CuCl_2\cdot2H_2O$
(c) Mass in kilograms of 2.88×10^{22} formula units of $Bi(NO_3)_3\cdot5H_2O$

3.16 Calculate each of the following quantities:
(a) Mass in grams of 8.41 mol of copper(I) carbonate
(b) Mass in grams of 2.04×10^{21} molecules of dinitrogen pentaoxide
(c) Number of moles and formula units in 57.9 g of sodium perchlorate
(d) Number of sodium ions, perchlorate ions, Cl atoms, and O atoms in the mass of compound in part (c)

3.17 Calculate each of the following quantities:
(a) Mass in grams of 3.52 mol of chromium(III) sulfate decahydrate
(b) Mass in grams of 9.64×10^{24} molecules of dichlorine heptaoxide
(c) Number of moles and formula units in 56.2 g of lithium sulfate
(d) Number of lithium ions, sulfate ions, S atoms, and O atoms in the mass of compound in part (c)

3.18 Calculate each of the following:
(a) Mass % of H in ammonium bicarbonate
(b) Mass % of O in sodium dihydrogen phosphate heptahydrate

3.19 Calculate each of the following:
(a) Mass % of I in strontium periodate
(b) Mass % of Mn in potassium permanganate

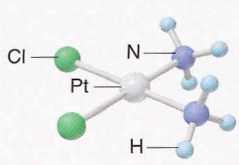
3.20 Calculate each of the following:
(a) Mass fraction of C in cesium acetate
(b) Mass fraction of O in uranyl sulfate trihydrate (the uranyl ion is UO_2^{2+})

3.21 Calculate each of the following:
(a) Mass fraction of Cl in calcium chlorate
(b) Mass fraction of P in tetraphosphorus hexaoxide

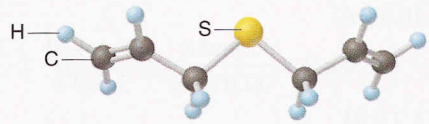
Problems in Context

3.22 Oxygen is required for the metabolic combustion of foods. Calculate the number of atoms in 38.0 g of oxygen gas, the amount absorbed from the lungs at rest in about 15 minutes.

3.23 Cisplatin *(right)*, or Platinol, is a powerful drug used in the treatment of certain cancers. Calculate (a) the moles of compound in 285.3 g of cisplatin; (b) the number of hydrogen atoms in 0.98 mol of cisplatin.



3.24 Allyl sulfide *(below)* gives garlic its characteristic odor.



Calculate (a) the mass in grams of 1.63 mol of allyl sulfide; (b) the number of carbon atoms in 4.77 g of allyl sulfide.

3.25 Iron reacts slowly with oxygen and water to form a compound commonly called rust ($Fe_2O_3\cdot4H_2O$). For 65.2 kg of rust, calculate (a) the moles of compound; (b) the moles of Fe_2O_3; (c) the grams of iron.

3.26 Propane is widely used in liquid form as a fuel for barbecue grills and camp stoves. For 75.3 g of propane, calculate (a) the moles of compound; (b) the grams of carbon.

3.27 The effectiveness of a nitrogen fertilizer is determined mainly by its mass % N. Rank the following fertilizers in terms of their effectiveness: potassium nitrate; ammonium nitrate; ammonium sulfate; urea, $CO(NH_2)_2$.

3.28 The mineral galena is composed of lead(II) sulfide and has an average density of 7.46 g/cm^3. (a) How many moles of lead(II) sulfide are in 1.00 ft^3 of galena? (b) How many lead atoms are in 1.00 dm^3 of galena?

3.29 Hemoglobin, a protein in red blood cells, carries O_2 from the lungs to the body's cells. Iron (as ferrous ion, Fe^{2+}) makes up 0.33 mass % of hemoglobin. If the molar mass of hemoglobin is 6.8×10^4 g/mol, how many Fe^{2+} ions are in one molecule?

Determining the Formula of an Unknown Compound

(Sample Problems 3.4 to 3.6)

Concept Review Questions

3.30 List three ways compositional data may be given in a problem that involves finding an empirical formula.

3.31 Which of the following sets of information allows you to obtain the molecular formula of a covalent compound? In each case that allows it, explain how you would proceed (write a solution "Plan").
(a) Number of moles of each type of atom in a given sample of the compound
(b) Mass % of each element and the total number of atoms in a molecule of the compound
(c) Mass % of each element and the number of atoms of one element in a molecule of the compound
(d) Empirical formula and the mass % of each element in the compound
(e) Structural formula of the compound

3.32 Is $MgCl_2$ an empirical or a molecular formula for magnesium chloride? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

3.33 What is the empirical formula and empirical formula mass for each of the following compounds?
(a) C_2H_4 (b) $C_2H_6O_2$ (c) N_2O_5 (d) $Ba_3(PO_4)_2$ (e) Te_4I_{16}

3.34 What is the empirical formula and empirical formula mass for each of the following compounds?
(a) C_4H_8 (b) $C_3H_6O_3$ (c) P_4O_{10} (d) $Ga_2(SO_4)_3$ (e) Al_2Br_6

3.35 What is the molecular formula of each compound?
(a) Empirical formula CH_2 ($\mathcal{M}$ = 42.08 g/mol)
(b) Empirical formula NH_2 ($\mathcal{M}$ = 32.05 g/mol)

(c) Empirical formula NO_2 ($\mathcal{M}$ = 92.02 g/mol)
(d) Empirical formula CHN ($\mathcal{M}$ = 135.14 g/mol)

3.36 What is the molecular formula of each compound?
(a) Empirical formula CH ($\mathcal{M}$ = 78.11 g/mol)
(b) Empirical formula $C_3H_6O_2$ ($\mathcal{M}$ = 74.08 g/mol)
(c) Empirical formula HgCl ($\mathcal{M}$ = 472.1 g/mol)
(d) Empirical formula $C_7H_4O_2$ ($\mathcal{M}$ = 240.20 g/mol)

3.37 Determine the empirical formula of each of the following compounds:
(a) 0.063 mol of chlorine atoms combined with 0.22 mol of oxygen atoms
(b) 2.45 g of silicon combined with 12.4 g of chlorine
(c) 27.3 mass % carbon and 72.7 mass % oxygen

3.38 Determine the empirical formula of each of the following compounds:
(a) 0.039 mol of iron atoms combined with 0.052 mol of oxygen atoms
(b) 0.903 g of phosphorus combined with 6.99 g of bromine
(c) A hydrocarbon with 79.9 mass % carbon

3.39 An oxide of nitrogen contains 30.45 mass % N. (a) What is the empirical formula of the oxide? (b) If the molar mass is 90 ± 5 g/mol, what is the molecular formula?

3.40 A chloride of silicon contains 79.1 mass % Cl. (a) What is the empirical formula of the chloride? (b) If the molar mass is 269 g/mol, what is the molecular formula?

3.41 A sample of 0.600 mol of a metal M reacts completely with excess fluorine to form 46.8 g of MF_2.
(a) How many moles of F are in the sample of MF_2 that forms?
(b) How many grams of M are in this sample of MF_2?
(c) What element is represented by the symbol M?

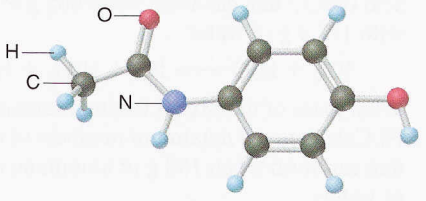
3.42 A sample of 0.370 mol of a metal oxide (M_2O_3) weighs 55.4 g.
(a) How many moles of O are in the sample?
(b) How many grams of M are in the sample?
(c) What element is represented by the symbol M?

Problems in Context

3.43 Nicotine is a poisonous, addictive compound found in tobacco. A sample of nicotine contains 6.16 mmol of C, 8.56 mmol of H, and 1.23 mmol of N [1 mmol (1 millimole) = 10^{-3} mol]. What is the empirical formula?

3.44 Cortisol ($\mathcal{M}$ = 362.47 g/mol), one of the major steroid hormones, is a key factor in the synthesis of protein. Its profound effect on the reduction of inflammation explains its use in the treatment of rheumatoid arthritis. Cortisol is 69.6% C, 8.34% H, and 22.1% O by mass. What is its molecular formula?

3.45 Acetaminophen *(right)* is a popular nonaspirin, "over-the-counter" pain reliever. What is the mass % of each element in acetaminophen?



3.46 Menthol ($\mathcal{M}$ = 156.3 g/mol), a strong-smelling substance used in cough drops, is a compound of carbon, hydrogen, and oxygen. When 0.1595 g of menthol was subjected to combustion analysis, it produced 0.449 g of CO_2 and 0.184 g of H_2O. What is menthol's molecular formula?

Writing and Balancing Chemical Equations

(Sample Problem 3.7)

Concept Review Questions

3.47 What three types of information does a balanced chemical equation provide? How?

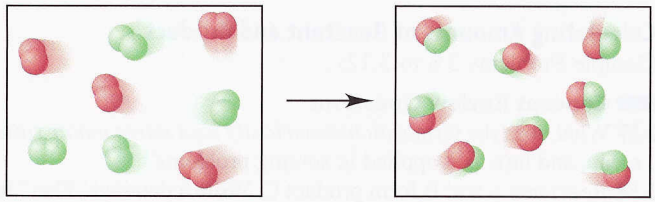
3.48 How does a balanced chemical equation apply the law of conservation of mass?

3.49 In the process of balancing the equation

$$Al + Cl_2 \longrightarrow AlCl_3$$

Student I writes: $Al + Cl_2 \longrightarrow AlCl_2$
Student II writes: $Al + Cl_2 + Cl \longrightarrow AlCl_3$
Student III writes: $2Al + 3Cl_2 \longrightarrow 2AlCl_3$
Is the approach of Student I valid? Student II? Student III? Explain.

3.50 The boxes below represent a chemical reaction between elements A (red) and B (green):



Which of the following best represents the balanced equation for the reaction?
(a) $2A + 2B \longrightarrow A_2 + B_2$ (b) $A_2 + B_2 \longrightarrow 2AB$
(c) $B_2 + 2AB \longrightarrow 2B_2 + A_2$ (d) $4A_2 + 4B_2 \longrightarrow 8AB$

Skill-Building Exercises *(grouped in similar pairs)*

3.51 Write balanced equations for each of the following by inserting the correct coefficients in the blanks:
(a) $__Cu(s) + __S_8(s) \longrightarrow __Cu_2S(s)$
(b) $__P_4O_{10}(s) + __H_2O(l) \longrightarrow __H_3PO_4(l)$
(c) $__B_2O_3(s) + __NaOH(aq) \longrightarrow __Na_3BO_3(aq) + __H_2O(l)$
(d) $__CH_3NH_2(g) + __O_2(g) \longrightarrow __CO_2(g) + __H_2O(g) + __N_2(g)$

3.52 Write balanced equations for each of the following by inserting the correct coefficients in the blanks:
(a) $__Cu(NO_3)_2(aq) + __KOH(aq) \longrightarrow __Cu(OH)_2(s) + __KNO_3(aq)$
(b) $__BCl_3(g) + __H_2O(l) \longrightarrow __H_3BO_3(s) + __HCl(g)$
(c) $__CaSiO_3(s) + __HF(g) \longrightarrow __SiF_4(g) + __CaF_2(s) + __H_2O(l)$
(d) $__(CN)_2(g) + __H_2O(l) \longrightarrow __H_2C_2O_4(aq) + __NH_3(g)$

3.53 Write balanced equations for each of the following by inserting the correct coefficients in the blanks:
(a) $__SO_2(g) + __O_2(g) \longrightarrow __SO_3(g)$
(b) $__Sc_2O_3(s) + __H_2O(l) \longrightarrow __Sc(OH)_3(s)$
(c) $__H_3PO_4(aq) + __NaOH(aq) \longrightarrow __Na_2HPO_4(aq) + __H_2O(l)$
(d) $__C_6H_{10}O_5(s) + __O_2(g) \longrightarrow __CO_2(g) + __H_2O(g)$

3.54 Write balanced equations for each of the following by inserting the correct coefficients in the blanks:
(a) $__As_4S_6(s) + __O_2(g) \longrightarrow __As_4O_6(s) + __SO_2(g)$
(b) $__Ca_3(PO_4)_2(s) + __SiO_2(s) + __C(s) \longrightarrow __P_4(g) + __CaSiO_3(l) + __CO(g)$
(c) $__Fe(s) + __H_2O(g) \longrightarrow __Fe_3O_4(s) + __H_2(g)$
(d) $__S_2Cl_2(l) + __NH_3(g) \longrightarrow __S_4N_4(s) + __S_8(s) + __NH_4Cl(s)$

3.55 Convert the following into balanced equations:
(a) When gallium metal is heated in oxygen gas, it melts and forms solid gallium(III) oxide.
(b) Liquid hexane burns in oxygen gas to form carbon dioxide gas and water vapor.
(c) When solutions of calcium chloride and sodium phosphate are mixed, solid calcium phosphate forms and sodium chloride remains in solution.

3.56 Convert the following into balanced equations:
(a) When lead(II) nitrate solution is added to potassium iodide solution, solid lead(II) iodide forms and potassium nitrate solution remains.
(b) Liquid disilicon hexachloride reacts with water to form solid silicon dioxide, hydrogen chloride gas, and hydrogen gas.
(c) When nitrogen dioxide is bubbled into water, a solution of nitric acid forms and gaseous nitrogen monoxide is released.

Calculating Amounts of Reactant and Product

(Sample Problems 3.8 to 3.12)

Concept Review Questions

3.57 What does the term *stoichiometrically equivalent molar ratio* mean, and how is it applied in solving problems?

3.58 Reactants A and B form product C. Write a detailed "Plan" to find the mass of C when 5 g of A reacts with excess B.

3.59 Reactants D and E form product F. Write a detailed "Plan" to find the mass of F when 17 g of D reacts with 11 g of E.

3.60 Percent yields are generally calculated from mass quantities. Would the result be the same if mole quantities were used instead? Why?

Skill-Building Exercises *(grouped in similar pairs)*

3.61 Chlorine gas can be made in the laboratory by the reaction of hydrochloric acid and manganese(IV) oxide:

$$4HCl(aq) + MnO_2(s) \longrightarrow MnCl_2(aq) + 2H_2O(g) + Cl_2(g)$$

When 1.82 mol of HCl reacts with excess MnO_2, (a) how many moles of Cl_2 form? (b) How many grams of Cl_2 form?

3.62 Bismuth oxide reacts with carbon to form bismuth metal:

$$Bi_2O_3(s) + 3C(s) \longrightarrow 2Bi(s) + 3CO(g)$$

When 352 g of Bi_2O_3 reacts with excess carbon, (a) how many moles of Bi_2O_3 react? (b) How many moles of Bi form?

3.63 Potassium nitrate decomposes on heating, producing potassium oxide and gaseous nitrogen and oxygen:

$$4KNO_3(s) \longrightarrow 2K_2O(s) + 2N_2(g) + 5O_2(g)$$

To produce 88.6 kg of oxygen, how many (a) moles of KNO_3 must be heated? (b) Grams of KNO_3 must be heated?

3.64 Chromium(III) oxide reacts with hydrogen sulfide (H_2S) gas to form chromium(III) sulfide and water:

$$Cr_2O_3(s) + 3H_2S(g) \longrightarrow Cr_2S_3(s) + 3H_2O(l)$$

To produce 421 g of Cr_2S_3, (a) how many moles of Cr_2O_3 are required? (b) How many grams of Cr_2O_3 are required?

3.65 Calculate the mass of each product formed when 33.61 g of diborane (B_2H_6) reacts with excess water:

$$B_2H_6(g) + H_2O(l) \longrightarrow H_3BO_3(s) + H_2(g) \text{ [unbalanced]}$$

3.66 Calculate the mass of each product formed when 174 g of silver sulfide reacts with excess hydrochloric acid:

$$Ag_2S(s) + HCl(aq) \longrightarrow AgCl(s) + H_2S(g) \text{ [unbalanced]}$$

3.67 Elemental phosphorus occurs as tetratomic molecules, P_4. What mass of chlorine gas is needed to react completely with 355 g of phosphorus to form phosphorus pentachloride?

3.68 Elemental sulfur occurs as octatomic molecules, S_8. What mass of fluorine gas is needed to react completely with 17.8 g of sulfur to form sulfur hexafluoride?

3.69 Solid iodine trichloride is prepared by reaction between solid iodine and gaseous chlorine to form iodine monochloride crystals, followed by treatment with additional chlorine.
(a) Write a balanced equation for each step.
(b) Write an overall balanced equation for the formation of iodine trichloride.
(c) How many grams of iodine are needed to prepare 31.4 kg of final product?

3.70 Lead can be prepared from galena [lead(II) sulfide] by first roasting the galena in oxygen gas to form lead(II) oxide and sulfur dioxide. Heating the metal oxide with more galena forms the molten metal and more sulfur dioxide.
(a) Write a balanced equation for each step.
(b) Write an overall balanced equation for the process.
(c) How many metric tons of sulfur dioxide form for every metric ton of lead obtained?

3.71 Many metals react with oxygen gas to form the metal oxide. For example, calcium reacts as follows:

$$2Ca(s) + O_2(g) \longrightarrow 2CaO(s)$$

You wish to calculate the mass of calcium oxide that can be prepared from 4.20 g of Ca and 2.80 g of O_2.
(a) How many moles of CaO can be produced from the given mass of Ca?
(b) How many moles of CaO can be produced from the given mass of O_2?
(c) Which is the limiting reactant?
(d) How many grams of CaO can be produced?

3.72 Metal hydrides react with water to form hydrogen gas and the metal hydroxide. For example,

$$SrH_2(s) + 2H_2O(l) \longrightarrow Sr(OH)_2(s) + 2H_2(g)$$

You wish to calculate the mass of hydrogen gas that can be prepared from 5.63 g of SrH_2 and 4.80 g of H_2O.
(a) How many moles of H_2 can be produced from the given mass of SrH_2?
(b) How many moles of H_2 can be produced from the given mass of H_2O?
(c) Which is the limiting reactant?
(d) How many grams of H_2 can be produced?

3.73 Calculate the maximum numbers of moles and grams of iodic acid (HIO_3) that can form when 685 g of iodine trichloride reacts with 117.4 g of water:

$$ICl_3 + H_2O \longrightarrow ICl + HIO_3 + HCl \text{ [unbalanced]}$$

What mass of the excess reactant remains?

3.74 Calculate the maximum numbers of moles and grams of H_2S that can form when 158 g of aluminum sulfide reacts with 131 g of water:

$$Al_2S_3 + H_2O \longrightarrow Al(OH)_3 + H_2S \text{ [unbalanced]}$$

What mass of the excess reactant remains?

3.75 When 0.100 mol of carbon is burned in a closed vessel with 8.00 g of oxygen, how many grams of carbon dioxide can form?

Which reactant is in excess, and how many grams of it remain after the reaction?

3.76 A mixture of 0.0359 g of hydrogen and 0.0175 mol of oxygen in a closed container is sparked to initiate a reaction. How many grams of water can form? Which reactant is in excess, and how many grams of it remain after the reaction?

3.77 Aluminum nitrite and ammonium chloride react to form aluminum chloride, nitrogen, and water. What mass of each substance is present after 62.5 g of aluminum nitrite and 54.6 g of ammonium chloride react completely?

3.78 Calcium nitrate and ammonium fluoride react to form calcium fluoride, dinitrogen monoxide, and water vapor. What mass of each substance is present after 16.8 g of calcium nitrate and 17.50 g of ammonium fluoride react completely?

3.79 Two successive reactions, A $\longrightarrow$ B and B $\longrightarrow$ C, have yields of 82% and 65%, respectively. What is the overall percent yield for conversion of A to C?

3.80 Two successive reactions, D $\longrightarrow$ E and E $\longrightarrow$ F, have yields of 48% and 73%, respectively. What is the overall percent yield for conversion of D to F?

3.81 What is the percent yield of a reaction in which 41.5 g of tungsten(VI) oxide (WO_3) reacts with excess hydrogen gas to produce metallic tungsten and 9.50 mL of water ($d = 1.00$ g/mL)?

3.82 What is the percent yield of a reaction in which 200. g of phosphorus trichloride reacts with excess water to form 128 g of HCl and aqueous phosphorous acid (H_3PO_3)?

3.83 When 18.5 g of methane and 43.0 g of chlorine gas undergo a reaction that has an 80.0% yield, what mass of chloromethane (CH_3Cl) forms? Hydrogen chloride also forms.

3.84 When 56.6 g of calcium and 30.5 g of nitrogen gas undergo a reaction that has a 93.0% yield, what mass of calcium nitride forms?

Problems in Context

3.85 Cyanogen, $(CN)_2$, has been observed in the atmosphere of Titan, Saturn's largest moon, and in the gases of interstellar nebulas. On Earth, it is used as a welding gas and a fumigant. In its reaction with fluorine gas, carbon tetrafluoride and nitrogen trifluoride gases are produced. What mass of carbon tetrafluoride forms when 80.0 g of each reactant is used?

3.86 An intermediate step in the industrial production of nitric acid involves the reaction of ammonia with oxygen gas to form nitrogen monoxide and water. How many grams of nitrogen monoxide can form by the reaction of 466 g of ammonia with 812 g of oxygen?

3.87 Gaseous butane is compressed and used as a liquid fuel in disposable cigarette lighters and lightweight camping stoves. Suppose a lighter contains 6.50 mL of butane ($d = 0.579$ g/mL).
(a) How many grams of oxygen are needed to burn the butane completely?
(b) How many moles of CO_2 form when all the butane burns?
(c) How many total molecules of gas form when the butane burns completely?

3.88 Sodium borohydride ($NaBH_4$) is used industrially in many organic syntheses. One way to prepare it is by reacting sodium hydride with gaseous diborane (B_2H_6). Assuming a 95.5% yield, how many grams of $NaBH_4$ can be prepared by reacting 7.88 g of sodium hydride and 8.12 g of diborane?

Fundamentals of Solution Stoichiometry

(Sample Problems 3.13 to 3.17)

Concept Review Questions

3.89 Box A represents a unit volume of a solution. Choose from boxes B and C the one representing the same unit volume of solution that has (a) more solute added; (b) more solvent added; (c) higher molarity; (d) lower concentration.

3.90 Given the volume and molarity of a $CaCl_2$ solution, how do you determine the number of moles and the mass of solute?

3.91 Are the following instructions for diluting a 10.0 *M* solution to a 1.00 *M* solution correct: "Take 100.0 mL of the 10.0 *M* solution and add 900.0 mL water"? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

3.92 Calculate each of the following quantities:
(a) Grams of solute in 175.8 mL of 0.207 *M* calcium acetate
(b) Molarity of 500. mL of solution containing 21.1 g of potassium iodide
(c) Moles of solute in 145.6 L of 0.850 *M* sodium cyanide

3.93 Calculate each of the following quantities:
(a) Volume in liters of 2.26 *M* potassium hydroxide that contains 8.42 g of solute
(b) Number of Cu^{2+} ions in 52 L of 2.3 *M* copper(II) chloride
(c) Molarity of 275 mL of solution containing 135 mmol of glucose

3.94 Calculate each of the following quantities:
(a) Grams of solute needed to make 475 mL of 5.62×10^{-2} *M* potassium sulfate
(b) Molarity of a solution that contains 6.55 mg of calcium chloride in each milliliter
(c) Number of Mg^{2+} ions in each milliliter of 0.184 *M* magnesium bromide

3.95 Calculate each of the following quantities:
(a) Molarity of the solution resulting from dissolving 46.0 g of silver nitrate in enough water to give a final volume of 335 mL
(b) Volume in liters of 0.385 *M* manganese(II) sulfate that contains 57.0 g of solute
(c) Volume in milliliters of 6.44×10^{-2} *M* adenosine triphosphate (ATP) that contains 1.68 mmol of ATP

3.96 Calculate each of the following quantities:
(a) Molarity of a solution prepared by diluting 37.00 mL of 0.250 *M* potassium chloride to 150.00 mL
(b) Molarity of a solution prepared by diluting 25.71 mL of 0.0706 *M* ammonium sulfate to 500.00 mL
(c) Molarity of sodium ion in a solution made by mixing 3.58 mL of 0.288 *M* sodium chloride with 500. mL of 6.51×10^{-3} *M* sodium sulfate (assume volumes are additive)

3.97 Calculate each of the following quantities:
(a) Volume of 2.050 *M* copper(II) nitrate that must be diluted with water to prepare 750.0 mL of a 0.8543 *M* solution
(b) Volume of 1.03 *M* calcium chloride that must be diluted with water to prepare 350. mL of a 2.66×10^{-2} *M* chloride ion solution
(c) Final volume of a 0.0700 *M* solution prepared by diluting 18.0 mL of 0.155 *M* lithium carbonate with water

3.98 A sample of concentrated nitric acid has a density of 1.41 g/mL and contains 70.0% HNO_3 by mass.
(a) What mass of HNO_3 is present per liter of solution?
(b) What is the molarity of the solution?

3.99 Concentrated sulfuric acid (18.3 *M*) has a density of 1.84 g/mL.
(a) How many moles of sulfuric acid are present per milliliter of solution?
(b) What is the mass % of H_2SO_4 in the solution?

3.100 How many milliliters of 0.383 *M* HCl are needed to react with 16.2 g of $CaCO_3$?

$$2HCl(aq) + CaCO_3(s) \longrightarrow CaCl_2(aq) + CO_2(g) + H_2O(l)$$

3.101 How many grams of NaH_2PO_4 are needed to react with 38.74 mL of 0.275 *M* NaOH?

$$NaH_2PO_4(s) + 2NaOH(aq) \longrightarrow Na_3PO_4(aq) + 2H_2O(l)$$

3.102 How many grams of solid barium sulfate form when 25.0 mL of 0.160 *M* barium chloride reacts with 68.0 mL of 0.055 *M* sodium sulfate? Aqueous sodium chloride is the other product.

3.103 Which reactant is in excess and by how many moles when 350.0 mL of 0.210 *M* sulfuric acid reacts with 0.500 L of 0.196 *M* sodium hydroxide to form water and aqueous sodium sulfate?

Problems in Context

3.104 Ordinary household bleach is an aqueous solution of sodium hypochlorite. What is the molarity of a bleach solution that contains 20.5 g of sodium hypochlorite in a total volume of 375 mL?

3.105 Muriatic acid, an industrial grade of concentrated HCl, is used to clean masonry and etch cement for painting. Its concentration is 11.7 *M*.
(a) Write instructions for diluting the concentrated acid to make 5.0 gallons of 3.5 *M* acid for routine use (1 gal = 4 qt; 1 qt = 0.946 L).
(b) How many milliliters of the muriatic acid solution contain 9.55 g of HCl?

3.106 A sample of impure magnesium was analyzed by allowing it to react with excess HCl solution:

$$Mg(s) + 2HCl(aq) \longrightarrow MgCl_2(aq) + H_2(g)$$

After 1.32 g of the impure metal was treated with 0.100 L of 0.750 *M* HCl, 0.0125 mol of HCl remained. Assuming the impurities do not react with the acid, what is the mass % of Mg in the sample?

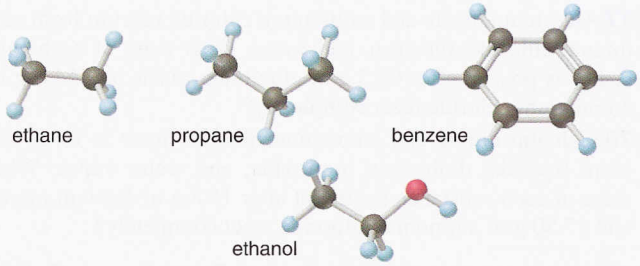
Comprehensive Problems

3.107 The mole is defined in terms of the carbon-12 atom. Use the definition to find (a) the mass in grams equal to 1 atomic mass unit; (b) the ratio of the gram to the atomic mass unit.

3.108 The study of sulfur-nitrogen compounds is an active area of chemical research, made more so by the discovery in the early 1980s of one such compound that conducts electricity like a metal. The first sulfur-nitrogen compound was prepared in 1835 and serves today as a reactant for preparing many of the others. Mass spectrometry of the compound shows a molar mass of 184.27 g/mol, and analysis shows it to contain 2.288 g of S for every 1.000 g of N. What is its molecular formula?

3.109 Narceine is a narcotic in opium. It crystallizes from water solution as a hydrate that contains 10.8 mass % water. If the molar mass of narceine hydrate is 499.52 g/mol, determine *x* in narceine·xH_2O.

3.110 Hydrogen-containing fuels have a "fuel value" based on their mass % H. Rank the following compounds from highest mass % H to lowest: ethane, propane, benzene, ethanol, cetyl palmitate (whale oil, $C_{32}H_{64}O_2$).

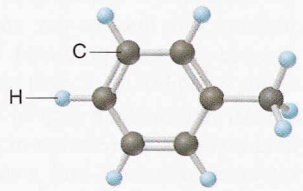


3.111 Serotonin ($\mathcal{M}$ = 176 g/mol) is a compound that transmits nerve impulses between neurons. It contains 68.2 mass % C, 6.86 mass % H, 15.9 mass % N, and 9.08 mass % O. What is its molecular formula?

3.112 Convert the following descriptions of reactions into balanced equations:
(a) In a gaseous reaction, hydrogen sulfide burns in oxygen to form sulfur dioxide and water vapor.
(b) When crystalline potassium chlorate is heated to just above its melting point, it reacts to form two different crystalline compounds, potassium chloride and potassium perchlorate.
(c) When hydrogen gas is passed over powdered iron(III) oxide, iron metal and water vapor form.
(d) The combustion of gaseous ethane in air forms carbon dioxide and water vapor.
(e) Iron(II) chloride is converted to iron(III) fluoride by treatment with chlorine trifluoride gas. Chlorine gas is also formed.

3.113 Isobutylene is a hydrocarbon used in the manufacture of synthetic rubber. When 0.847 g of isobutylene was analyzed by combustion (using an apparatus similar to that in Figure 3.5), the gain in mass of the CO_2 absorber was 2.657 g and that of the H_2O absorber was 1.089 g. What is the empirical formula of isobutylene?

3.114 One of the compounds used to increase the octane rating of gasoline is toluene *(right)*. Suppose 15.0 mL of toluene (d = 0.867 g/mL) is consumed when a sample of gasoline burns in air.



(a) How many grams of oxygen are needed for complete combustion of the toluene?
(b) How many total moles of gaseous products form?
(c) How many molecules of water vapor form?

3.115 The smelting of ferric oxide to form elemental iron occurs at high temperatures in a blast furnace through a reaction sequence with carbon monoxide. In the first step, ferric oxide reacts with carbon monoxide to form Fe_3O_4. This substance reacts with more carbon monoxide to form iron(II) oxide, which reacts with still more carbon monoxide to form molten iron. Carbon dioxide is also produced in each step. (a) Write an overall balanced equation for the iron-smelting process. (b) How many grams of carbon monoxide are required to form 40.0 metric tons of iron from ferric oxide?

3.116 During studies of the reaction in Sample Problem 3.11,

$$N_2O_4(l) + 2N_2H_4(l) \longrightarrow 3N_2(g) + 4H_2O(g)$$

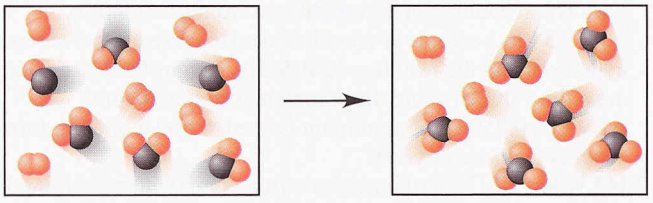
a chemical engineer measured a less-than-expected yield of N_2 and discovered that the following side reaction occurs:

$$2N_2O_4(l) + N_2H_4(l) \longrightarrow 6NO(g) + 2H_2O(g)$$

In one experiment, 10.0 g of NO formed when 100.0 g of each reactant was used. What is the highest percent yield of N_2 that can be expected?

3.117 A mathematical equation useful for dilution calculations is $M_{dil} \times V_{dil} = M_{conc} \times V_{conc}$. What does each symbol mean, and why does the equation work?

3.118 The following boxes represent a chemical reaction between AB_2 and B_2:

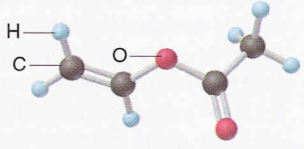


(a) Write a balanced equation for the reaction.
(b) What is the limiting reactant in this reaction?
(c) How many moles of product can be made from 3.0 mol of B_2 and 5.0 mol of AB_2?
(d) How many moles of excess reactant remain after the reaction in part (c)?

3.119 Calculate each of the following quantities:
(a) Volume of 18.0 *M* sulfuric acid that must be added to water to prepare 2.00 L of a 0.309 *M* solution
(b) Molarity of the solution obtained by diluting 80.6 mL of 0.225 *M* ammonium chloride to 0.250 L
(c) Volume of water added to 0.150 L of 0.0262 *M* sodium hydroxide to obtain a 0.0100 *M* solution (assume the volumes are additive at these low concentrations)
(d) Mass of calcium nitrate in each milliliter of a solution prepared by diluting 64.0 mL of 0.745 *M* calcium nitrate to a final volume of 0.100 L

3.120 Agricultural biochemists often use 6-benzylaminopurine ($C_{12}H_{11}N_5$) in trace amounts as a plant growth regulator. In a typical application, 150. mL of a solution contains 0.030 mg of the compound. What is the molarity of the solution?

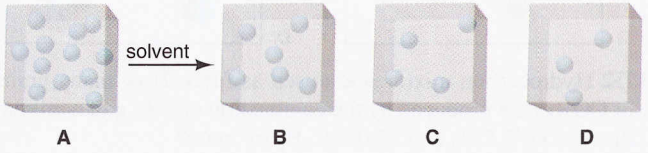
3.121 One of Germany's largest chemical manufacturers has built a plant to produce 3.74×10^8 lb of vinyl acetate per year. This compound *(right)* is used to make some of the polymers in adhesives, paints, fabric coatings, floppy disks, plastic films, and so on. Assuming production goals are met, how many moles of vinyl acetate will the plant produce each month?



3.122 Seawater is approximately 4.0% by mass dissolved ions. About 85% of the mass of the dissolved ions is from NaCl.
(a) Calculate the mass percent of NaCl in seawater.
(b) Calculate the mass percent of Na^+ ions and of Cl^- ions in seawater.
(c) Calculate the molarity of NaCl in seawater at 15°C (*d* of seawater at 15°C = 1.025 g/mL).

3.123 Is each of the following statements true or false? Correct any that are false:
(a) A mole of one substance has the same number of atoms as a mole of any other substance.
(b) The theoretical yield for a reaction is based on the balanced chemical equation.
(c) A limiting-reactant problem is presented when the quantity of available material is given in moles for one of the reactants.
(d) To prepare 1.00 L of 3.00 *M* NaCl, weigh 175.5 g of NaCl and dissolve it in 1.00 L of distilled water.
(e) The concentration of a solution is an intensive property, but the amount of solute in a solution is an extensive property.

3.124 Box A represents one unit volume of solution A. Which box—B, C, or D—represents one unit volume after adding enough solvent to solution A to (a) triple its volume; (b) double its volume; (c) quadruple its volume?



3.125 In each pair, choose the larger of the indicated quantities or state that the samples are equal:
(a) Entities: 0.4 mol of O_3 molecules or 0.4 mol of O atoms
(b) Grams: 0.4 mol of O_3 molecules or 0.4 mol of O atoms
(c) Moles: 4.0 g of N_2O_4 or 3.3 g of SO_2
(d) Grams: 0.6 mol of C_2H_4 or 0.6 mol of F_2
(e) Total ions: 2.3 mol of sodium chlorate or 2.2 mol of magnesium chloride
(f) Molecules: 1.0 g of H_2O or 1.0 g of H_2O_2
(g) Na^+ ions: 0.500 L of 0.500 *M* NaBr or 0.0146 kg of NaCl
(h) Mass: 6.02×10^{23} atoms of ^{235}U or 6.02×10^{23} atoms of ^{238}U

3.126 Balance the equation for the reaction between solid tetraphosphorus trisulfide and oxygen gas to form solid tetraphosphorus decaoxide and gaseous sulfur dioxide. Tabulate the equation (see Table 3.5) in terms of (a) molecules, (b) moles, and (c) grams.

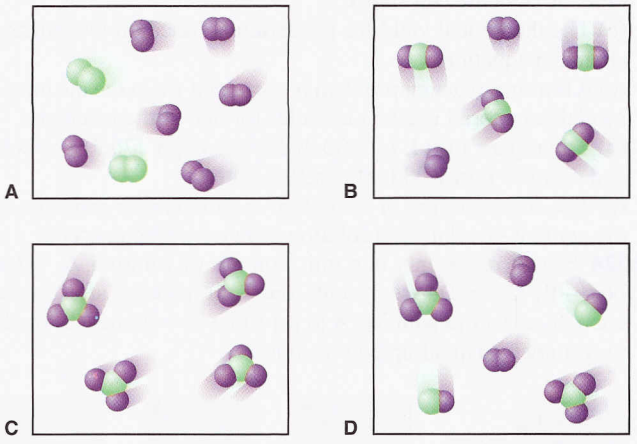
3.127 Hydrogen gas has been suggested as a clean fuel because it produces only water vapor when it burns. If the reaction has a 98.8% yield, what mass of hydrogen forms 85.0 kg of water?

3.128 Assuming that the volumes are additive, what is the concentration of KBr in a solution prepared by mixing 0.200 L of 0.053 *M* KBr with 0.550 L of 0.078 *M* KBr?

3.129 Solar winds composed of free protons, electrons, and α particles bombard Earth constantly, knocking gas molecules out of the atmosphere. In this way, Earth loses about 3.0 kg of matter per second. It is estimated that the atmosphere will be gone in about 50 billion years. Use this estimate to calculate (a) the mass (kg) of Earth's atmosphere and (b) the amount (mol) of nitrogen, which makes up 75.5 mass % of the atmosphere.

3.130 Calculate each of the following quantities:
(a) Moles of compound in 0.588 g of ammonium bromide
(b) Number of potassium ions in 68.5 g of potassium nitrate
(c) Mass in grams of 5.85 mol of glycerol ($C_3H_8O_3$)
(d) Volume of 2.55 mol of chloroform ($CHCl_3$; d = 1.48 g/mL)
(e) Number of sodium ions in 2.11 mol of sodium carbonate
(f) Number of atoms in 10.0 μg of cadmium
(g) Number of atoms in 0.0015 mol of fluorine gas

3.131 Elements X (green) and Y (purple) react according to the following equation: $X_2 + 3Y_2 \longrightarrow 2XY_3$. Which molecular scene represents the product of the reaction?



3.132 Hydrocarbon mixtures are used as fuels. How many grams of $CO_2(g)$ are produced by the combustion of 200. g of a mixture that is 25.0% CH_4 and 75.0% C_3H_8 by mass?

3.133 To 1.20 L of 0.325 *M* HCl, you add 3.37 L of a second HCl solution of unknown concentration. The resulting solution is 0.893 *M* HCl. Assuming the volumes are additive, calculate the molarity of the second HCl solution.

3.134 Nitrogen (N), phosphorus (P), and potassium (K) are the main nutrients in plant fertilizers. According to an industry convention, the numbers on the label refer to the mass percents of N, P_2O_5, and K_2O, in that order. Calculate the N:P:K ratio of a 30:10:10 fertilizer in terms of moles of each element, and express it as *x*:*y*:1.0.

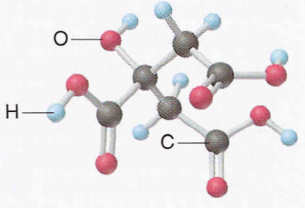
3.135 A 0.652-g sample of a pure strontium halide reacts with excess sulfuric acid, and the solid strontium sulfate formed is separated, dried, and found to weigh 0.755 g. What is the formula of the original halide?

3.136 Methane and ethane are the two simplest hydrocarbons. What is the mass % C in a mixture that is 40.0% methane and 60.0% ethane by mass?

3.137 When carbon-containing compounds are burned in a limited amount of air, some $CO(g)$ as well as $CO_2(g)$ is produced. A gaseous product mixture is 35.0 mass % CO and 65.0 mass % CO_2. What is the mass % C in the mixture?

3.138 Ferrocene, first synthesized in 1951, was the first organic iron compound with Fe—C bonds. An understanding of the structure of ferrocene gave rise to new ideas about chemical bonding and led to the preparation of many useful compounds. In the combustion analysis of ferrocene, which contains only Fe, C, and H, a 0.9437-g sample produced 2.233 g of CO_2 and 0.457 g of H_2O. What is the empirical formula of ferrocene?

3.139 Citric acid *(right)* is concentrated in citrus fruits and plays a central metabolic role in nearly every animal and plant cell. (a) What are the molar mass and formula of citric acid? (b) How many moles of citric acid are in 1.50 qt of lemon juice (d = 1.09 g/mL) that is 6.82% citric acid by mass?



3.140 Various nitrogen oxides, as well as sulfur oxides, contribute to acidic rainfall through complex reaction sequences. Atmospheric nitrogen and oxygen combine to form nitrogen monoxide gas, which reacts with more oxygen to form nitrogen dioxide gas. In contact with water vapor, nitrogen dioxide forms aqueous nitric acid and more nitrogen monoxide. (a) Write balanced equations for these reactions. (b) Use the three equations to write one overall balanced equation that does *not* include nitrogen monoxide and nitrogen dioxide. (c) How many metric tons (t) of nitric acid form when 1.25×10^3 t of atmospheric nitrogen is consumed (1 t = 1000 kg)?

3.141 Alum [$KAl(SO_4)_2\cdot xH_2O$] is used in food preparation, dye fixation, and water purification. To prepare alum, aluminum is reacted with potassium hydroxide and the product with sulfuric acid. Upon cooling, alum crystallizes from the solution.
(a) A 0.5404-g sample of alum is heated to drive off the waters of hydration, and the resulting $KAl(SO_4)_2$ weighs 0.2941 g. Determine the value of x and the complete formula of alum.
(b) When 0.7500 g of aluminum is used, 8.500 g of alum forms. What is the percent yield?

3.142 When 1.5173 g of an organic iron compound containing Fe, C, H, and O was burned in O_2, 2.838 g of CO_2 and 0.8122 g of H_2O were produced. In a separate experiment to determine the mass % of iron, 0.3355 g of the compound yielded 0.0758 g of Fe_2O_3. What is the empirical formula of the compound?

3.143 Fluorine is so reactive that it forms compounds with materials inert to other treatments.
(a) When 0.327 g of platinum is heated in fluorine, 0.519 g of a dark red, volatile solid forms. What is its empirical formula?
(b) When 0.265 g of this red solid reacts with excess xenon gas, 0.378 g of an orange-yellow solid forms. What is the empirical formula of this compound, the first noble gas compound formed?
(c) Fluorides of xenon can be formed by direct reaction of the elements at high pressure and temperature. Depending on conditions, the product mixture may include the difluoride, the tetrafluoride, and the hexafluoride. Under conditions that produce only the tetra- and hexafluorides, 1.85×10^{-4} mol of xenon reacted with 5.00×10^{-4} mol of fluorine, and 9.00×10^{-6} mol of xenon was found in excess. What are the mass percents of each xenon fluoride in the product mixture?

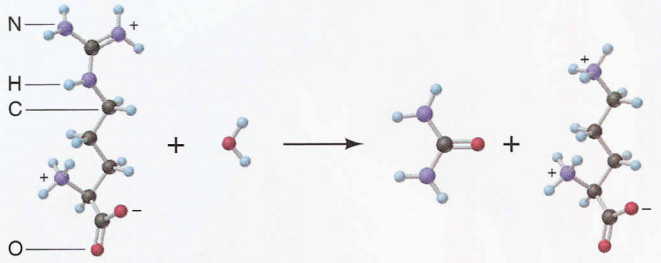
3.144 Hemoglobin is 6.0% heme ($C_{34}H_{32}FeN_4O_4$) by mass. To remove the heme, hemoglobin is treated with acetic acid and NaCl to form hemin ($C_{34}H_{32}N_4O_4FeCl$). At a crime scene, a blood sample contains 0.45 g of hemoglobin.
(a) How many grams of heme are in the sample?
(b) How many moles of heme?
(c) How many grams of Fe?
(d) How many grams of hemin could be formed for a forensic chemist to measure?

3.145 Manganese is a key component of extremely hard steel. The element occurs naturally in many oxides. A 542.3-g sample of a manganese oxide has an Mn:O ratio of 1.00:1.42 and consists of braunite (Mn_2O_3) and manganosite (MnO).
(a) What masses of braunite and manganosite are in the ore?
(b) What is the ratio Mn^{3+}:Mn^{2+} in the ore?

3.146 Sulfur dioxide is a major industrial gas used primarily for the production of sulfuric acid, but also as a bleach and food preservative. One way to produce it is by roasting iron pyrite (iron

disulfide, FeS_2) in oxygen, which yields the gas and solid iron(III) oxide. What mass of each of the other three substances are involved in producing 1.00 kg of sulfur dioxide?

3.147 The human body excretes nitrogen in the form of urea, NH_2CONH_2. The key biochemical step in urea formation is the reaction of water with arginine to produce urea and ornithine:



(a) What is the mass percent of nitrogen in urea, arginine, and ornithine? (b) How many grams of nitrogen can be excreted as urea when 143.2 g of ornithine is produced?

3.148 Aspirin (acetylsalicylic acid, $C_9H_8O_4$) can be made by reacting salicylic acid ($C_7H_6O_3$) with acetic anhydride [$(CH_3CO)_2O$]:

$$C_7H_6O_3(s) + (CH_3CO)_2O(l) \longrightarrow C_9H_8O_4(s) + CH_3COOH(l)$$

In one reaction, 3.027 g of salicylic acid and 6.00 mL of acetic anhydride react to form 3.261 g of aspirin.

(a) Which is the limiting reactant (d of acetic anhydride = 1.080 g/mL)?

(b) What is the percent yield of this reaction?

(c) What is the percent atom economy of this reaction?

3.149 The rocket fuel hydrazine (N_2H_4) is manufactured by the Raschig process, a three-step reaction with the following overall equation:

$$NaOCl(aq) + 2NH_3(aq) \longrightarrow N_2H_4(aq) + NaCl(aq) + H_2O(l)$$

What is the percent atom economy of this process?

3.150 Lead(II) chromate ($PbCrO_4$) is used as a yellow pigment to designate traffic lanes, but has been banned from house paint because of the potential for lead poisoning. The compound is produced from chromite ($FeCr_2O_4$), an ore of chromium:

$$4FeCr_2O_4(s) + 8K_2CO_3(aq) + 7O_2(g) \longrightarrow 2Fe_2O_3(s) + 8K_2CrO_4(aq) + 8CO_2(g)$$

Lead(II) ion then replaces the K^+ ion. If a yellow paint is 0.511% $PbCrO_4$ by mass, how many grams of chromite are needed per kilogram of paint?

3.151 Ethanol (CH_3CH_2OH), the intoxicant in alcoholic beverages, is also used to make many other organic compounds. In concentrated sulfuric acid, ethanol forms diethyl ether and water:

$$2CH_3CH_2OH(l) \longrightarrow CH_3CH_2OCH_2CH_3(l) + H_2O(g)$$

In a side reaction, some ethanol forms ethylene and water:

$$CH_3CH_2OH(l) \longrightarrow CH_2{=}CH_2(g) + H_2O(g)$$

(a) If 50.0 g of ethanol yields 33.9 g of diethyl ether, what is the percent yield of diethyl ether?

(b) During the process, 50.0% of the ethanol that did not produce diethyl ether reacts by the side reaction. What mass of ethylene is produced?

3.152 When powdered zinc is heated with sulfur, a violent reaction occurs, and zinc sulfide forms:

$$Zn(s) + S_8(s) \longrightarrow ZnS(s) \text{ [unbalanced]}$$

Some of the reactants also combine with oxygen in air to form zinc oxide and sulfur dioxide. When 85.2 g of Zn reacts with 52.4 g of S_8, 105.4 g of ZnS forms. What is the percent yield of ZnS? (b) If all the remaining reactants combine with oxygen, how many grams of each of the two oxides form?

3.153 Cocaine ($C_{17}H_{21}O_4N$) is a natural substance found in coca leaves, which have been used for centuries as a local anesthetic and stimulant. Illegal cocaine arrives in the United States either as the pure compound or as the hydrochloride salt ($C_{17}H_{21}O_4NHCl$). At 25°C, the salt is very soluble in water (2.50 kg/L), but cocaine is much less so (1.70 g/L). (a) What is the maximum amount (in g) of the salt that can dissolve in 50.0 mL of water? (b) If the solution in part (a) is treated with NaOH, the salt is converted to cocaine. How much additional water (in L) is needed to dissolve it?

3.154 High-temperature superconducting oxides hold great promise in the utility, transportation, and computer industries. (a) One superconductor is $La_{2-x}Sr_xCuO_4$. Calculate the molar mass of this oxide when $x = 0$, $x = 1$, and $x = 0.163$ (the last characterizes the compound with optimum superconducting properties).

(b) Another common superconducting oxide is made by heating a mixture of barium carbonate, copper(II) oxide, and yttrium(III) oxide, followed by further heating in O_2:

$$4BaCO_3(s) + 6CuO(s) + Y_2O_3(s) \longrightarrow 2YBa_2Cu_3O_{6.5}(s) + 4CO_2(g)$$

$$2YBa_2Cu_3O_{6.5}(s) + \tfrac{1}{2}O_2(g) \longrightarrow 2YBa_2Cu_3O_7(s)$$

When equal masses of the three reactants are heated, which reactant is limiting?

(c) After the product in part (b) is removed, what is the mass percent of each reactant in the solid mixture remaining?

3.155 The zirconium oxalate $K_2Zr(C_2O_4)_3(H_2C_2O_4)\cdot H_2O$ was synthesized by mixing 1.60 g of $ZrOCl_2\cdot 8H_2O$ with 5.20 g of $H_2C_2O_4\cdot 2H_2O$ and an excess of aqueous KOH. After 2 months, 1.20 g of crystalline product was obtained, as well as aqueous KCl and water. Calculate the percent yield.

3.156 A student weighs a sample of carbon on a balance that is accurate to ±0.001 g.

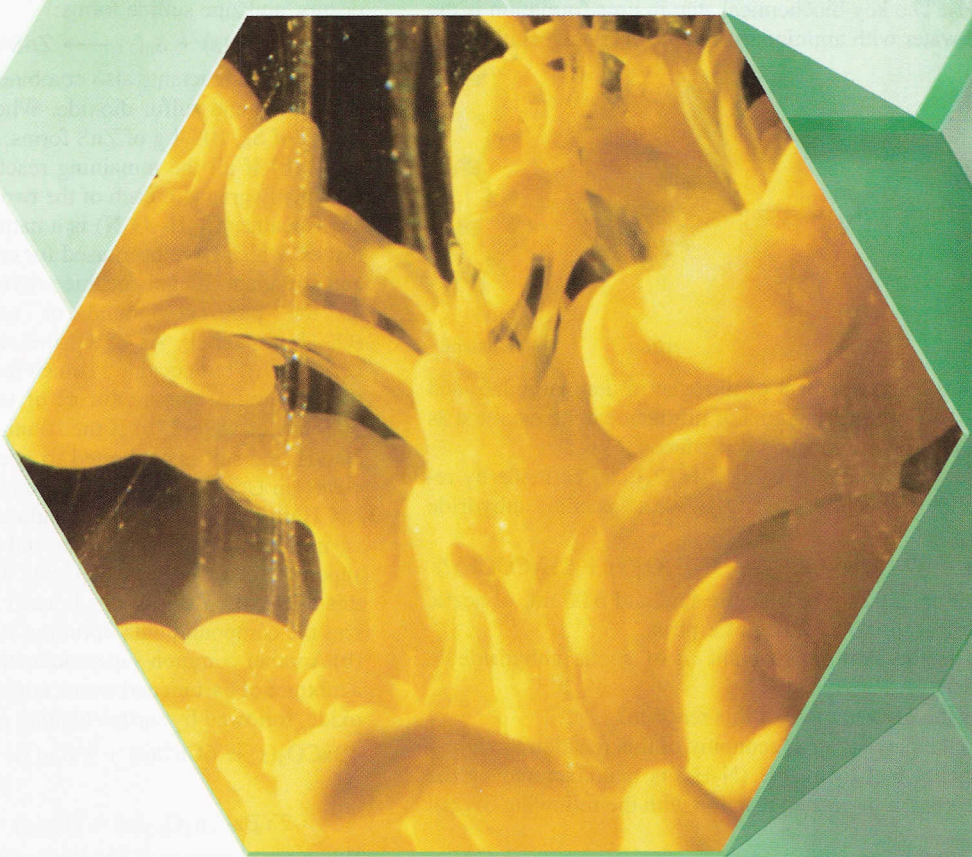
(a) How many atoms are in 0.001 g of C?

(b) The carbon is used in the following reaction:

$$Pb_3O_4(s) + C(s) \longrightarrow 3PbO(s) + CO(g)$$

What mass difference in the lead(II) oxide would be caused by an error in the carbon mass of 0.001 g?

3.157 Alcohols are organic compounds that contain an —OH group attached to a hydrocarbon chain. Draw structural formulas like those in Table 3.4 for the four alcohols with the formula $C_4H_{10}O$.



A Select Few Particles of solid lead(II) iodide swirling through a sodium nitrate solution are the products of this precipitation reaction, an example of one of a handful of major reaction classes. Distinguishing the key features of these classes and learning the role of water in many of them form the focus of the chapter.

Oxidation Numbers
Balancing Redox Equations
Redox Titrations

4.6 **Elements in Redox Reactions**

4.7 **Reversible Reactions: An Introduction to Chemical Equilibrium**

Rapid chemical changes occur among gas molecules as sunlight bathes the atmosphere or lightning rips through a stormy sky. Aqueous reactions go on unceasingly in the gigantic containers we know as oceans. And, in every cell of your body, thousands of reactions taking place right now allow you to function. Indeed, the amazing variety in nature is largely a consequence of the amazing variety of chemical reactions.

Of the millions of chemical reactions occurring in and around you, we have examined only a tiny fraction so far, and it would be impossible to examine them all. Fortunately, it isn't necessary to catalog every reaction, because when we survey even a small percentage of reactions, a few major patterns emerge.

IN THIS CHAPTER . . . We examine the underlying nature of the three most common reaction processes. One of our main themes is aqueous reaction chemistry, so we first investigate how the molecular structure of water influences its crucial role as a solvent in these reactions. We see how to use ionic equations to describe reactions. We focus in turn on precipitation, acid-base, and oxidation-reduction reactions, examining why they occur and how to quantify them. We classify several important types of oxidation-reduction reactions that include elements as reactants or products. The chapter ends with an introductory look at the reversible nature of all reactions.

Concepts & Skills to Review

before you study this chapter

- names and formulas of compounds (Section 2.8)
- nature of ionic and covalent bonding (Section 2.7)
- mole-mass-number conversions (Section 3.1)
- molarity and mole-volume conversions (Section 3.5)
- balancing chemical equations (Section 3.3)
- calculating amounts of reactants and products (Section 3.4)

4.1 THE ROLE OF WATER AS A SOLVENT

Many reactions take place in aqueous solution, and our first step toward comprehending these reactions is to understand how water acts as a solvent. The role a solvent plays in a reaction depends on its chemical nature. Some solvents play a passive role, dispersing the dissolved substances into individual molecules but doing nothing further. Water plays a much more active role, interacting strongly with the substances and, in some cases, even reacting with them. To understand this active role, we'll examine the structure of water and how it interacts with ionic and covalent solutes.

The Polar Nature of Water

Of the many thousands of reactions that occur in the environment and in organisms, nearly all take place in water. Water's remarkable power as a solvent results from two features of its molecules: *the distribution of the bonding electrons* and *the overall shape*.

Recall from Section 2.7 that the electrons in a covalent bond are shared between the bonded atoms. In a covalent bond between identical atoms (as in H_2, Cl_2, O_2, etc.), the sharing is equal, so no imbalance of charge appears (Figure 4.1A). On the other hand, in covalent bonds between nonidentical atoms, the sharing is unequal: one atom attracts the electron pair more strongly than the other. For reasons discussed in Chapter 9, an O atom attracts electrons more strongly than an H atom. Therefore, in each O—H bond in water, the shared electrons spend more time closer to the O atom (Figure 4.1B).

This unequal distribution of negative charge creates partially charged "poles" at the ends of each O—H bond. The O end acts as a slightly negative pole (represented by the red shading and the $\delta-$), and the H end acts as a slightly positive pole (represented by the blue shading and the $\delta+$). Figure 4.1C indicates the bond's polarity with a *polar arrow* (the arrowhead points to the negative pole and the tail is crossed to make a "plus").

The H—O—H arrangement forms an angle, so the water molecule is bent. The combined effects of its bent shape and its polar bonds make water a **polar molecule:** the O portion of the molecule is the partially negative pole, and the region midway between the H atoms is the partially positive pole (Figure 4.1D).

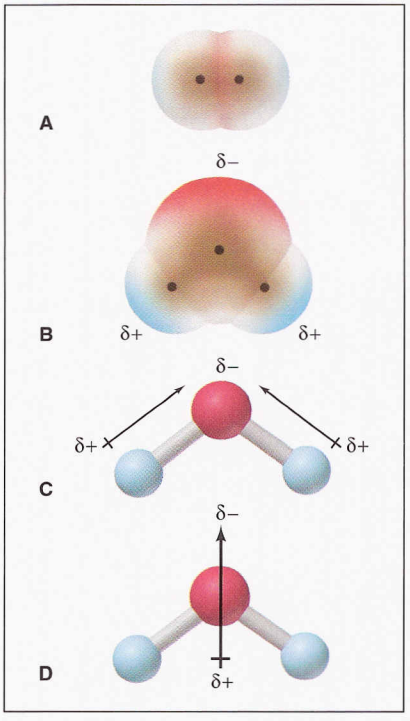

Figure 4.1 Electron distribution in molecules of H_2 and H_2O. A, In H_2, the identical nuclei attract the electrons equally. The central region of higher electron density (red) is balanced by the two outer regions of lower electron density (blue). **B,** In H_2O, the O nucleus attracts the shared electrons more strongly than the H nucleus. **C,** In this ball-and-stick model, a polar arrow points to the negative end of each O—H bond. **D,** The two polar O—H bonds and the bent shape give rise to the polar H_2O molecule.

Ionic Compounds in Water

In an ionic solid, the oppositely charged ions are held next to each other by electrostatic attraction (see Figure 1.3C). *Water separates the ions by replacing that attraction with one between the water molecules and the ions.* Imagine a granule of an ionic compound surrounded by bent, polar water molecules. The negative ends of some water molecules are attracted to the cations, and the positive ends of others are attracted to the anions (Figure 4.2). Gradually, the attraction between each ion and the nearby water molecules outweighs the attraction of the ions for each other. By this process, the ions separate (dissociate) and become **solvated,** surrounded tightly by solvent molecules, as they move randomly in the solution. A similar scene occurs whenever an ionic compound dissolves in water.

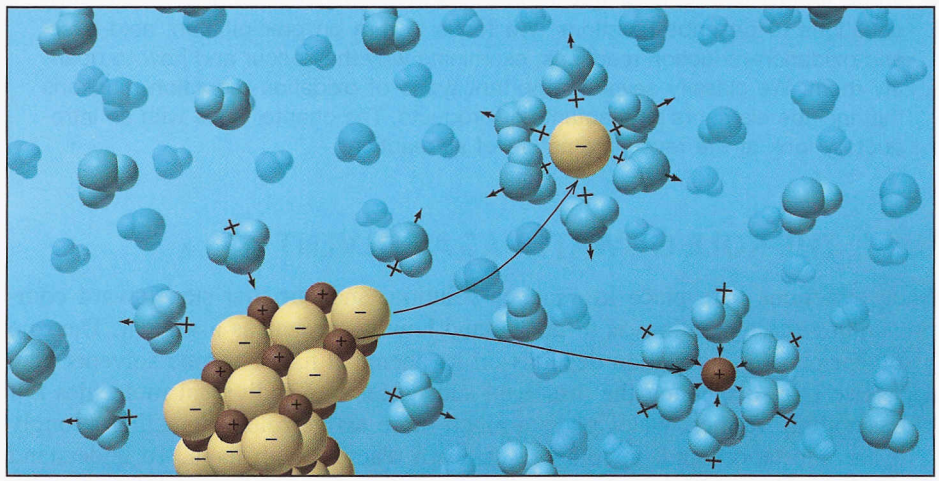

Figure 4.2 The dissolution of an ionic compound. When an ionic compound dissolves in water, H_2O molecules separate, surround, and disperse the ions into the liquid. The negative ends of the H_2O molecules face the positive ions and the positive ends face the negative ions.

Although many ionic compounds dissolve in water, many others do not. In the latter cases, the electrostatic attraction among ions in the compound remains greater than the attraction between ions and water molecules, so the solid stays largely intact. Actually, these so-called insoluble substances *do* dissolve to a very small extent, usually several orders of magnitude less than so-called soluble substances. Compare, for example, the solubilities of NaCl (a "soluble" compound) and AgCl (an "insoluble" compound):

Solubility of NaCl in H_2O at 20°C = 365 g/L
Solubility of AgCl in H_2O at 20°C = 0.009 g/L

Actually, the process of dissolving is more complex than just a contest between the relative energies of attraction of the particles for each other and for the solvent. In Chapter 13, we'll see that it also involves the natural tendency of the particles to disperse randomly through the solution.

Animation: Dissolution of an Ionic and a Covalent Compound
Online Learning Center

When an ionic compound dissolves, an important change occurs in the solution. Figure 4.3 shows this change with a simple apparatus that demonstrates *electrical conductivity,* the flow of electric current. When the electrodes are immersed in pure water or pushed into an ionic solid, such as potassium bromide (KBr), no current flows. In an aqueous KBr solution, however, a significant current flows, as shown by the brightly lit bulb. This current flow implies the *movement of charged particles:* when KBr dissolves in water, the K^+ and Br^- ions dissociate, become solvated, and move toward the electrode of opposite charge. A substance that conducts a current when dissolved in water is an **electrolyte.** Soluble ionic compounds are called *strong* electrolytes because they dissociate completely into

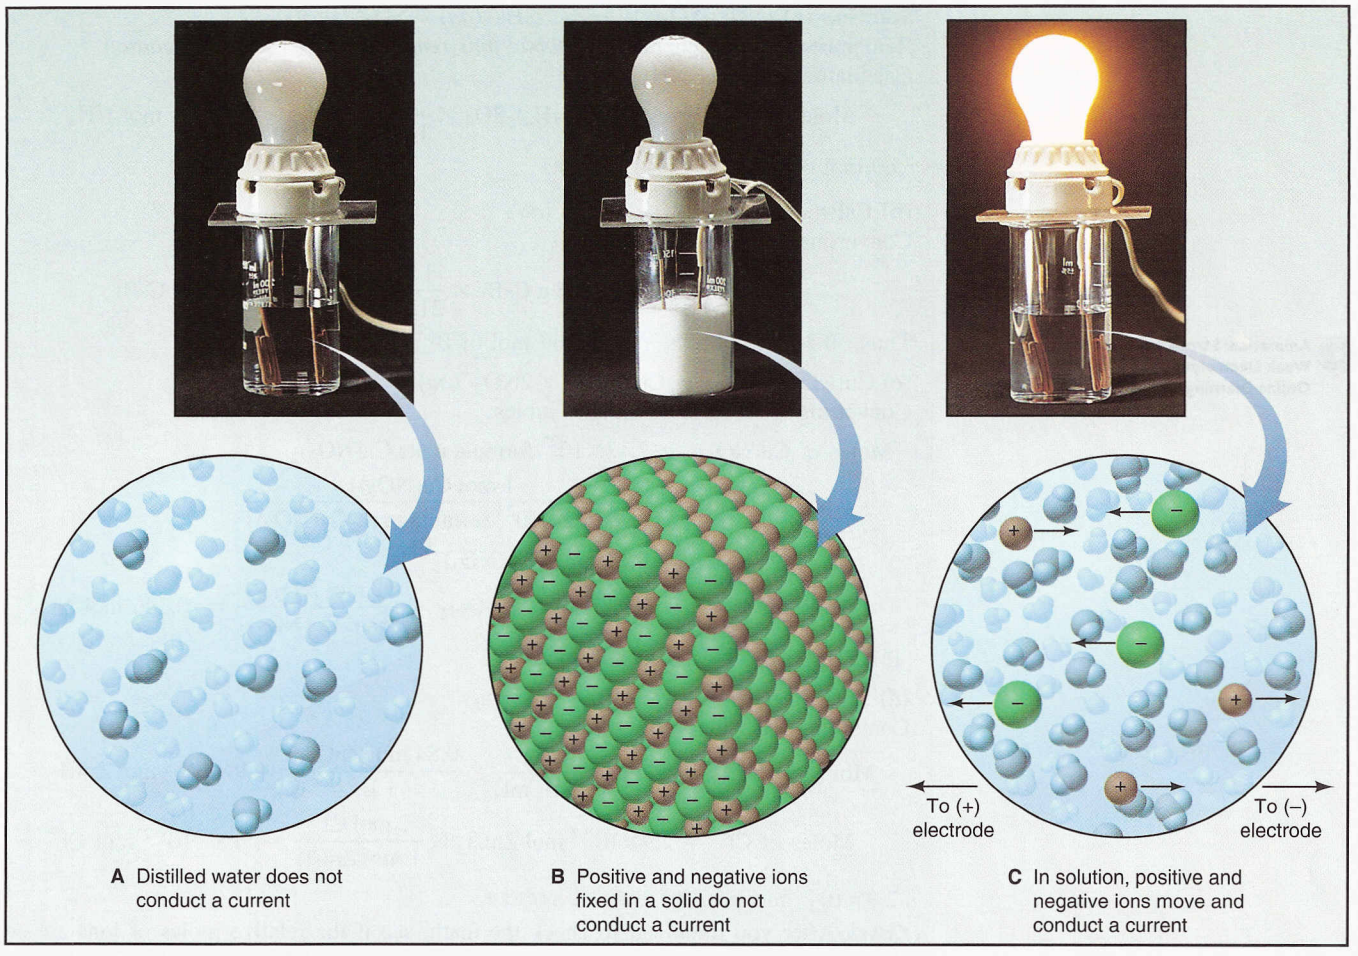

Figure 4.3 The electrical conductivity of ionic solutions. A, When electrodes connected to a power source are placed in distilled water, no current flows and the bulb is unlit. **B,** A solid ionic compound, such as KBr, conducts no current because the ions are bound tightly together. **C,** When KBr dissolves in H_2O, the ions separate and move through the solution toward the oppositely charged electrodes, thereby conducting a current.

ions and create a large current. We express the dissociation of KBr into solvated ions in water as follows:

$$KBr(s) \xrightarrow{H_2O} K^+(aq) + Br^-(aq)$$

The "H_2O" above the arrow indicates that water is required as the solvent but is not a reactant in the usual sense.

The formula of the compound tells the number of moles of different ions that result when the compound dissolves. Thus, 1 mol of KBr dissociates into 2 mol of ions—1 mol of K^+ and 1 mol of Br^-. The upcoming sample problem goes over this idea.

SAMPLE PROBLEM 4.1 Determining Moles of Ions in Aqueous Ionic Solutions

Problem How many moles of each ion are in each solution?
(a) 5.0 mol of ammonium sulfate dissolved in water
(b) 78.5 g of cesium bromide dissolved in water
(c) 7.42×10^{22} formula units of copper(II) nitrate dissolved in water
(d) 35 mL of 0.84 *M* zinc chloride

Plan We write an equation that shows 1 mol of compound dissociating into ions. In **(a)**, we multiply the moles of ions by 5.0. In **(b)**, we first convert grams to moles. In **(c)**, we first convert formula units to moles. In **(d)**, we first convert molarity and volume to moles.

Solution **(a)** $(NH_4)_2SO_4(s) \xrightarrow{H_2O} 2NH_4^+(aq) + SO_4^{2-}(aq)$
Remember that, in general, *polyatomic ions remain as intact units in solution.*
Calculating moles of NH_4^+ ions:

$$\text{Moles of } NH_4^+ = 5.0 \text{ mol } (NH_4)_2SO_4 \times \frac{2 \text{ mol } NH_4^+}{1 \text{ mol } (NH_4)_2SO_4} = 10. \text{ mol } NH_4^+$$

5.0 mol of SO_4^{2-} is also present.

(b) $CsBr(s) \xrightarrow{H_2O} Cs^+(aq) + Br^-(aq)$
Converting from grams to moles:

$$\text{Moles of CsBr} = 78.5 \text{ g CsBr} \times \frac{1 \text{ mol CsBr}}{212.8 \text{ g CsBr}} = 0.369 \text{ mol CsBr}$$

Thus, 0.369 mol of Cs^+ and 0.369 mol of Br^- are present.

Animation: Strong Electrolytes, Weak Electrolytes, and Nonelectrolytes Online Learning Center

(c) $Cu(NO_3)_2(s) \xrightarrow{H_2O} Cu^{2+}(aq) + 2NO_3^-(aq)$
Converting from formula units to moles:

$$\text{Moles of } Cu(NO_3)_2 = 7.42\times10^{22} \text{ formula units } Cu(NO_3)_2 \times \frac{1 \text{ mol } Cu(NO_3)_2}{6.022\times10^{23} \text{ formula units } Cu(NO_3)_2}$$

$$= 0.123 \text{ mol } Cu(NO_3)_2$$

$$\text{Moles of } NO_3^- = 0.123 \text{ mol } Cu(NO_3)_2 \times \frac{2 \text{ mol } NO_3^-}{1 \text{ mol } Cu(NO_3)_2} = 0.246 \text{ mol } NO_3^-$$

0.123 mol of Cu^{2+} is also present.

(d) $ZnCl_2(aq) \longrightarrow Zn^{2+}(aq) + 2Cl^-(aq)$
Converting from liters to moles:

$$\text{Moles of } ZnCl_2 = 35 \text{ mL} \times \frac{1 \text{ L}}{10^3 \text{ mL}} \times \frac{0.84 \text{ mol } ZnCl_2}{1 \text{ L}} = 2.9\times10^{-2} \text{ mol } ZnCl_2$$

$$\text{Moles of } Cl^- = 2.9\times10^{-2} \text{ mol } ZnCl_2 \times \frac{2 \text{ mol } Cl^-}{1 \text{ mol } ZnCl_2} = 5.8\times10^{-2} \text{ mol } Cl^-$$

2.9×10^{-2} mol of Zn^{2+} is also present.

Check After you round off to check the math, see if the relative moles of ions are consistent with the formula. For instance, in **(a)**, 10 mol NH_4^+/5.0 mol SO_4^{2-} = 2 NH_4^+/1 SO_4^{2-}, or $(NH_4)_2SO_4$. In **(d)**, 0.029 mol Zn^{2+}/0.058 mol Cl^- = 1 Zn^{2+}/2 Cl^-, or $ZnCl_2$.

FOLLOW-UP PROBLEM 4.1 How many moles of each ion are in each solution?
(a) 2 mol of potassium perchlorate dissolved in water
(b) 354 g of magnesium acetate dissolved in water
(c) 1.88×10^{24} formula units of ammonium chromate dissolved in water
(d) 1.32 L of 0.55 *M* sodium bisulfate

Covalent Compounds in Water

Water dissolves many covalent compounds also. Table sugar (sucrose, $C_{12}H_{22}O_{11}$), beverage (grain) alcohol (ethanol, CH_3CH_2OH), and automobile antifreeze (ethylene glycol, $HOCH_2CH_2OH$) are some familiar examples. All contain their own polar O—H bonds, which interact with those of water. However, even though these substances dissolve, they do not dissociate into ions but remain as intact molecules. As a result, their aqueous solutions do not conduct an electric current, and these substances are called **nonelectrolytes.** Many other covalent substances, such as benzene (C_6H_6) and octane (C_8H_{18}), do not contain polar bonds, and these substances do not dissolve appreciably in water.

Acids and the Solvated Proton A small, but extremely important, group of H-containing covalent compounds interacts so strongly with water that their molecules *do* dissociate into ions. In aqueous solution, these substances are all *acids,* as you'll see shortly. The molecules contain polar bonds to hydrogen, in which

the atom bonded to H pulls more strongly on the shared electron pair. A good example is hydrogen chloride gas. The Cl end of the HCl molecule is partially negative, and the H end is partially positive. When HCl dissolves in water, the partially charged poles of H_2O molecules are attracted to the oppositely charged poles of HCl. The H—Cl bond breaks, with the H becoming the solvated cation $H^+(aq)$ (but see the discussion following the sample problem) and the Cl becoming the solvated anion $Cl^-(aq)$. Hydrogen bromide behaves similarly when it dissolves in water:

$$HBr(g) \xrightarrow{H_2O} H^+(aq) + Br^-(aq)$$

SAMPLE PROBLEM 4.2 Determining the Molarity of H^+ Ions in an Aqueous Solution of an Acid

Problem Nitric acid is a major chemical in the fertilizer and explosives industries. In aqueous solution, each molecule dissociates and the H becomes a solvated H^+ ion. What is the molarity of $H^+(aq)$ in 1.4 *M* nitric acid?

Plan We know the molarity of acid (1.4 *M*), so we just need the formula to find the number of moles of $H^+(aq)$ present in 1 L of solution.

Solution Nitrate ion is NO_3^-, so nitric acid is HNO_3. Thus, 1 mol of $H^+(aq)$ is released per mole of acid:

$$HNO_3(l) \xrightarrow{H_2O} H^+(aq) + NO_3^-(aq)$$

Therefore, 1.4 *M* HNO_3 contains 1.4 mol of $H^+(aq)$ per liter and is 1.4 *M* $H^+(aq)$.

FOLLOW-UP PROBLEM 4.2 How many moles of $H^+(aq)$ are present in 451 mL of 3.20 *M* hydrobromic acid?

Water interacts strongly with many ions, but most strongly with the hydrogen cation, H^+, a very unusual species. The H atom is a proton surrounded by an electron, so the H^+ ion is just a proton. Because its full positive charge is concentrated in such a tiny volume, H^+ attracts the negative pole of surrounding water molecules so strongly that it actually forms a covalent bond to one of them. We usually show this interaction by writing the aqueous H^+ ion as H_3O^+ (hydronium ion). Thus, to show more accurately what takes place when $HBr(g)$ dissolves, we should write

$$HBr(g) + H_2O(l) \longrightarrow H_3O^+(aq) + Br^-(aq)$$

To make a point here about the interactions with water, let's write the hydronium ion as $(H_2O)H^+$. The hydronium ion associates with other water molecules to give species such as $H_5O_2^+$ [or $(H_2O)_2H^+$], $H_7O_3^+$ [or $(H_2O)_3H^+$], $H_9O_4^+$ [or $(H_2O)_4H^+$], and still larger aggregates; $H_7O_3^+$ is shown in Figure 4.4. These various species exist together, but we use $H^+(aq)$ as a general, simplified notation. Later in this chapter and much of the rest of the text, we show the solvated proton as $H_3O^+(aq)$ to emphasize water's role.

Water interacts covalently with many metal ions as well. For example, Fe^{3+} exists in water as $Fe(H_2O)_6^{3+}$, an Fe^{3+} ion bound to six H_2O molecules. Similarly, Zn^{2+} exists as $Zn(H_2O)_4^{2+}$ and Ni^{2+} as $Ni(H_2O)_6^{2+}$. We discuss these species fully in later chapters.

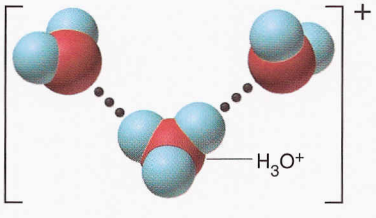

Figure 4.4 The hydrated proton. The charge of the H^+ ion is highly concentrated because the ion is so small. In aqueous solution, it forms a covalent bond to a water molecule, yielding an H_3O^+ ion that associates tightly with other H_2O molecules. Here, the $H_7O_3^+$ ion is shown.

SECTION SUMMARY

Water plays an active role in dissolving ionic compounds because it consists of polar molecules that are attracted to the ions. When an ionic compound dissolves in water, the ions dissociate from each other and become solvated by water molecules. Because the ions are free to move, their solutions conduct electricity. Water also dissolves many covalent substances with polar bonds. It interacts with some H-containing molecules so strongly it breaks their bonds and dissociates them into $H^+(aq)$ ions and anions. In water, the H^+ ion is bonded to an H_2O, forming an H_3O^+.

4.2 WRITING EQUATIONS FOR AQUEOUS IONIC REACTIONS

Chemists use three types of equations to represent aqueous ionic reactions: molecular, total ionic, and net ionic equations. As you'll see in the two types of ionic equations, by balancing the atoms, we also balance the charges.

Let's examine a reaction to see what each of these equations shows. When solutions of silver nitrate and sodium chromate are mixed, the brick-red solid silver chromate (Ag_2CrO_4) forms. Figure 4.5 depicts three views of this reaction: the change you would see if you mixed these solutions in the lab, how you might imagine the change at the atomic level among the ions, and how you can symbolize the change with the three types of equations.

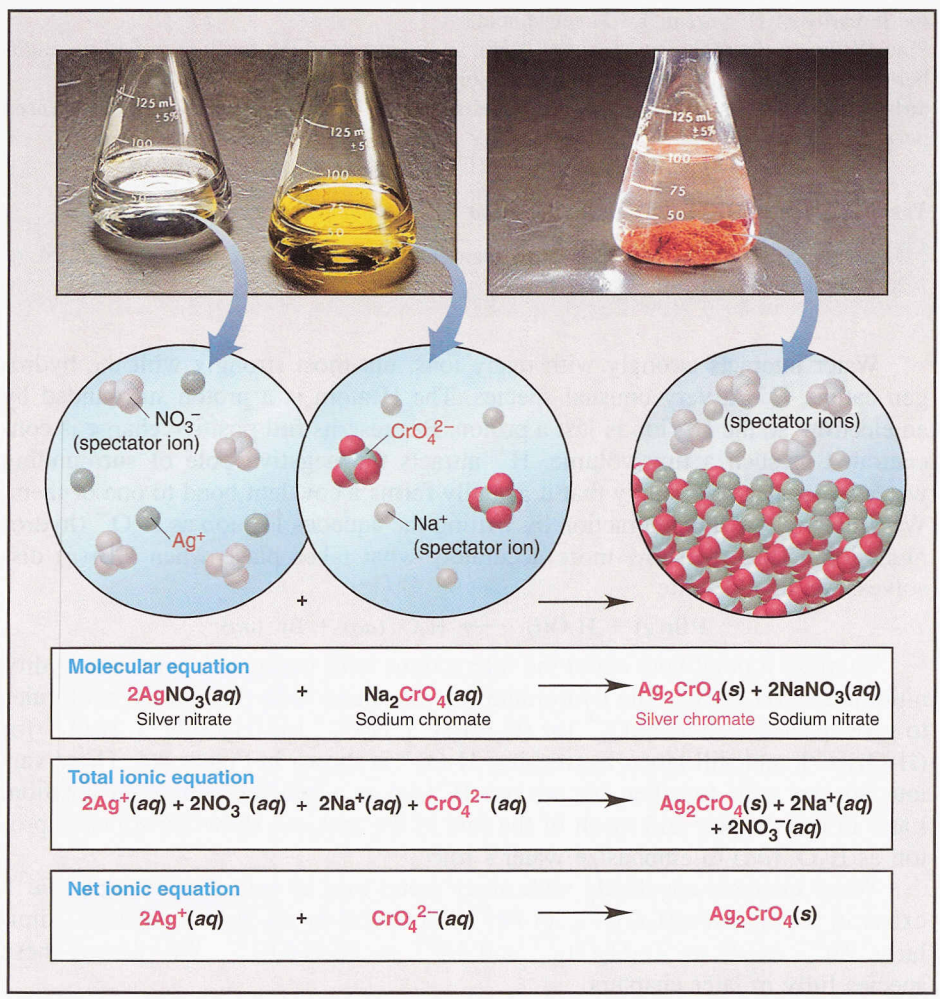

Figure 4.5 An aqueous ionic reaction and its equations. When silver nitrate and sodium chromate solutions are mixed, a reaction occurs that forms solid silver chromate and a solution of sodium nitrate. The photos present the macroscopic view of the reaction, the view the chemist sees in the lab. The blow-up arrows lead to an atomic-scale view, a representation of the chemist's mental picture of the reactants and products. (The pale ions are spectator ions, present for electrical neutrality, but not involved in the reaction.) Three equations represent the reaction in symbols. The *molecular equation* shows all substances intact. The *total ionic equation* shows all *soluble* substances as separate, solvated ions. The *net ionic equation* eliminates the spectator ions to show only the reacting species.

The **molecular equation** (*top*) reveals the least about the species in solution and is actually somewhat misleading, because *it shows all the reactants and products as if they were intact, undissociated compounds*:

$$2AgNO_3(aq) + Na_2CrO_4(aq) \longrightarrow Ag_2CrO_4(s) + 2NaNO_3(aq)$$

Only by examining the state-of-matter designations (*s*) and (*aq*), can you tell the change that has occurred.

The **total ionic equation** *(middle)* is a much more accurate representation of the reaction because *it shows all the soluble ionic substances dissociated into ions*. Now the $Ag_2CrO_4(s)$ stands out as the only undissociated substance:

$$2Ag^+(aq) + 2NO_3^-(aq) + 2Na^+(aq) + CrO_4^{2-}(aq) \longrightarrow Ag_2CrO_4(s) + 2Na^+(aq) + 2NO_3^-(aq)$$

Notice that charges balance: there are four positive and four negative charges on the left for a net zero charge, and there are two positive and two negative charges on the right for a net zero charge.

Note that $Na^+(aq)$ and $NO_3^-(aq)$ appear in the same form on both sides of the equation. They are called **spectator ions** because they are not involved in the actual chemical change. These ions are present as part of the reactants to balance the charge. That is, we can't add an Ag^+ ion without also adding an anion, in this case, NO_3^- ion.

The **net ionic equation** *(bottom)* is the most useful because *it eliminates the spectator ions and shows the actual chemical change taking place*:

$$2Ag^+(aq) + CrO_4^{2-}(aq) \longrightarrow Ag_2CrO_4(s)$$

The formation of solid silver chromate from silver ions and chromate ions *is* the only change. In fact, if we had originally mixed solutions of potassium chromate, $K_2CrO_4(aq)$, and silver acetate, $AgC_2H_3O_2(aq)$, instead of sodium chromate and silver nitrate, the same change would have occurred. Only the spectator ions would differ—$K^+(aq)$ and $C_2H_3O_2^-(aq)$ instead of $Na^+(aq)$ and $NO_3^-(aq)$.

Now, let's apply these types of equations to the three most important types of chemical reactions—precipitation, acid-base, and oxidation-reduction.

SECTION SUMMARY

A molecular equation for an aqueous ionic reaction shows undissociated substances. A total ionic equation shows all soluble ionic compounds as separate, solvated ions. Spectator ions appear unchanged on both sides of the equation. By eliminating them, you see the actual chemical change in a net ionic equation.

4.3 PRECIPITATION REACTIONS

Animation: Precipitation Reactions
Online Learning Center

Precipitation reactions are common in both nature and industry. Many geological formations, including coral reefs, some gems and minerals, and deep-sea structures form, in part, through this type of chemical process. And, as you'll see, the chemical industry employs precipitation methods to produce several important inorganic compounds.

The Key Event: Formation of a Solid from Dissolved Ions

In **precipitation reactions,** two soluble ionic compounds react to form an insoluble product, a **precipitate.** The reaction you just saw between silver nitrate and sodium chromate is an example. Precipitates form for the same reason that some ionic compounds do not dissolve: the electrostatic attraction between the ions outweighs the tendency of the ions to remain solvated and move randomly throughout the solution. When solutions of such ions are mixed, the ions collide and stay

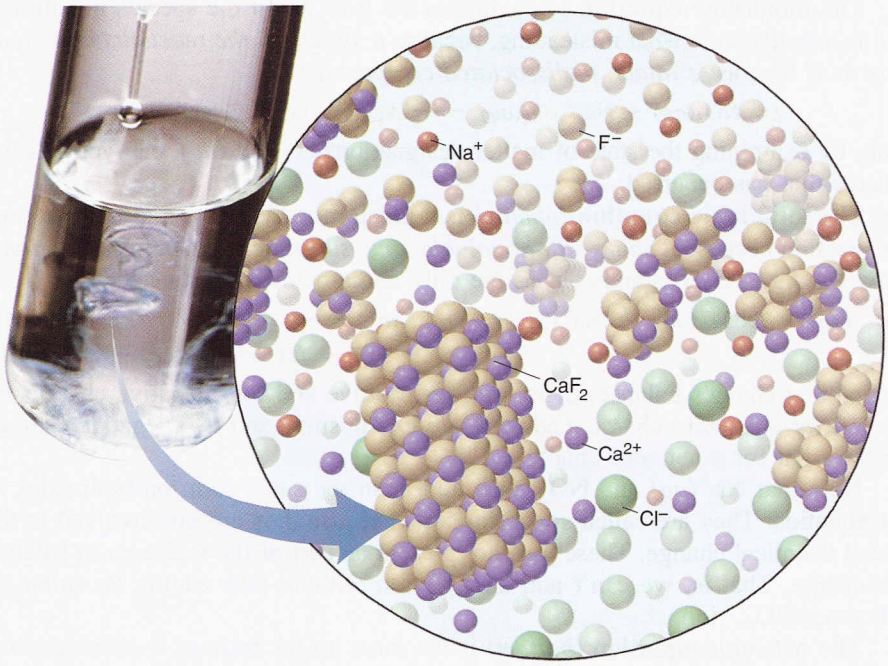

Figure 4.6 The precipitation of calcium fluoride. When an aqueous solution of NaF is added to a solution of $CaCl_2$, Ca^{2+} and F^- ions form particles of solid CaF_2.

together, and the resulting substance "comes out of solution" as a solid, as shown in Figure 4.6 for calcium fluoride.

Thus, the key event in a precipitation reaction is *the formation of an insoluble product through the net removal of solvated ions from solution.* (As you'll see shortly, acid-base reactions have a similar result but the product is water instead of an ionic compound.)

Predicting Whether a Precipitate Will Form

If you mix aqueous solutions of two ionic compounds, can you predict if a precipitate will form? Consider this example. When solid sodium iodide and potassium nitrate are each dissolved in water, each solution consists of separated ions dispersed throughout the solution:

$$NaI(s) \xrightarrow{H_2O} Na^+(aq) + I^-(aq)$$
$$KNO_3(s) \xrightarrow{H_2O} K^+(aq) + NO_3^-(aq)$$

Let's follow three steps to predict whether a precipitate will form:

1. *Note the ions present in the reactants.* The reactant ions are
$$Na^+(aq) + I^-(aq) + K^+(aq) + NO_3^-(aq) \longrightarrow ?$$
2. *Consider the possible cation-anion combinations.* In addition to the two original ones, NaI and KNO_3, which you know are soluble, the other possible cation-anion combinations are $NaNO_3$ and KI.
3. *Decide whether any of the combinations is insoluble.* A reaction does *not* occur when you mix these starting solutions because all the combinations—NaI, KNO_3, $NaNO_3$, and KI—are soluble. All the ions remain in solution. (You'll see shortly a set of rules for deciding if a product is soluble or not.)

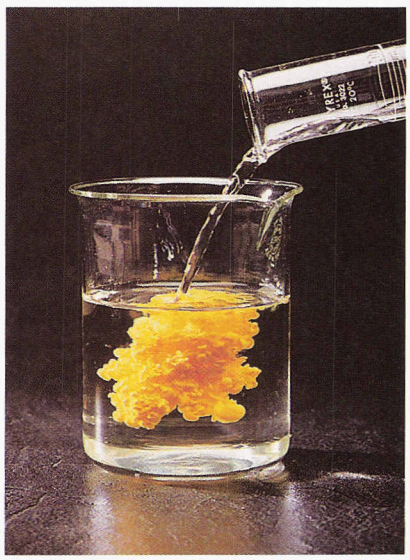

Figure 4.7 The reaction of $Pb(NO_3)_2$ and NaI. When aqueous solutions of these ionic compounds are mixed, the yellow solid PbI_2 forms.

Now, what happens if you substitute a solution of lead(II) nitrate, $Pb(NO_3)_2$, for the KNO_3? The reactant ions are Na^+, I^-, Pb^{2+}, and NO_3^-. In addition to the two soluble reactants, NaI and $Pb(NO_3)_2$, the other two possible cation-anion combinations are $NaNO_3$ and PbI_2. Lead(II) iodide is insoluble, so a reaction *does* occur because ions are removed from solution (Figure 4.7):

$$2Na^+(aq) + 2I^-(aq) + Pb^{2+}(aq) + 2NO_3^-(aq) \longrightarrow 2Na^+(aq) + 2NO_3^-(aq) + PbI_2(s)$$

Table 4.1 Solubility Rules for Ionic Compounds in Water

Soluble Ionic Compounds	Insoluble Ionic Compounds
1. All common compounds of Group 1A(1) ions (Li^+, Na^+, K^+, etc.) and ammonium ion (NH_4^+) are soluble.	1. All common metal hydroxides are insoluble, *except* those of Group 1A(1) and the larger members of Group 2A(2) (beginning with Ca^{2+}).
2. All common nitrates (NO_3^-), acetates (CH_3COO^- or $C_2H_3O_2^-$), and most perchlorates (ClO_4^-) are soluble.	2. All common carbonates (CO_3^{2-}) and phosphates (PO_4^{3-}) are insoluble, *except* those of Group 1A(1) and NH_4^+.
3. All common chlorides (Cl^-), bromides (Br^-), and iodides (I^-) are soluble, *except* those of Ag^+, Pb^{2+}, Cu^+, and Hg_2^{2+}. All common fluorides (F^-) are soluble, *except* those of Pb^{2+} and Group 2A(2).	3. All common sulfides are insoluble *except* those of Group 1A(1), Group 2A(2), and NH_4^+.
4. All common sulfates (SO_4^{2-}) are soluble, *except* those of Ca^{2+}, Sr^{2+}, Ba^{2+}, Ag^+, and Pb^{2+}.	

A close look (with color) at the molecular equation shows that *the ions are exchanging partners*:

$$2NaI(aq) + Pb(NO_3)_2(aq) \longrightarrow PbI_2(s) + 2NaNO_3(aq)$$

Such reactions are called double-displacement, or **metathesis** (pronounced *meh-TA-thuh-sis*) **reactions.** Several are important in industry, such as the preparation of silver bromide for the manufacture of black-and-white film:

$$AgNO_3(aq) + KBr(aq) \longrightarrow AgBr(s) + KNO_3(aq)$$

As we said, there is no simple way to decide whether any given ion combination is soluble or not, so Table 4.1 provides a short list of solubility rules to memorize. They allow you to predict the outcome of many precipitation reactions.

SAMPLE PROBLEM 4.3 Predicting Whether a Precipitation Reaction Occurs; Writing Ionic Equations

Problem Predict whether a reaction occurs when each of the following pairs of solutions are mixed. If a reaction does occur, write balanced molecular, total ionic, and net ionic equations, and identify the spectator ions.

(a) Sodium sulfate(aq) + strontium nitrate(aq) $\longrightarrow$

(b) Ammonium perchlorate(aq) + sodium bromide(aq) $\longrightarrow$

Plan For each pair of solutions, we note the ions present in the reactants, write the cation-anion combinations, and refer to Table 4.1 to see if any are insoluble. For the molecular equation, we predict the products. For the total ionic equation, we write the soluble compounds as separate ions. For the net ionic equation, we eliminate the spectator ions.

Solution **(a)** In addition to the reactants, the two other ion combinations are strontium sulfate and sodium nitrate. Table 4.1 shows that strontium sulfate is insoluble, so a reaction *does* occur. Writing the molecular equation:

$$Na_2SO_4(aq) + Sr(NO_3)_2(aq) \longrightarrow SrSO_4(s) + 2NaNO_3(aq)$$

Writing the total ionic equation:

$$2Na^+(aq) + SO_4^{2-}(aq) + Sr^{2+}(aq) + 2NO_3^-(aq) \longrightarrow SrSO_4(s) + 2Na^+(aq) + 2NO_3^-(aq)$$

Writing the net ionic equation:

$$Sr^{2+}(aq) + SO_4^{2-}(aq) \longrightarrow SrSO_4(s)$$

The spectator ions are Na^+ and NO_3^-.

(b) The other ion combinations are ammonium bromide and sodium perchlorate. Table 4.1 shows that all ammonium, sodium, and most perchlorate compounds are soluble, and all bromides are soluble except those of Ag^+, Pb^{2+}, Cu^+, and Hg_2^{2+}. Therefore, ***no*** reaction occurs. The compounds remain dissociated in solution as solvated ions.

FOLLOW-UP PROBLEM 4.3 Predict whether a reaction occurs, and write balanced total and net ionic equations:
(a) Iron(III) chloride(aq) + cesium phosphate(aq) ⟶
(b) Sodium hydroxide(aq) + cadmium nitrate(aq) ⟶
(c) Magnesium bromide(aq) + potassium acetate(aq) ⟶
(d) Silver sulfate(aq) + barium chloride(aq) ⟶

SECTION SUMMARY

Precipitation reactions involve the formation of an insoluble ionic compound from two soluble ones. They occur because electrostatic attractions among certain pairs of solvated ions are strong enough to cause their removal from solution. Such reactions can be predicted by noting whether any possible ion combinations are insoluble, based on a set of solubility rules.

Table 4.2 Strong and Weak Acids and Bases

Acids

Strong

Hydrochloric acid, HCl
Hydrobromic acid, HBr
Hydriodic acid, HI
Nitric acid, HNO_3
Sulfuric acid, H_2SO_4
Perchloric acid, $HClO_4$

Weak

Hydrofluoric acid, HF
Phosphoric acid, H_3PO_4
Acetic acid, CH_3COOH (or $HC_2H_3O_2$)

Bases

Strong

Sodium hydroxide, NaOH
Potassium hydroxide, KOH
Calcium hydroxide, $Ca(OH)_2$
Strontium hydroxide, $Sr(OH)_2$
Barium hydroxide, $Ba(OH)_2$

Weak

Ammonia, NH_3

Strong acids and bases are strong electrolytes.

Weak acids and bases are weak electrolytes.

4.4 ACID-BASE REACTIONS

Aqueous acid-base reactions involve water not only as solvent but also in the more active roles of reactant and product. These reactions occur in processes as diverse as the biochemical synthesis of proteins, the production of industrial fertilizer, and some of the methods for revitalizing lakes damaged by acid rain.

Obviously, an **acid-base reaction** (also called a **neutralization reaction**) occurs when an acid reacts with a base, but the definitions of these terms and the scope of this reaction category have changed considerably over the years. For our purposes at this point, we'll use definitions that apply to chemicals you commonly encounter in the lab:

- *An **acid** is a substance that produces H^+ ions when dissolved in water.*

$$HX \xrightarrow{H_2O} H^+(aq) + X^-(aq)$$

- *A **base** is a substance that produces OH^- ions when dissolved in water.*

$$MOH \xrightarrow{H_2O} M^+(aq) + OH^-(aq)$$

(Other definitions of *acid* and *base* are presented later in this section and again in Chapter 18, along with a fuller meaning of *neutralization*.)

Acids and bases are electrolytes and are often categorized in terms of their "strength," which refers to the degree to which they dissociate into ions in aqueous solution. Table 4.2 lists some acids and bases in terms of their strength. In water, *strong acids and strong bases dissociate completely* into ions. Therefore, like soluble ionic compounds, they are *strong* electrolytes and conduct a current well (see left photo). In contrast, *weak acids and weak bases dissociate into ions very little, and most of their molecules remain intact.* As a result, they conduct only a small current and are *weak* electrolytes (see right photo).

Strong and weak acids have one or more H atoms as part of their structure. Strong bases have either the OH^- or the O^{2-} ion as part of their structure. Soluble ionic oxides, such as K_2O, are strong bases because the oxide ion is not stable in water and reacts immediately to form hydroxide ion:

$$K_2O(s) + H_2O(l) \longrightarrow 2K^+(aq) + 2OH^-(aq)$$

Weak bases, such as ammonia, do not contain OH^- ions, but they produce them in a reaction with water that occurs to a small extent:

$$NH_3(g) + H_2O(l) \rightleftharpoons NH_4^+(aq) + OH^-(aq)$$

(Note the reaction arrow in the preceding equation. This type of arrow indicates that the reaction proceeds in both directions; we'll discuss this important idea further in Section 4.7.)

The Key Event: Formation of H_2O from H^+ and OH^-

Let's use ionic equations to see what occurs in acid-base reactions. We begin with the molecular equation for the reaction between the strong acid HCl and the strong base $Ba(OH)_2$:

$$2HCl(aq) + Ba(OH)_2(aq) \longrightarrow BaCl_2(aq) + 2H_2O(l)$$

Because HCl and $Ba(OH)_2$ dissociate completely and H_2O remains undissociated, the total ionic equation is

$$2H^+(aq) + 2Cl^-(aq) + Ba^{2+}(aq) + 2OH^-(aq) \longrightarrow Ba^{2+}(aq) + 2Cl^-(aq) + 2H_2O(l)$$

In the net ionic equation, we eliminate the spectator ions $Ba^{2+}(aq)$ and $Cl^-(aq)$ and see the actual reaction:

$$2H^+(aq) + 2OH^-(aq) \longrightarrow 2H_2O(l)$$

Or

$$H^+(aq) + OH^-(aq) \longrightarrow H_2O(l)$$

Thus, *the essential change in all aqueous reactions between a strong acid and a strong base is that an H^+ ion from the acid and an OH^- ion from the base form a water molecule. In fact,* only the spectator ions differ from one strong acid–strong base reaction to another.

Now it's easy to understand how these reactions take place: like precipitation reactions, acid-base reactions occur through *the electrostatic attraction of ions and their removal from solution* in the formation of the product. In this case, the ions are H^+ and OH^- and the product is H_2O, which consists almost entirely of undissociated molecules. (Actually, water molecules *do* dissociate, but *very* slightly. As you'll see in Chapter 18, this slight dissociation is very important, but the formation of water in a neutralization reaction nevertheless represents an enormous net removal of H^+ and OH^- ions.)

Evaporate the water from the above reaction mixture, and the ionic solid barium chloride remains. An ionic compound that results from the reaction of an acid and a base is called a **salt.** Thus, in a typical aqueous neutralization reaction, *the reactants are an acid and a base, and the products are a salt solution and water:*

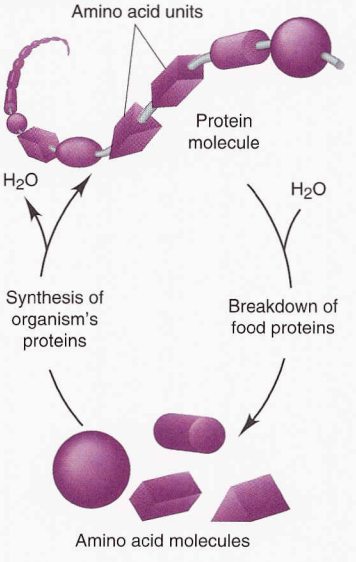
$$\underset{\text{acid}}{HX(aq)} + \underset{\text{base}}{MOH(aq)} \longrightarrow \underset{\text{salt}}{MX(aq)} + \underset{\text{water}}{H_2O(l)}$$

The color shows that *the cation of the salt comes from the base and the anion comes from the acid.*

Note that acid-base reactions, like precipitation reactions, are metathesis (double-displacement) reactions. The molecular equation for the reaction of aluminum hydroxide, the active ingredient in some antacid tablets, with HCl, the major component of stomach acid, shows this clearly:

$$3HCl(aq) + Al(OH)_3(s) \longrightarrow AlCl_3(aq) + 3H_2O(l)$$

Acid-base reactions occur frequently in the synthesis and breakdown of biological macromolecules.



Displacement Reactions Inside You

The digestion of food proteins and the formation of an organism's own proteins form a continuous cycle of displacement reactions. A protein consists of hundreds or thousands of smaller molecules, called *amino acids,* linked in a long chain. When you eat proteins, your digestive processes use H_2O to displace one amino acid at a time. These are transported by the blood to your cells, where other metabolic processes link them together, displacing H_2O, to make your own proteins.

SAMPLE PROBLEM 4.4 Writing Ionic Equations for Acid-Base Reactions

Problem Write balanced molecular, total ionic, and net ionic equations for each of the following acid-base reactions and identify the spectator ions:

(a) Strontium hydroxide(aq) + perchloric acid(aq) $\longrightarrow$

(b) Barium hydroxide(aq) + sulfuric acid(aq) $\longrightarrow$

Plan All are strong acids and bases (see Table 4.2), so the essential reaction is between H^+ and OH^-. The products are H_2O and a salt solution consisting of the spectator ions. Note that in **(b)**, the salt ($BaSO_4$) is insoluble (see Table 4.1), so virtually all ions are removed from solution.

Solution (a) Writing the molecular equation:

$$Sr(OH)_2(aq) + 2HClO_4(aq) \longrightarrow Sr(ClO_4)_2(aq) + 2H_2O(l)$$

Writing the total ionic equation:

$$Sr^{2+}(aq) + 2OH^-(aq) + 2H^+(aq) + 2ClO_4^-(aq) \longrightarrow Sr^{2+}(aq) + 2ClO_4^-(aq) + 2H_2O(l)$$

Writing the net ionic equation:

$$2OH^-(aq) + 2H^+(aq) \longrightarrow 2H_2O(l) \quad \text{or} \quad OH^-(aq) + H^+(aq) \longrightarrow H_2O(l)$$

$Sr^{2+}(aq)$ and $ClO_4^-(aq)$ are the spectator ions.

(b) Writing the molecular equation:

$$Ba(OH)_2(aq) + H_2SO_4(aq) \longrightarrow BaSO_4(s) + 2H_2O(l)$$

Writing the total ionic equation:

$$Ba^{2+}(aq) + 2OH^-(aq) + 2H^+(aq) + SO_4^{2-}(aq) \longrightarrow BaSO_4(s) + 2H_2O(l)$$

The net ionic equation is the same as the total ionic equation. This is a precipitation *and* a neutralization reaction. There are no spectator ions because all the ions are used to form the two products.

FOLLOW-UP PROBLEM 4.4 Write balanced molecular, total ionic, and net ionic equations for the reaction between aqueous solutions of calcium hydroxide and nitric acid.

Acid-Base Titrations

Chemists study acid-base reactions quantitatively through titrations. In any **titration,** *one solution of known concentration is used to determine the concentration of another solution through a monitored reaction.*

In a typical acid-base titration, a *standardized* solution of base, one whose concentration is *known,* is added slowly to an acid solution of *unknown* concentration (Figure 4.8). A known volume of the acid solution is placed in a flask, and a few drops of indicator solution are added. An *acid-base indicator* is a substance

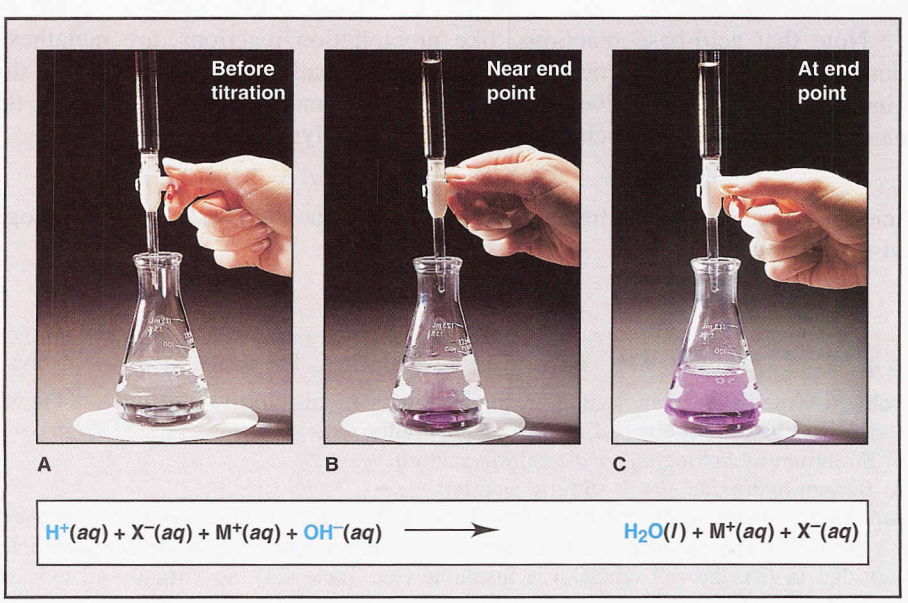


Figure 4.8 An acid-base titration. **A,** In this procedure, a measured volume of the unknown acid solution is placed in a flask beneath a buret containing the known (standardized) base solution. A few drops of indicator are added to the flask; the indicator used here is phenolphthalein, which is colorless in acid and pink in base. After an initial buret reading, base (OH^- ions) is added slowly to the acid (H^+ ions). **B,** Near the end of the titration, the indicator momentarily changes to its base color but reverts to its acid color with swirling. **C,** When the end point is reached, a tiny excess of OH^- is present, shown by the permanent change in color of the indicator. The difference between the final buret reading and the initial buret reading gives the volume of base used.

whose color is different in acid than in base. (We examine indicators in Chapters 18 and 19.) The standardized solution of base is added slowly to the flask from a buret. As the titration is close to its end, indicator molecules near a drop of added base change color due to the temporary excess of OH^- ions there. As soon as the solution is swirled, however, the indicator's acidic color returns. The **equivalence point** in the titration occurs when *all the moles of H^+ ions present in the original volume of acid solution have reacted with an equivalent number of moles of OH^- ions added from the buret:*

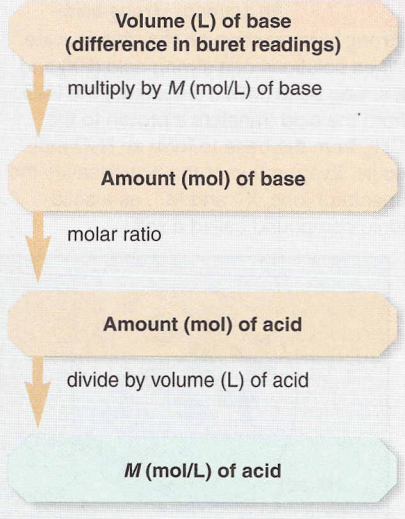
$$\text{Moles of } H^+ \text{ (originally in flask)} = \text{moles of } OH^- \text{ (added from buret)}$$

The **end point** of the titration occurs when a tiny excess of OH^- ions changes the indicator permanently to its color in base. In calculations, we assume this tiny excess is insignificant, and therefore *the amount of base needed to reach the end point is the same as the amount needed to reach the equivalence point.*

SAMPLE PROBLEM 4.5 Finding the Concentration of Acid from an Acid-Base Titration

Problem You perform an acid-base titration to standardize an HCl solution by placing 50.00 mL of HCl in a flask with a few drops of indicator solution. You put 0.1524 *M* NaOH into the buret, and the initial reading is 0.55 mL. At the end point, the buret reading is 33.87 mL. What is the concentration of the HCl solution?

Plan We must find the molarity of acid from the volume of acid (50.00 mL), the initial (0.55 mL) and final (33.87 mL) volumes of base, and the molarity of base (0.1524 *M*). First, we balance the equation. We find the volume of base added from the difference in buret readings and use the base's molarity to calculate the amount (mol) of base added. Then, we use the molar ratio from the balanced equation to find the amount (mol) of acid originally present and divide by the acid's original volume to find the molarity.



Solution Writing the balanced equation:

$$NaOH(aq) + HCl(aq) \longrightarrow NaCl(aq) + H_2O(l)$$

Finding volume (L) of NaOH solution added:

$$\text{Volume (L) of solution} = (33.87 \text{ mL soln} - 0.55 \text{ mL soln}) \times \frac{1 \text{ L}}{1000 \text{ mL}}$$
$$= 0.03332 \text{ L soln}$$

Finding amount (mol) of NaOH added:

$$\text{Moles of NaOH} = 0.03332 \text{ L soln} \times \frac{0.1524 \text{ mol NaOH}}{1 \text{ L soln}}$$
$$= 5.078\times10^{-3} \text{ mol NaOH}$$

Finding amount (mol) of HCl originally present: Since the molar ratio is 1:1,

$$\text{Moles of HCl} = 5.078\times10^{-3} \text{ mol NaOH} \times \frac{1 \text{ mol HCl}}{1 \text{ mol NaOH}} = 5.078\times10^{-3} \text{ mol HCl}$$

Calculating molarity of HCl:

$$\text{Molarity of HCl} = \frac{5.078\times10^{-3} \text{ mol HCl}}{50.00 \text{ mL}} \times \frac{1000 \text{ mL}}{1 \text{ L}}$$
$$= 0.1016 \text{ } M \text{ HCl}$$

Check The answer makes sense: a larger volume of less concentrated acid neutralized a smaller volume of more concentrated base. Rounding shows that the moles of H^+ and OH^- are about equal: 50 mL × 0.1 *M* H^+ = 0.005 mol = 33 mL × 0.15 *M* OH^-.

FOLLOW-UP PROBLEM 4.5 What volume of 0.1292 *M* $Ba(OH)_2$ would neutralize 50.00 mL of the HCl solution standardized in the preceding sample problem?

Proton Transfer: A Closer Look at Acid-Base Reactions

We gain deeper insight into acid-base reactions if we look closely at the species in solution. Let's see what takes place when HCl gas dissolves in water. Polar water molecules pull apart each HCl molecule and the H^+ ion bonds to a water molecule. In essence, we can say that HCl *transfers its proton* to H_2O:

$$HCl(g) + H_2O(l) \xrightarrow{H^+ \text{ transfer}} H_3O^+(aq) + Cl^-(aq)$$

Thus, hydrochloric acid (an aqueous solution of HCl gas) actually consists of solvated H_3O^+ and Cl^- ions.

When sodium hydroxide solution is added, the H_3O^+ ion transfers a proton to the OH^- ion of the base (with the product water shown here as HOH):

$$[H_3O^+(aq) + Cl^-(aq)] + [Na^+(aq) + OH^-(aq)] \xrightarrow{H^+ \text{ transfer}} H_2O(l) + Cl^-(aq) + Na^+(aq) + HOH(l)$$

Without the spectator ions, the transfer of a proton from H_3O^+ to OH^- is obvious:

$$H_3O^+(aq) + OH^-(aq) \xrightarrow{H^+ \text{ transfer}} H_2O(l) + HOH(l) \quad [\text{or } 2H_2O(l)]$$

This net ionic equation is identical with the one we saw earlier (see p. 145),

$$H^+(aq) + OH^-(aq) \longrightarrow H_2O(l)$$

with the additional H_2O molecule coming from the H_3O^+. Thus, *an acid-base reaction is a proton-transfer process.* In this case, the Na^+ and Cl^- ions remain in solution, and if the water is evaporated, they crystallize as the salt NaCl. Figure 4.9 shows this process on the atomic level.

In the early 20th century, the chemists Johannes Brønsted and Thomas Lowry realized the proton-transfer nature of acid-base reactions. They defined *an acid as a molecule (or ion) that donates a proton, and a base as a molecule (or ion) that accepts a proton.* Therefore, in the aqueous reaction between strong acid and

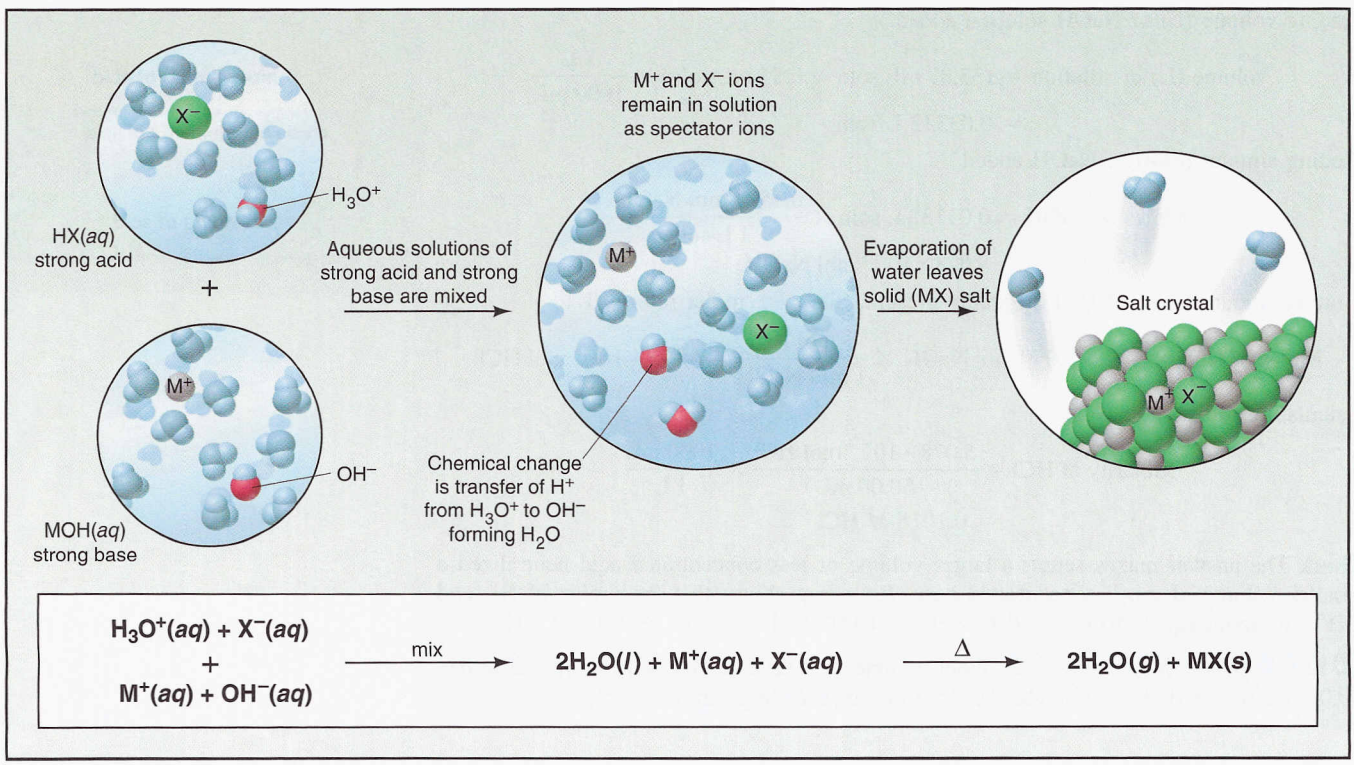


Figure 4.9 An aqueous strong acid–strong base reaction on the atomic scale. When solutions of a strong acid (HX) and a strong base (MOH) are mixed, the H_3O^+ from the acid transfers a proton to the OH^- from the base to form an H_2O molecule. Evaporation of the water leaves the spectator ions, X^- and M^+, as a solid ionic compound called a *salt.*

strong base, *H_3O^+ ion acts as the acid and OH^- ion acts as the base.* Because it ionizes completely, a given amount of strong acid (or strong base) creates an equivalent amount of H_3O^+ (or OH^-) when it dissolves in water. (We discuss the Brønsted-Lowry concept thoroughly in Chapter 18.)

Gas-Forming Reactions Thinking of acid-base reactions as proton-transfer processes helps us understand another common type of aqueous ionic reaction, those that form a gaseous product. For example, when an ionic carbonate, such as K_2CO_3, is treated with an acid, such as HCl, one of the products is carbon dioxide. *Such reactions occur through the formation of a gas **and** water because both products remove reactant ions from solution:*

$$2HCl(aq) + K_2CO_3(aq) \longrightarrow 2KCl(aq) + [H_2CO_3(aq)]$$
$$[H_2CO_3(aq)] \longrightarrow H_2O(l) + CO_2(g)$$

The product H_2CO_3 is shown in square brackets to indicate that it is very unstable. It decomposes immediately into water and carbon dioxide. Combining these two equations gives the overall equation:

$$2HCl(aq) + K_2CO_3(aq) \longrightarrow 2KCl(aq) + H_2O(l) + CO_2(g)$$

When we show H_3O^+ ions from the HCl as the actual species in solution and write the net ionic equation, Cl^- and K^+ ions are eliminated. Note that each of the two H_3O^+ ions transfers a proton to the carbonate ion:

$$2H_3O^+(aq) + CO_3^{2-}(aq) \longrightarrow 2H_2O(l) + [H_2CO_3(aq)] \longrightarrow 3H_2O(l) + CO_2(g)$$

($2H^+$ transfer)

In essence, this is an acid-base reaction with carbonate ion accepting the protons and, thus, acting as the base. Several other polyatomic ions react similarly with an acid. In the formation of SO_2 from ionic sulfites, the net ionic equation is

$$2H_3O^+(aq) + SO_3^{2-}(aq) \longrightarrow 2H_2O(l) + [H_2SO_3(aq)] \longrightarrow 3H_2O(l) + SO_2(g)$$

($2H^+$ transfer)

Reactions of Weak Acids Ionic equations are written differently for the reactions of weak acids. When solutions of sodium hydroxide and acetic acid (CH_3COOH) are mixed, the total and net ionic equations are

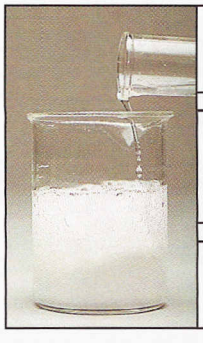
Total ionic equation:

$$CH_3COOH(aq) + Na^+(aq) + OH^-(aq) \longrightarrow CH_3COO^-(aq) + Na^+(aq) + H_2O(l)$$

Net ionic equation:

$$CH_3COOH(aq) + OH^-(aq) \longrightarrow CH_3COO^-(aq) + H_2O(l)$$

Acetic acid dissociates very little because it is a weak acid (see Table 4.2). To show this, *it appears undissociated in both ionic equations*. Note that H_3O^+ does not appear; rather, the proton is transferred from CH_3COOH. Therefore, only $Na^+(aq)$ is a spectator ion; $CH_3COO^-(aq)$ is not. Figure 4.10 shows the gas-forming reaction between vinegar (an aqueous 5% solution of acetic acid) and baking soda (sodium hydrogen carbonate) solution.



Molecular equation

$$NaHCO_3(aq) + CH_3COOH(aq) \longrightarrow CH_3COONa(aq) + CO_2(g) + H_2O(l)$$

Total ionic equation

$$Na^+(aq) + HCO_3^-(aq) + CH_3COOH(aq) \longrightarrow CH_3COO^-(aq) + Na^+(aq) + CO_2(g) + H_2O(l)$$

Net ionic equation

$$HCO_3^-(aq) + CH_3COOH(aq) \longrightarrow CH_3COO^-(aq) + CO_2(g) + H_2O(l)$$

Figure 4.10 An acid-base reaction that forms a gaseous product. Carbonates and hydrogen carbonates react with acids to form gaseous CO_2 and H_2O. Here, dilute acetic acid solution (vinegar) is added to sodium hydrogen carbonate (baking soda) solution, and bubbles of CO_2 gas form. (Note that the net ionic equation includes acetic acid because it does *not* dissociate into ions to an appreciable extent.)

SECTION SUMMARY

Acid-base (neutralization) reactions occur when an acid (an H^+-yielding substance) and a base (an OH^--yielding substance) react and the H^+ and OH^- ions form a water molecule. Strong acids and bases dissociate completely in water; weak acids and bases dissociate slightly. In a titration, a known concentration of one reactant is used to determine the concentration of the other. An acid-base reaction can also be viewed as the transfer of a proton from an acid to a base. An ionic gas-forming reaction is an acid-base reaction in which an acid transfers a proton to a polyatomic ion (carbonate or sulfite), forming a gas that leaves the reaction mixture. Because weak acids dissociate very little, equations involving them show the acid as an intact molecule.

4.5 OXIDATION-REDUCTION (REDOX) REACTIONS

Redox reactions are the third and, perhaps, most important type of chemical process. They include the formation of a compound from its elements (and vice versa), all combustion reactions, the reactions that generate electricity in batteries, the reactions that produce cellular energy, and many others. In this section, we examine the process, learn some essential terminology, and see one way to balance redox equations and one way to apply them quantitatively.

The Key Event: Movement of Electrons Between Reactants

Animation: Oxidation-Reduction Reactions
Online Learning Center

In **oxidation-reduction** (or **redox**) **reactions,** the key chemical event is the *net movement of electrons from one reactant to the other*. This movement of electrons occurs *from the reactant (or atom in the reactant) with less attraction for electrons to the reactant (or atom) with more attraction for electrons.*

Such movement of electron charge occurs in the formation of both ionic and covalent compounds. As an example, let's reconsider the flashbulb reaction (see Figure 3.8, p. 103), in which an ionic compound, MgO, forms from its elements:

$$2Mg(s) + O_2(g) \longrightarrow 2MgO(s)$$

Figure 4.11A shows that during the reaction, each Mg atom loses two electrons and each O atom gains them; that is, two electrons move from each Mg atom to each O atom. This change represents a ***transfer*** *of electron charge* away from

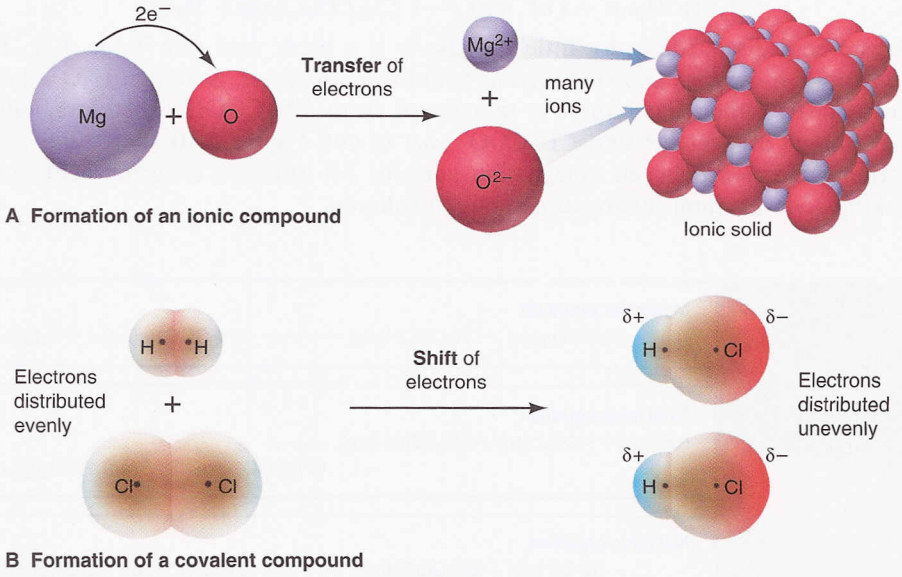


Figure 4.11 The redox process in compound formation. A, In forming the ionic compound MgO, each Mg atom transfers two electrons to each O atom. (Note that atoms become smaller when they lose electrons and larger when they gain electrons.) The resulting Mg^{2+} and O^{2-} ions aggregate with many others to form an ionic solid. **B,** In the reactants H_2 and Cl_2, the electron pairs are shared equally (indicated by even electron density shading). In the covalent product HCl, Cl attracts the shared electrons more strongly than H does. In effect, the H electron shifts toward Cl, as shown by higher electron density *(red)* near the Cl end of the molecule and lower electron density *(blue)* near the H end.

each Mg atom toward each O atom, resulting in the formation of Mg^{2+} and O^{2-} ions. The ions aggregate and form an ionic solid.

During the formation of a covalent compound from its elements, there is again a net movement of electrons, but it is more of a *shift* in electron charge than a full transfer. Thus, *ions do not form*. Consider the formation of HCl gas:

$$H_2(g) + Cl_2(g) \longrightarrow 2HCl(g)$$

To see the electron movement here, compare the electron charge distributions in the reactant bonds and in the product bonds. As Figure 4.11B shows, H_2 and Cl_2 molecules are each held together by covalent bonds in which the electrons are shared equally between the atoms (the tan shading is symmetrical). In the HCl molecule, the electrons are shared unequally because the Cl atom attracts them more strongly than the H atom does. Thus, in HCl, the H has less electron charge *(blue shading)* than it had in H_2, and the Cl has more charge *(red shading)* than it had in Cl_2. In other words, in the formation of HCl, there has been a relative ***shift*** *of electron charge* away from the H atom toward the Cl atom. This electron *shift* is not nearly as extreme as the electron *transfer* during MgO formation. In fact, in some reactions, the net movement of electrons may be very slight, but the reaction is still a redox process.

Some Essential Redox Terminology

Chemists use some important terminology to describe the movement of electrons in oxidation-reduction reactions. **Oxidation** is the *loss* of electrons, and **reduction** is the *gain* of electrons. (The original meaning of *reduction* comes from the process of reducing large amounts of metal ore to smaller amounts of metal, but you'll see shortly why we use the term for the act of gaining.)

For example, during the formation of magnesium oxide, Mg undergoes oxidation (electron loss) and O_2 undergoes reduction (electron gain). The loss and gain are simultaneous, but we can imagine them occurring in separate steps:

Oxidation (electron loss by Mg): $Mg \longrightarrow Mg^{2+} + 2e^-$

Reduction (electron gain by O_2): $\frac{1}{2}O_2 + 2e^- \longrightarrow O^{2-}$

One reactant acts on the other. Thus, we say that *O_2 oxidizes Mg*, and that O_2 is the **oxidizing agent,** the species doing the oxidizing. Similarly, *Mg reduces O_2*, so Mg is the **reducing agent,** the species doing the reducing.

Note especially that O_2 removes the electrons that Mg loses or, put the other way around, Mg gives up the electrons that O_2 gains. This give-and-take of electrons means that *the oxidizing agent is reduced* because it removes the electrons (and thus gains them), and *the reducing agent is oxidized* because it gives up the electrons (and thus loses them). In the formation of HCl, Cl_2 oxidizes H_2 (H loses some electron charge and Cl gains it), which is the same as saying that H_2 reduces Cl_2. The reducing agent, H_2, is oxidized and the oxidizing agent, Cl_2, is reduced.

Using Oxidation Numbers to Monitor the Movement of Electron Charge

Chemists have devised a useful "bookkeeping" system to monitor which atom loses electron charge and which atom gains it. Each atom in a molecule (or ionic compound) is assigned an **oxidation number (O.N.),** or *oxidation state,* the charge the atom would have *if* electrons were not shared but were transferred completely. Oxidation numbers are determined by the set of rules in Table 4.3. [Note that an oxidation number has the sign *before* the number (+2), whereas an ionic charge has the sign *after* the number (2+).]

Table 4.3 Rules for Assigning an Oxidation Number (O.N.)

General Rules

1. For an atom in its elemental form (Na, O_2, Cl_2, etc.): O.N. = 0
2. For a monatomic ion: O.N. = ion charge
3. The sum of O.N. values for the atoms in a molecule or formula unit of a compound equals zero. The sum of O.N. values for the atoms in a polyatomic ion equals the ion's charge.

Rules for Specific Atoms or Periodic Table Groups

1.	For Group 1A(1):	O.N. = +1 in all compounds
2.	For Group 2A(2):	O.N. = +2 in all compounds
3.	For hydrogen:	O.N. = +1 in combination with nonmetals
		O.N. = −1 in combination with metals and boron
4.	For fluorine:	O.N. = −1 in all compounds
5.	For oxygen:	O.N. = −1 in peroxides
		O.N. = −2 in all other compounds (except with F)
6.	For Group 7A(17):	O.N. = −1 in combination with metals, nonmetals (except O), and other halogens lower in the group

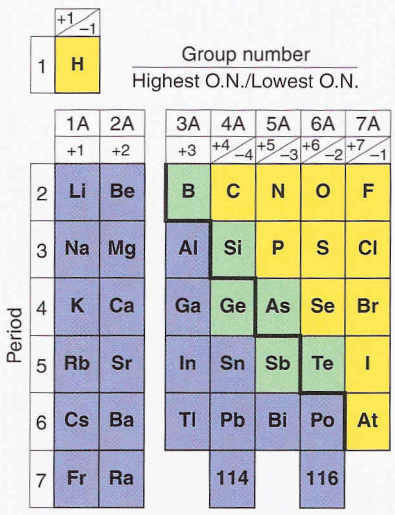

Figure 4.12 Highest and lowest oxidation numbers of reactive main-group elements. The A-group number shows the highest possible oxidation number (O.N.) for a main-group element. (Two important exceptions are O, which never has an O.N. of +6, and F, which never has an O.N. of +7.) For nonmetals *(yellow)* and metalloids *(green)*, the A-group number minus 8 gives the lowest possible oxidation number.

SAMPLE PROBLEM 4.6 Determining the Oxidation Number of an Element

Problem Determine the oxidation number (O.N.) of each element in these compounds:
(a) Zinc chloride **(b)** Sulfur trioxide **(c)** Nitric acid

Plan We apply Table 4.3, noting the general rules that the O.N. values in a compound add up to zero, and the O.N. values in a polyatomic ion add up to the ion's charge.

Solution **(a)** $ZnCl_2$. The sum of O.N.s for the monatomic ions in the compound must equal zero. The O.N. of the Zn^{2+} ion is +2. The O.N. of each Cl^- ion is −1, for a total of −2. The sum of O.N.s is +2 + (−2), or 0.

(b) SO_3. The O.N. of each oxygen is −2, for a total of −6. Since the O.N.s must add up to zero, the O.N. of S is +6.

(c) HNO_3. The O.N. of H is +1, so the O.N.s of the NO_3 group must add up to −1 to give zero for the compound. The O.N. of each O is −2 for a total of −6. Therefore, the O.N. of N is +5.

FOLLOW-UP PROBLEM 4.6 Determine the O.N. of each element in the following:
(a) Scandium oxide (Sc_2O_3) **(b)** Gallium chloride ($GaCl_3$)
(c) Hydrogen phosphate ion **(d)** Iodine trifluoride

The periodic table is a great help in learning the highest and lowest oxidation numbers of most main-group elements, as Figure 4.12 shows:

- For most main-group elements, the A-group number (1A, 2A, and so on) is the *highest* oxidation number (always positive) of any element in the group. The exceptions are O and F (see Table 4.3).
- For main-group nonmetals and some metalloids, the A-group number minus 8 is the *lowest* oxidation number (always negative) of any element in the group.

For example, the highest oxidation number of S (Group 6A) is +6, as in SF_6, and the lowest is (6 − 8), or −2, as in FeS and other metal sulfides.

As you can see, the oxidation number for an element in a binary *ionic* compound has a realistic value, because it usually equals the ionic charge. On the other hand, the oxidation number for an element in a *covalent* compound (or in a polyatomic ion) has an unrealistic value because the atoms don't have whole charges.

Another way to define a redox reaction is one in which *the oxidation numbers of the species change,* and the most important use of oxidation numbers is to monitor these changes:

- If a given atom has a higher (more positive or less negative) oxidation number in the product than it had in the reactant, the reactant species that contains the atom was oxidized (lost electrons). Thus, *oxidation is represented by an increase in oxidation number.*
- If an atom has a lower (more negative or less positive) oxidation number in the product than it had in the reactant, the reactant species that contains the atom was reduced (gained electrons). Thus, *the gain of electrons is represented by a decrease (a "reduction") in oxidation number.* (Reduction, as mentioned earlier, refers to an ore being "reduced" to the metal. The reducing agents provide electrons that convert the ore's metal ions to atoms.)

Figure 4.13 summarizes redox terminology. Oxidation numbers are assigned according to the relative attraction of an atom for electrons, so they are ultimately based on atomic properties, as you'll see in Chapters 8 and 9. (For the remainder of this section and the next, blue oxidation numbers represent oxidation, and red oxidation numbers indicate reduction.)

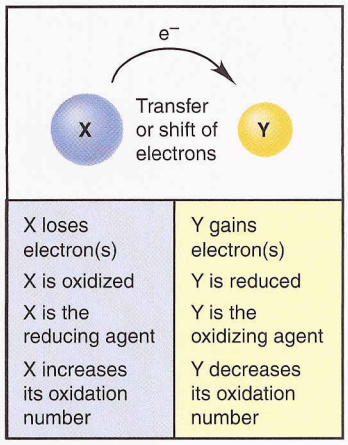

Figure 4.13 **A summary of terminology for oxidation-reduction (redox) reactions.**

SAMPLE PROBLEM 4.7 Recognizing Oxidizing and Reducing Agents

Problem Identify the oxidizing agent and reducing agent in each of the following:

(a) $2Al(s) + 3H_2SO_4(aq) \longrightarrow Al_2(SO_4)_3(aq) + 3H_2(g)$

(b) $PbO(s) + CO(g) \longrightarrow Pb(s) + CO_2(g)$

(c) $2H_2(g) + O_2(g) \longrightarrow 2H_2O(g)$

Plan We first assign an oxidation number (O.N.) to each atom (or ion) based on the rules in Table 4.3. The reactant is the reducing agent if it contains an atom that is oxidized (O.N. increased from left side to right side of the equation). The reactant is the oxidizing agent if it contains an atom that is reduced (O.N. decreased).

Solution **(a)** Assigning oxidation numbers:

$$\overset{0}{2Al(s)} + \overset{+1}{3H_2}\overset{+6}{S}\overset{-2}{O_4}(aq) \longrightarrow \overset{+3}{Al_2}(\overset{+6}{S}\overset{-2}{O_4})_3(aq) + \overset{0}{3H_2}(g)$$

The O.N. of Al increased from 0 to +3 (Al lost electrons), so Al was oxidized; Al is the reducing agent.

The O.N. of H decreased from +1 to 0 (H gained electrons), so H^+ was reduced; H_2SO_4 is the oxidizing agent.

(b) Assigning oxidation numbers:

$$\overset{+2}{Pb}\overset{-2}{O}(s) + \overset{+2}{C}\overset{-2}{O}(g) \longrightarrow \overset{0}{Pb}(s) + \overset{+4}{C}\overset{-2}{O_2}(g)$$

Pb decreased its O.N. from +2 to 0, so PbO was reduced; PbO is the oxidizing agent.

C increased its O.N. from +2 to +4, so CO was oxidized; CO is the reducing agent.

In general, when a substance (such as CO) becomes one with more O atoms (as in CO_2), it is oxidized; and when a substance (such as PbO) becomes one with fewer O atoms (as in Pb), it is reduced.

(c) Assigning oxidation numbers:

$$\overset{0}{2H_2}(g) + \overset{0}{O_2}(g) \longrightarrow \overset{+1-2}{2H_2O}(g)$$

O_2 was reduced (O.N. of O decreased from 0 to −2); O_2 is the oxidizing agent.

H_2 was oxidized (O.N. of H increased from 0 to +1); H_2 is the reducing agent.

Oxygen is always the oxidizing agent in a combustion reaction.

Comment 1. Compare the O.N. values in (c) with those in another common reaction that forms water—the net ionic equation for an acid-base reaction:

$$\overset{+1}{H^+}(aq) + \overset{-2}{\overset{+1}{OH^-}}(aq) \longrightarrow \overset{+1-2}{H_2O}(l)$$

Note that the O.N. values remain the same on both sides of the acid-base equation. Therefore, *an acid-base reaction is* **not** *a redox reaction.*

2. If a substance occurs in its elemental form on one side of an equation, it can't possibly be in its elemental form on the other side, so the reaction must be a redox process. Notice that elements appear in all three parts of this problem.

FOLLOW-UP PROBLEM 4.7 Identify each oxidizing agent and each reducing agent:

(a) $2Fe(s) + 3Cl_2(g) \longrightarrow 2FeCl_3(s)$

(b) $2C_2H_6(g) + 7O_2(g) \longrightarrow 4CO_2(g) + 6H_2O(g)$

(c) $5CO(g) + I_2O_5(s) \longrightarrow I_2(s) + 5CO_2(g)$

Balancing Redox Equations

It is essential to realize that *the reducing agent loses electrons and the oxidizing agent gains them* ***simultaneously***. A chemical change can be an "oxidation-reduction reaction" but *not* an "oxidation reaction" *or* a "reduction reaction." The transferred electrons are never free, which means that we can balance a redox reaction by making sure that *the number of electrons lost by the reducing agent equals the number of electrons gained by the oxidizing agent.*

Two methods used to balance redox equations are the *oxidation number* method and the *half-reaction* method. This section describes the oxidation number method in detail; the half-reaction method is covered in Chapter 21. (If your professor chooses to cover that section here, it is completely transferable with no loss in continuity.)

The **oxidation number method** for balancing redox equations consists of five steps that use the changes in oxidation numbers to generate balancing coefficients. The first two steps are identical to those in Sample Problem 4.7:

Step 1. Assign oxidation numbers to all elements in the reaction.

Step 2. From the changes in oxidation numbers, identify the oxidized and reduced species.

Step 3. Compute the number of electrons lost in the oxidation and gained in the reduction from the oxidation number changes. (Draw tie-lines between these atoms to show the changes.)

Step 4. Multiply one or both of these numbers by appropriate factors to make the electrons lost equal the electrons gained, and use the factors as balancing coefficients.

Step 5. Complete the balancing by inspection, adding states of matter.

SAMPLE PROBLEM 4.8 Balancing Redox Equations by the Oxidation Number Method

Problem Use the oxidation number method to balance the following equations:

(a) $Cu(s) + HNO_3(aq) \longrightarrow Cu(NO_3)_2(aq) + NO_2(g) + H_2O(l)$

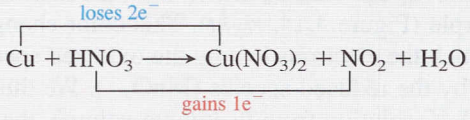
(b) $PbS(s) + O_2(g) \longrightarrow PbO(s) + SO_2(g)$

Solution **(a)** *Step 1.* Assign oxidation numbers to all elements:

$$\overset{0}{Cu} + \overset{+5}{\overset{+1}{H}}\overset{-2}{N}\overset{-2}{O_3} \longrightarrow \overset{+5}{\overset{+2}{Cu}}\overset{-2}{(N}\overset{-2}{O_3)_2} + \overset{-2}{\overset{+4}{N}}\overset{-2}{O_2} + \overset{+1-2}{H_2O}$$

Step 2. Identify oxidized and reduced species. The O.N. of Cu increased from 0 (in Cu metal) to +2 (in Cu^{2+}); Cu was oxidized. The O.N. of N decreased from +5 (in HNO_3) to +4 (in NO_2); HNO_3 was reduced. Note that some NO_3^- also acts as a spectator ion, appearing unchanged in the $Cu(NO_3)_2$; this is common in redox reactions.

Step 3. Compute e^- lost and e^- gained and draw tie-lines between the atoms. In the oxidation, $2e^-$ were lost from Cu. In the reduction, $1e^-$ was gained by N:



Step 4. Multiply by factors to make e^- lost equal e^- gained, and use the factors as coefficients. Cu lost $2e^-$, so the $1e^-$ gained by N should be multiplied by 2. We put the coefficient 2 before NO_2 and HNO_3:

$$Cu + 2HNO_3 \longrightarrow Cu(NO_3)_2 + 2NO_2 + H_2O$$

Step 5. Complete the balancing by inspection. Balancing N atoms requires a 4 in front of HNO_3 because two additional N atoms are in the NO_3^- ions in $Cu(NO_3)_2$:

$$Cu + 4HNO_3 \longrightarrow Cu(NO_3)_2 + 2NO_2 + H_2O$$

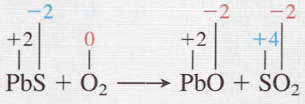
Then, balancing H atoms requires a 2 in front of H_2O, and we add states of matter:

$$Cu(s) + 4HNO_3(aq) \longrightarrow Cu(NO_3)_2(aq) + 2NO_2(g) + 2H_2O(l)$$

Check (a)

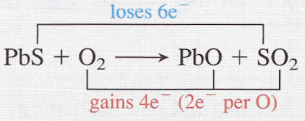
Reactants (1 Cu, 4 H, 4 N, 12 O) ⟶ products [1 Cu, 4 H, (2 + 2) N, (6 + 4 + 2) O]

Solution (b) *Step 1.* Assign oxidation numbers:



Step 2. Identify species that are oxidized and reduced. PbS was oxidized: the O.N. of S increased from −2 in PbS to +4 in SO_2. O_2 was reduced: the O.N. of O decreased from 0 in O_2 to −2 in PbO and in SO_2.

Step 3. Compute e^- lost and e^- gained and draw tie-lines. The S lost $6e^-$, and each O gained $2e^-$:



Step 4. Multiply by factors to make e^- lost equal e^- gained. The S atom loses $6e^-$, and each O in O_2 gains $2e^-$, for a total gain of $4e^-$. Thus, placing the coefficient $\frac{3}{2}$ before O_2 gives 3 O atoms that each gain $2e^-$, for a total gain of $6e^-$:

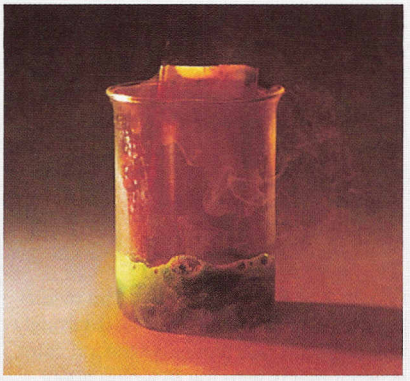
$$PbS + \tfrac{3}{2}O_2 \longrightarrow PbO + SO_2$$

Step 5. Complete the balancing by inspection. The atoms are balanced, but all coefficients must be multiplied by 2 to obtain integers, and we add states of matter:

$$2PbS(s) + 3O_2(g) \longrightarrow 2PbO(s) + 2SO_2(g)$$

Check (b) Reactants (2 Pb, 2 S, 6 O) ⟶ products [2 Pb, 2 S, (2 + 4) O]

FOLLOW-UP PROBLEM 4.8 Use the oxidation number method to balance the following: $K_2Cr_2O_7(aq) + HI(aq) \longrightarrow KI(aq) + CrI_3(aq) + I_2(s) + H_2O(l)$



Copper in nitric acid

Redox Titrations

In an acid-base titration, a known concentration of base is used to find an unknown concentration of an acid (or vice versa). Similarly, in a redox titration, a known concentration of oxidizing agent is used to find an unknown concentration of reducing agent (or vice versa). This application of stoichiometry is used in a wide range of situations, including measuring the iron content in drinking water and the vitamin C content in fruits and vegetables.

The permanganate ion, MnO_4^-, is a common oxidizing agent in these titrations because it is strongly colored and, thus, also serves as an indicator. In Figure 4.14, MnO_4^- is used to oxidize the oxalate ion, $C_2O_4^{2-}$, to determine its concentration. As long as any $C_2O_4^{2-}$ is present, it reduces the deep purple MnO_4^- to the very faint pink (nearly colorless) Mn^{2+} ion (Figure 4.14, *left*). As soon as all the available $C_2O_4^{2-}$ has been oxidized, the next drop of MnO_4^- turns the solution light purple (Figure 4.14, *right*). This color change indicates the end point, the point at which the electrons lost by the oxidized species ($C_2O_4^{2-}$) equal the electrons gained by the reduced species (MnO_4^-). We then calculate the concentration of the $C_2O_4^{2-}$ solution from its known volume, the known volume and concentration of the MnO_4^- solution, and the balanced equation. Preparing a sample for a redox titration sometimes requires several laboratory steps, as shown in Sample Problem 4.9 for the determination of the Ca^{2+} ion concentration of blood.

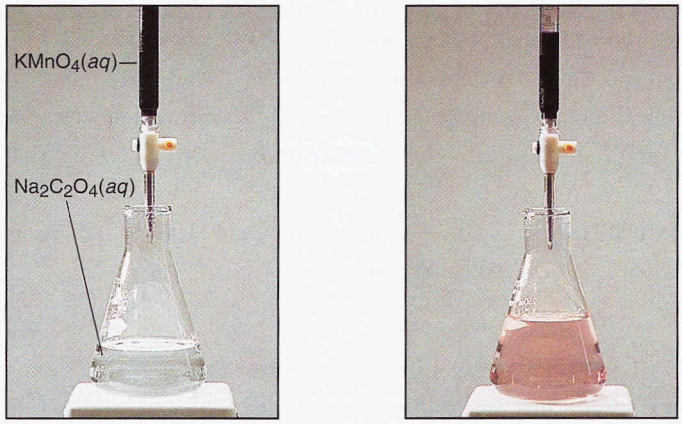


Figure 4.14 A redox titration. The oxidizing agent in the buret, $KMnO_4$, is strongly colored, so it also serves as the indicator. When it reacts with the reducing agent $C_2O_4^{2-}$ in the flask, its color changes from deep purple to very faint pink (nearly colorless) *(left)*. When all the $C_2O_4^{2-}$ is oxidized, the next drop of $KMnO_4$ remains unreacted and turns the solution light purple *(right)*, signaling the end point of the titration.

Net ionic equation:

$$\overset{+7}{2MnO_4^-}(aq) + 5\overset{+3}{C_2O_4^{2-}}(aq) + 16H^+(aq) \longrightarrow \overset{+2}{2Mn^{2+}}(aq) + 10\overset{+4}{CO_2}(g) + 8H_2O(l)$$

SAMPLE PROBLEM 4.9 Finding a Concentration by a Redox Titration

Problem Calcium ion (Ca^{2+}) is required for blood to clot and for many other cell processes. An abnormal Ca^{2+} concentration is indicative of disease. To measure the Ca^{2+} concentration, 1.00 mL of human blood is treated with $Na_2C_2O_4$ solution. The resulting CaC_2O_4 precipitate is filtered and dissolved in dilute H_2SO_4 to release $C_2O_4^{2-}$ into solution and allow it to be oxidized. This solution required 2.05 mL of 4.88×10^{-4} M $KMnO_4$ to reach the end point. The unbalanced equation is

$$KMnO_4(aq) + CaC_2O_4(s) + H_2SO_4(aq) \longrightarrow MnSO_4(aq) + K_2SO_4(aq) + CaSO_4(s) + CO_2(g) + H_2O(l)$$

(a) Calculate the amount (mol) of Ca^{2+}.
(b) Calculate the Ca^{2+} ion concentration expressed in units of mg Ca^{2+}/100 mL blood.

Volume (L) of $KMnO_4$ solution
↓ multiply by M (mol/L)
Amount (mol) of $KMnO_4$
↓ molar ratio
Amount (mol) of CaC_2O_4
↓ ratio of elements in chemical formula
Amount (mol) of Ca^{2+}

(a) Calculating the moles of Ca^{2+}

Plan As always, we first balance the equation. All the Ca^{2+} ion in the 1.00-mL blood sample is precipitated and then dissolved in the H_2SO_4. We find the number of moles of $KMnO_4$ needed to reach the end point from the volume (2.05 mL) and molarity (4.88×10^{-4} M) and use the molar ratio to calculate the number of moles of CaC_2O_4 dissolved in the H_2SO_4. Then, from the chemical formula, we find moles of Ca^{2+} ions.

Solution Balancing the equation:

$$2KMnO_4(aq) + 5CaC_2O_4(s) + 8H_2SO_4(aq) \longrightarrow 2MnSO_4(aq) + K_2SO_4(aq) + 5CaSO_4(s) + 10CO_2(g) + 8H_2O(l)$$

Converting from milliliters and molarity to moles of $KMnO_4$ to reach the end point:

$$\text{Moles of } KMnO_4 = 2.05 \text{ mL soln} \times \frac{1 \text{ L}}{1000 \text{ mL}} \times \frac{4.88\times10^{-4} \text{ mol } KMnO_4}{1 \text{ L soln}}$$
$$= 1.00\times10^{-6} \text{ mol } KMnO_4$$

Converting from moles of $KMnO_4$ to moles of CaC_2O_4 titrated:

$$\text{Moles of } CaC_2O_4 = 1.00\times10^{-6} \text{ mol } KMnO_4 \times \frac{5 \text{ mol } CaC_2O_4}{2 \text{ mol } KMnO_4} = 2.50\times10^{-6} \text{ mol } CaC_2O_4$$

Finding moles of Ca^{2+} present:

$$\text{Moles of } Ca^{2+} = 2.50\times10^{-6} \text{ mol } CaC_2O_4 \times \frac{1 \text{ mol } Ca^{2+}}{1 \text{ mol } CaC_2O_4}$$
$$= 2.50\times10^{-6} \text{ mol } Ca^{2+}$$

Check A very small volume of dilute $KMnO_4$ is needed, so 10^{-6} mol of $KMnO_4$ seems reasonable. The molar ratio of 5:2 for CaC_2O_4 to $KMnO_4$ gives 2.5×10^{-6} mol of CaC_2O_4 and thus 2.5×10^{-6} mol of Ca^{2+}.

(b) Expressing the Ca^{2+} concentration as mg/100 mL blood

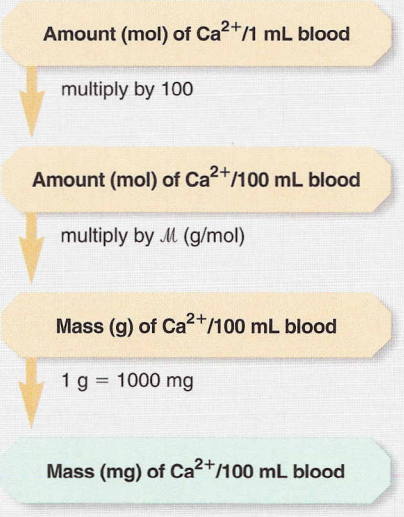
Plan The amount in part (a) is the moles of Ca^{2+} ion present in 1.00 mL of blood. We multiply by 100 to obtain the moles of Ca^{2+} ion in 100 mL of blood and then use the atomic mass of Ca to convert that amount to grams and then milligrams.

Solution Finding moles of Ca^{2+}/100 mL blood:

$$\text{Moles of } Ca^{2+}/100 \text{ mL blood} = \frac{2.50\times10^{-6} \text{ mol } Ca^{2+}}{1.00 \text{ mL blood}} \times 100$$
$$= 2.50\times10^{-4} \text{ mol } Ca^{2+}/100 \text{ mL blood}$$

Converting from moles of Ca^{2+} to milligrams:

$$\text{Mass (mg) } Ca^{2+}/100 \text{ mL blood} = \frac{2.50\times10^{-4} \text{ mol } Ca^{2+}}{100 \text{ mL blood}} \times \frac{40.08 \text{ g } Ca^{2+}}{1 \text{ mol } Ca^{2+}} \times \frac{1000 \text{ mg}}{1 \text{ g}}$$
$$= 10.0 \text{ mg } Ca^{2+}/100 \text{ mL blood}$$



Check The relative amounts of Ca^{2+} make sense. If there is 2.5×10^{-6} mol/mL blood, there is 2.5×10^{-4} mol/100 mL blood. A molar mass of about 40 g/mol for Ca^{2+} gives 100×10^{-4} g, or 10×10^{-3} g/100 mL blood. It is easy to make an order-of-magnitude (power of 10) error in this type of calculation, so be sure to include all units.

Comment **1.** The normal range for the Ca^{2+} concentration in a human adult is 9.0 to 11.5 mg Ca^{2+}/100 mL blood, so our value seems reasonable.

2. When blood is donated, the receiving bag contains $Na_2C_2O_4$ solution, which precipitates the Ca^{2+} ion and, thus, prevents clotting.

3. A redox titration is analogous to an acid-base titration: in redox processes, electrons are lost and gained, whereas in acid-base processes, H^+ ions are lost and gained.

FOLLOW-UP PROBLEM 4.9 A 2.50-mL sample of low-fat milk was treated with sodium oxalate, and the precipitate was filtered and dissolved in H_2SO_4. This solution required 6.53 mL of 4.56×10^{-3} *M* $KMnO_4$ to reach the end point.

(a) Calculate the molarity of Ca^{2+} in the milk.

(b) What is the concentration of Ca^{2+} in g/L? Is this value consistent with the typical value in milk of about 1.2 g Ca^{2+}/L?

SECTION SUMMARY

When one reactant has a greater attraction for electrons than another, there is a net movement of electron charge, and a redox reaction takes place. Electron gain (reduction) and electron loss (oxidation) occur simultaneously. The redox process is tracked by assigning oxidation numbers to each atom in a reaction. The species that is oxidized (contains an atom that increases in oxidation number) is the reducing agent; the species that is reduced (contains an atom that decreases in oxidation number) is the oxidizing agent. Redox reactions can be balanced by keeping track of the changes in oxidation number. A redox titration is used to determine the concentration of either the oxidizing or the reducing agent from the known concentration of the other.

4.6 ELEMENTS IN REDOX REACTIONS

As we saw in Sample Problem 4.7, if a substance appears as a free element on one side of an equation, it must appear in a different form on the other side, which means there must have been a change in oxidation state. Therefore, *whenever a reaction includes a free element as either reactant or product, it is a redox reaction*. And, while there are many redox reactions that do *not* involve free elements, such as the one between MnO_4^- and $C_2O_4^{2-}$ that we saw earlier, we'll focus here on the many others that do. One way to classify these is by comparing the numbers of reactants and products. By that approach, we have three types:

- *Combination reactions*: two or more reactants form one product:

$$X + Y \longrightarrow Z$$

- *Decomposition reactions:* one reactant forms two or more products:

$$Z \longrightarrow X + Y$$

- *Displacement reactions:* the number of substances is the same but atoms (or ions) exchange places:

$$X + YZ \longrightarrow XZ + Y$$

Combining Two Elements Two elements may react to form binary ionic or covalent compounds. Here are some important examples:

1. *Metal and nonmetal form an ionic compound.* Figure 4.15 shows the reaction between an alkali metal and a halogen on the observable and atomic scales. Note the change in oxidation numbers. As you can see, K is oxidized, so it is the reducing agent; Cl_2 is reduced, so it is the oxidizing agent.

Aluminum reacts with O_2, as does nearly every metal, to form an ionic oxide:

$$\overset{0}{4Al(s)} + \overset{0}{3O_2(g)} \longrightarrow \overset{+3\ -2}{2Al_2O_3(s)}$$

2. *Two nonmetals form a covalent compound.* In one of thousands of examples, ammonia forms from nitrogen and hydrogen in a reaction that occurs in industry on an enormous scale:

$$\overset{0}{N_2(g)} + \overset{0}{3H_2(g)} \longrightarrow \overset{+1}{\overset{-3}{2NH_3(g)}}$$

Halogens form many compounds with other nonmetals, as in the formation of phosphorus trichloride, a major reactant in the production of pesticides and other organic compounds:

$$\overset{0}{P_4(s)} + \overset{0}{6Cl_2(g)} \longrightarrow \overset{-1}{\overset{+3}{4PCl_3(l)}}$$

Nearly every nonmetal reacts with O_2 to form a covalent oxide, as when nitrogen monoxide forms at the very high temperatures created in air by lightning:

$$\overset{0}{N_2(g)} + \overset{0}{O_2(g)} \longrightarrow \overset{-2}{\overset{+2}{2NO(g)}}$$

Combining Compound and Element Many binary covalent compounds react with nonmetals to form larger compounds. Many nonmetal oxides react with additional O_2 to form "higher" oxides (those with more O atoms in each molecule). For example,

$$\overset{-2}{\overset{+2}{2NO(g)}} + \overset{0}{O_2(g)} \longrightarrow \overset{-2}{\overset{+4}{2NO_2(g)}}$$

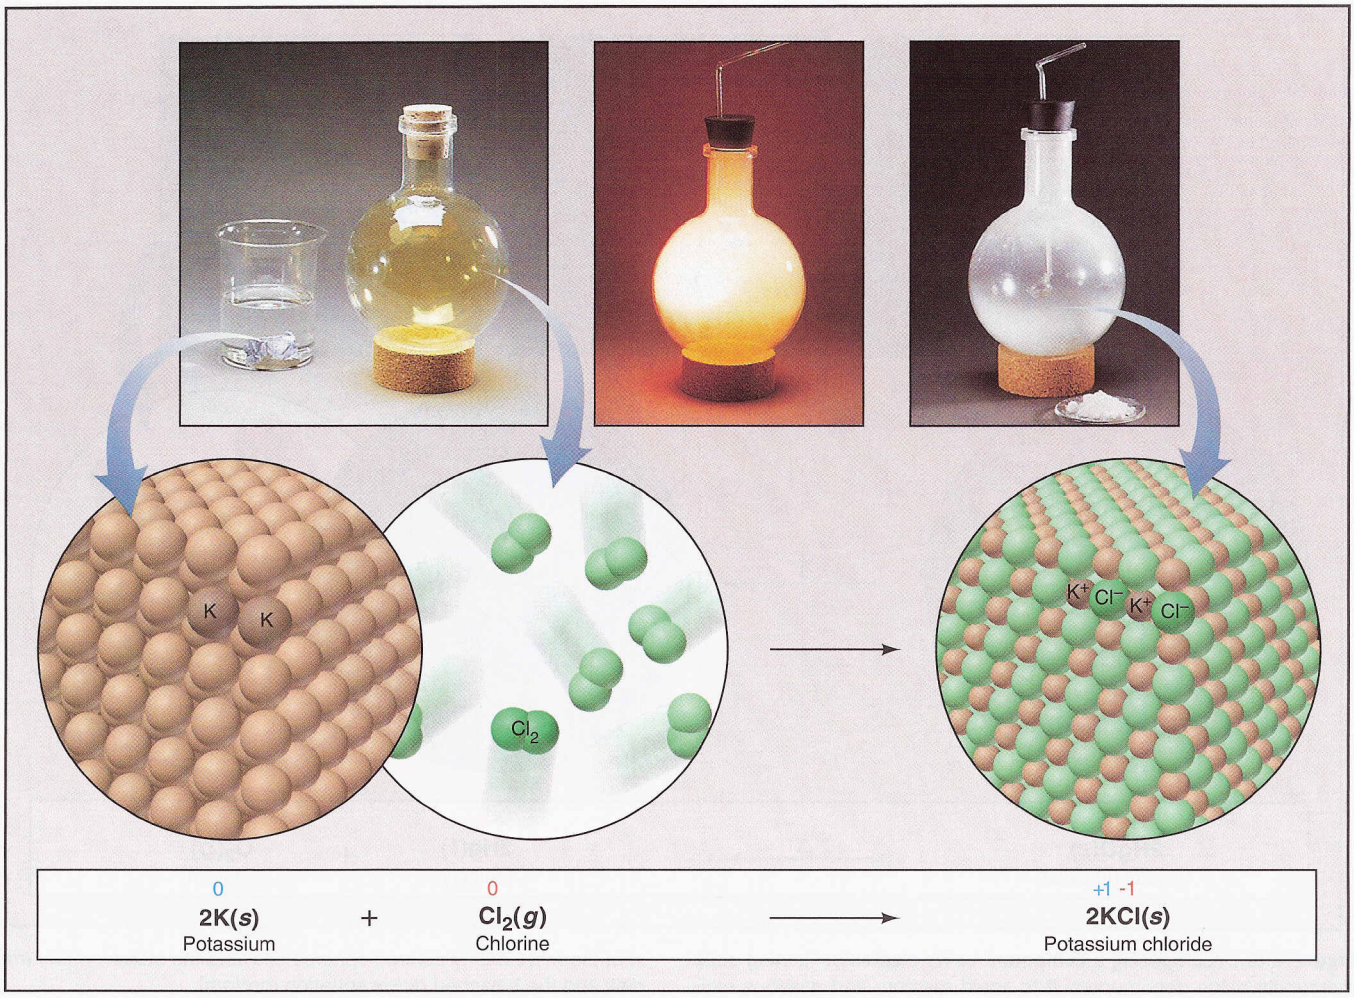


Figure 4.15 Combining elements to form an ionic compound. When the metal potassium and the nonmetal chlorine react, they form the solid ionic compound potassium chloride. The photos *(top)* present the view the chemist sees in the laboratory. The blow-up arrows lead to an atomic-scale view *(middle);* the stoichiometry is indicated by the more darkly colored spheres. The balanced redox equation is shown with oxidation numbers *(bottom).*

Similarly, many nonmetal halides combine with additional halogen:

$$\overset{+3}{\underset{}{PCl_3}}(l) + \overset{0}{Cl_2}(g) \longrightarrow \overset{+5}{PCl_5}(s)$$

Decomposing Compounds into Elements A decomposition reaction occurs when a reactant absorbs enough energy for one or more of its bonds to break. The energy can take many forms—heat, electricity, light, mechanical, and so forth—but we'll focus in this discussion on heat and electricity. The products are either elements or elements and smaller compounds. Following are several common examples:

1. *Thermal decomposition.* When the energy absorbed is heat, the reaction is a thermal decomposition. (A Greek *delta*, Δ, above a reaction arrow indicates that heat is required for the reaction.) Many metal oxides, chlorates, and perchlorates release oxygen when strongly heated. The decomposition of mercury(II) oxide, used by Lavoisier and Priestley in their classic experiments, is shown on the

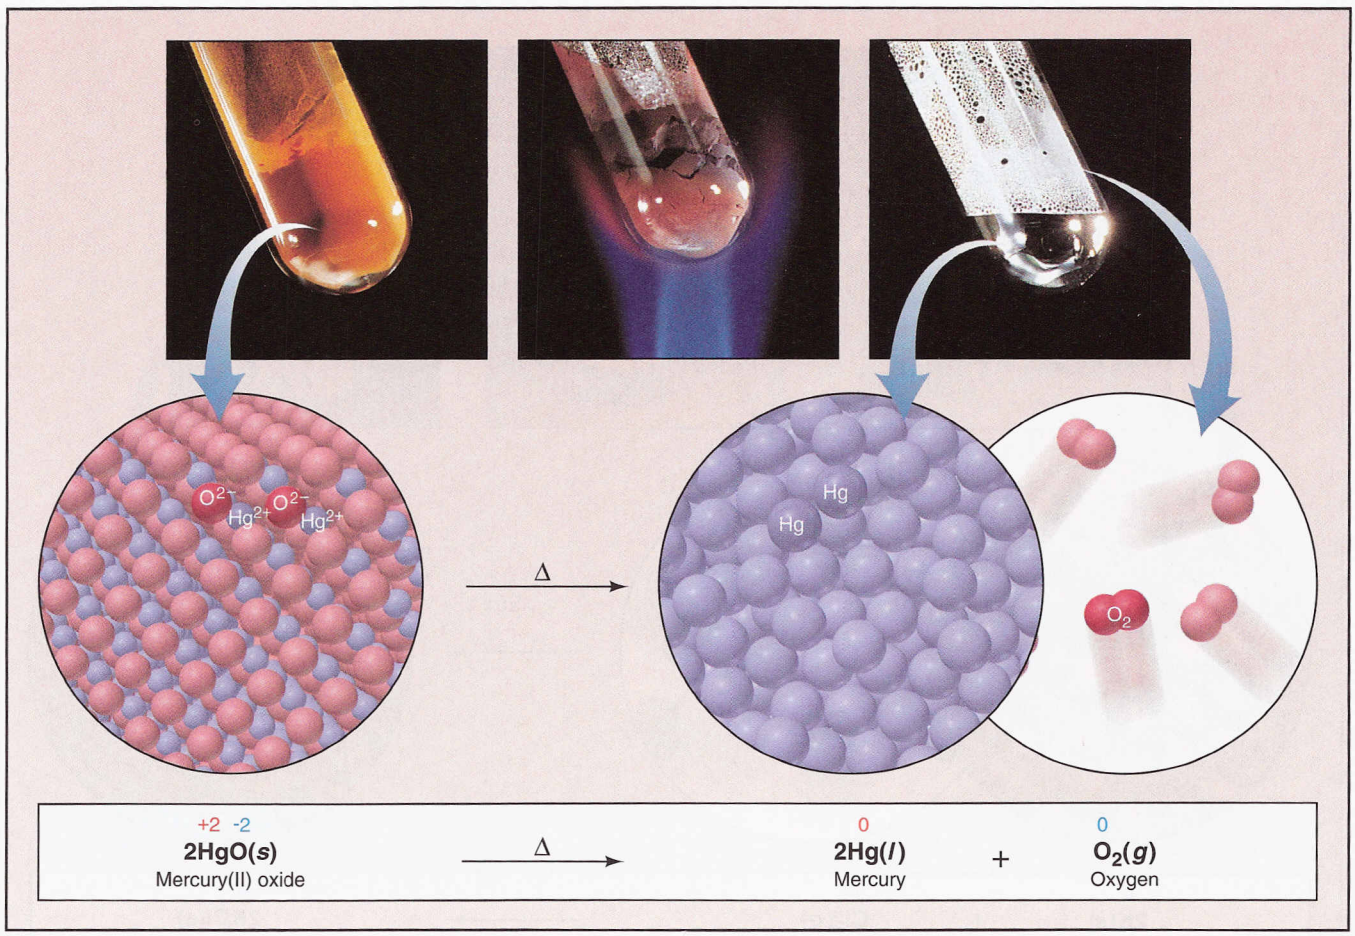

Figure 4.16 Decomposing a compound to its elements. Heating solid mercury(II) oxide decomposes it to liquid mercury and gaseous oxygen: the macroscopic (laboratory) view *(top);* the atomic-scale view, with the more darkly colored spheres showing the stoichiometry *(middle);* and the balanced redox equation *(bottom).*

macroscopic and atomic scales in Figure 4.16. Heating potassium chlorate is a modern method for forming small amounts of oxygen in the laboratory; the same reaction occurs in some explosives and fireworks:

$$\overset{+1}{\underset{|}{}}\overset{+5}{\underset{|}{}}\overset{-2}{\underset{|}{}} \qquad \overset{+1}{\underset{|}{}}\overset{-1}{\underset{|}{}} \qquad \overset{0}{\underset{|}{}}$$
$$2KClO_3(s) \xrightarrow{\Delta} 2KCl(s) + 3O_2(g)$$

Notice that, in these cases, the lone reactant is the oxidizing *and* the reducing agent. For example, with HgO, O^{2-} reduces Hg^{2+} (and Hg^{2+} oxidizes O^{2-}).

2. *Electrolytic decomposition.* In the process of *electrolysis,* a compound absorbs electrical energy and decomposes into its elements. Observing the electrolysis of water was crucial in the establishment of atomic masses:

$$\overset{+1}{\underset{|}{}}\overset{-2}{\underset{|}{}} \qquad \overset{0}{\underset{|}{}} \qquad \overset{0}{\underset{|}{}}$$
$$2H_2O(l) \xrightarrow{\text{electricity}} 2H_2(g) + O_2(g)$$

Many active metals, such as sodium, magnesium, and calcium, are produced industrially by electrolysis of their molten halides:

$$\overset{+2}{\underset{|}{}}\overset{-1}{\underset{|}{}} \qquad \overset{0}{\underset{|}{}} \qquad \overset{0}{\underset{|}{}}$$
$$MgCl_2(l) \xrightarrow{\text{electricity}} Mg(l) + Cl_2(g)$$

(We'll examine the details of electrolysis in Chapters 21 and 22.)

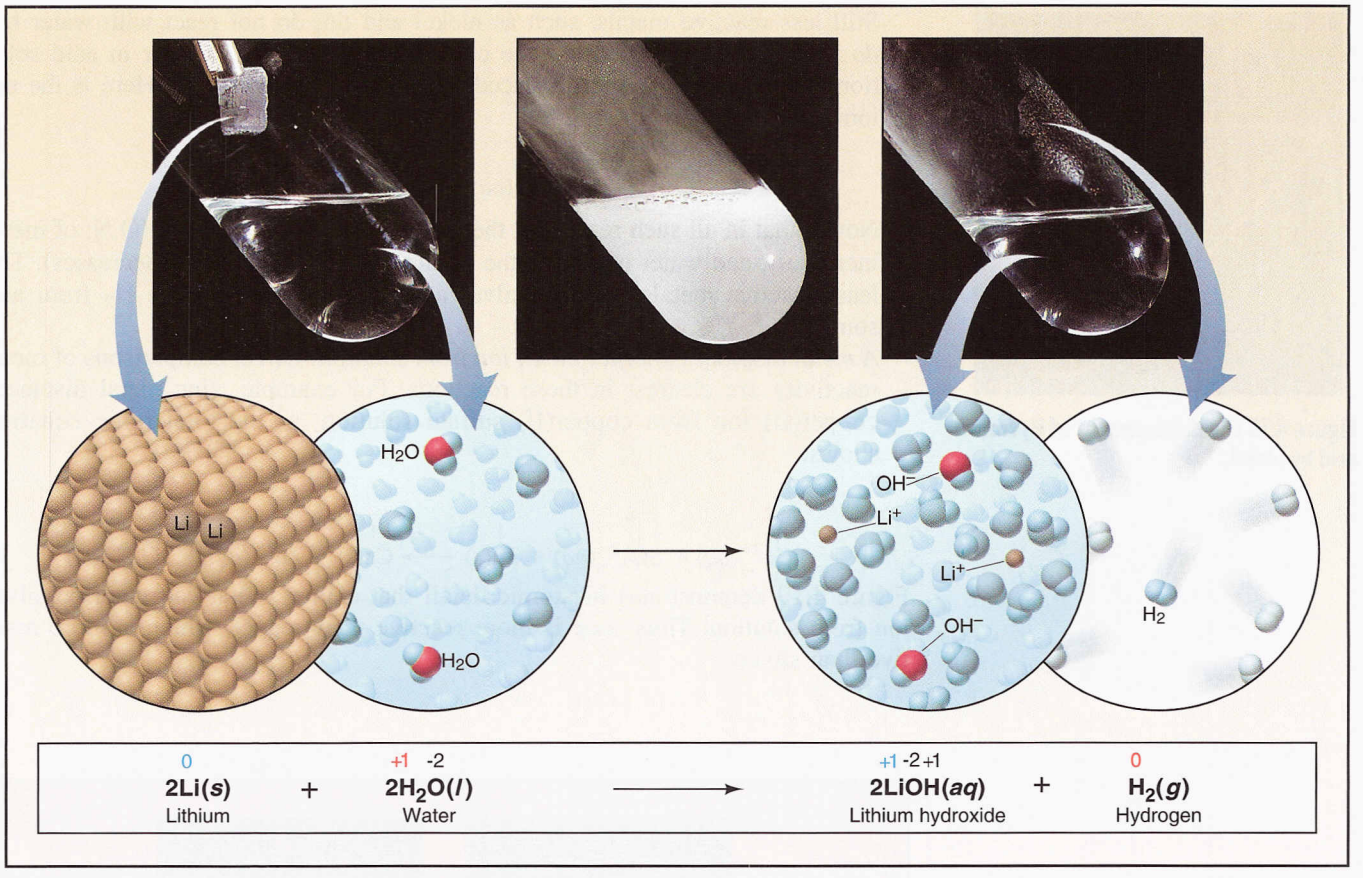

Figure 4.17 An active metal displacing hydrogen from water. Lithium displaces hydrogen from water in a vigorous reaction that yields an aqueous solution of lithium hydroxide and hydrogen gas, as shown on the macroscopic scale *(top)*, at the atomic scale *(middle)*, and as a balanced equation *(bottom)*. (For clarity, the atomic-scale view of water has been greatly simplified, and only water molecules involved in the reaction are colored red and blue.)

Displacing One Element by Another; Activity Series As we said, displacement reactions have the same number of reactants as products. We mentioned double-displacement (metathesis) reactions in discussing precipitation and acid-base reactions. The other type, *single-displacement* reactions, are all oxidation-reduction processes. They occur when one atom displaces the ion of a different atom from solution. When the reaction involves metals, the atom reduces the ion; when it involves nonmetals (specifically halogens), the atom oxidizes the ion. Chemists rank various elements into activity series—one for metals and one for halogens—in order of their ability to displace one another.

1. *The activity series of the metals.* Metals can be ranked by their ability to displace H_2 from various sources or by their ability to displace one another from solution.

- *A metal displaces H_2 from water or acid.* The most reactive metals, such as those from Group 1A(1) and Ca, Sr, and Ba from Group 2A(2), displace H_2 from water, and they do so vigorously. Figure 4.17 shows this reaction for lithium. Heat is needed to speed the reaction of slightly less reactive metals, such as Al and Zn, so these metals displace H_2 from steam:

$$\overset{0}{2Al(s)} + \overset{+1\,-2}{6H_2O(g)} \longrightarrow \overset{+3\,-2\,+1}{2Al(OH)_3(s)} + \overset{0}{3H_2(g)}$$

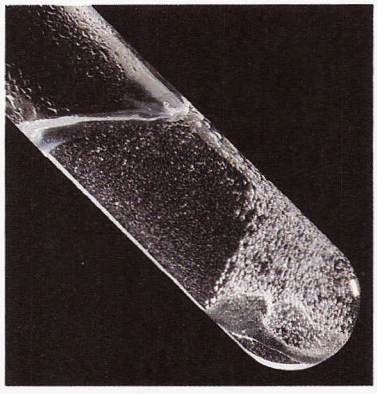

Figure 4.18 The displacement of H_2 from acid by nickel.

Still less reactive metals, such as nickel and tin, do not react with water but *do* react with acids. Because the concentration of H^+ is higher in acid solutions than in water, H_2 is displaced more easily (Figure 4.18). Here is the net ionic equation:

$$\overset{0}{\text{Ni}}(s) + 2\overset{+1}{\text{H}}^+(aq) \longrightarrow \overset{+2}{\text{Ni}}^{2+}(aq) + \overset{0}{\text{H}_2}(g)$$

Notice that in all such reactions, the metal is the reducing agent (O.N. of metal increases), and water or acid is the oxidizing agent (O.N. of H decreases). The least reactive metals, such as silver and gold, cannot displace H_2 from any source.

- *A metal displaces another metal ion from solution.* Direct comparisons of metal reactivity are clearest in these reactions. For example, zinc metal displaces copper(II) ion from copper(II) sulfate solution, as the total ionic equation shows:

$$\overset{+2}{\text{Cu}}^{2+}(aq) + \overset{+6\ -2}{\text{SO}_4}^{2-}(aq) + \overset{0}{\text{Zn}}(s) \longrightarrow \overset{0}{\text{Cu}}(s) + \overset{+2}{\text{Zn}}^{2+}(aq) + \overset{+6\ -2}{\text{SO}_4}^{2-}(aq)$$

Figure 4.19 demonstrates in atomic detail that copper metal can displace silver ion from solution. Thus, zinc is more reactive than copper, which is more reactive than silver.

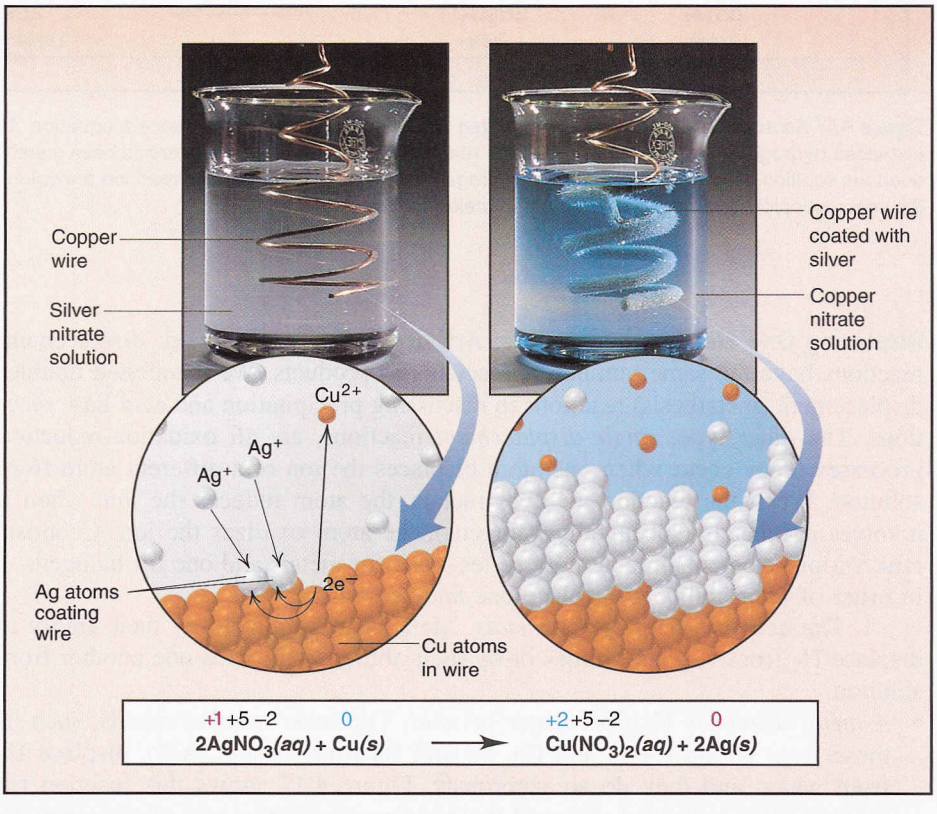

Figure 4.19 Displacing one metal by another. More reactive metals displace less reactive metals from solution. In this reaction, Cu atoms each give up two electrons as they become Cu^{2+} ions and leave the wire. The electrons are transferred to two Ag^+ ions that become Ag atoms and deposit on the wire. With time, a coating of crystalline silver coats the wire. Thus, copper has displaced silver from solution. The reaction is depicted as the laboratory view *(top),* the atomic-scale view *(middle),* and the balanced redox equation *(bottom).*

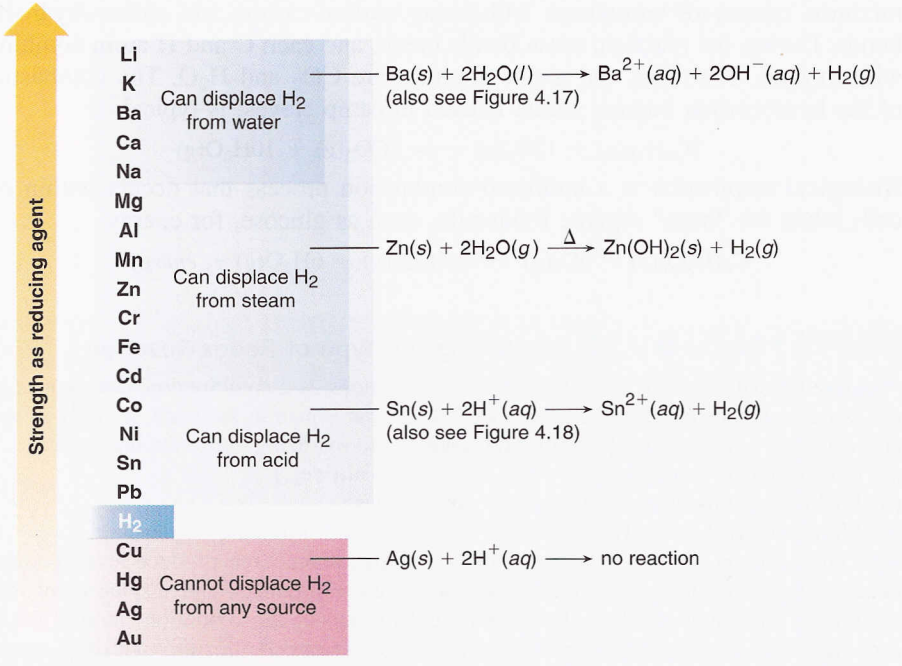

Figure 4.20 The activity series of the metals. This list of metals (and H_2) is arranged with the most active metal (strongest reducing agent) at the top and the least active metal (weakest reducing agent) at the bottom. The four metals below H_2 cannot displace it from any source. An example from each group appears to the right as a net ionic equation. (The ranking refers to behavior of ions in aqueous solution.)

The results of many such reactions between metals and water, aqueous acids, and metal-ion solutions form the basis of the **activity series of the metals.** In Figure 4.20 elements higher on the list are stronger reducing agents than elements lower down; that is, for those that are stable in water, elements higher on the list can reduce aqueous ions of elements lower down. The list also shows whether the metal can displace H_2 and, if so, from which source. Look at the metals in the equations we've just discussed. Note that Li, Al, and Ni lie above H_2, while Ag lies below it; also, Zn lies above Cu, which lies above Ag. The most reactive metals on the list are in Groups 1A(1) and 2A(2) of the periodic table, and the least reactive lie at the right of the transition elements in Groups 1B(11) and 2B(12).

2. *The activity series of the halogens.* Reactivity decreases down Group 7A(17), so we can arrange the halogens into their own activity series:

$$F_2 > Cl_2 > Br_2 > I_2$$

A halogen higher in the periodic table is a stronger oxidizing agent than one lower down. Thus, chlorine can oxidize bromide ions or iodide ions from solution, and bromine can oxidize iodide ions. Here, chlorine displaces bromine:

$$\overset{-1}{2Br^-}(aq) + \overset{0}{Cl_2}(aq) \longrightarrow \overset{0}{Br_2}(aq) + \overset{-1}{2Cl^-}(aq)$$

Combustion Reactions Combustion is the process of combining with oxygen, often with the release of heat and light, as in a flame. Combustion reactions do not fall neatly into classes based on the number of reactants and products, but *all are redox processes* because elemental oxygen is a reactant:

$$2CO(g) + O_2(g) \longrightarrow 2CO_2(g)$$

The combustion reactions that we commonly use to produce energy involve organic mixtures such as coal, gasoline, and natural gas as reactants. These

Space-Age Combustion Without a Flame Combustion reactions are used to generate large amounts of energy. In most applications, the fuel is burned and the energy is released as heat (e.g., in a furnace) or as a combination of work and heat (e.g., in a combustion engine). Aboard the space shuttle, *fuel cells* generate electrical energy from the flameless combustion of hydrogen gas. Here H_2 is the reducing agent, and O_2 is the oxidizing agent in a controlled reaction process that yields water—which the astronauts use for drinking. On Earth, fuel cells based on the reaction of either H_2 or methanol (CH_3OH) with O_2 are being developed for use in car engines.

mixtures consist of substances with many carbon-carbon and carbon-hydrogen bonds. During the reaction, these bonds break, and each C and H atom combines with oxygen. Therefore, the major products are CO_2 and H_2O. The combustion of the hydrocarbon butane, which is used in camp stoves, is typical:

$$2C_4H_{10}(g) + 13O_2(g) \longrightarrow 8CO_2(g) + 10H_2O(g)$$

Biological *respiration* is a multistep combustion process that occurs within our cells when we "burn" organic foodstuffs, such as glucose, for energy:

$$C_6H_{12}O_6(s) + 6O_2(g) \longrightarrow 6CO_2(g) + 6H_2O(g) + \textit{energy}$$

SAMPLE PROBLEM 4.10 Identifying the Type of Redox Reaction

Problem Classify each of the following redox reactions as a combination, decomposition, or displacement reaction, write a balanced molecular equation for each, as well as total and net ionic equations for part **(c)**, and identify the oxidizing and reducing agents:

(a) Magnesium(s) + nitrogen(g) ⟶ magnesium nitride(s)

(b) Hydrogen peroxide(l) ⟶ water + oxygen gas

(c) Aluminum(s) + lead(II) nitrate(aq) ⟶ aluminum nitrate(aq) + lead(s)

Plan To decide on reaction type, recall that combination reactions produce fewer products than reactants, decomposition reactions produce more products, and displacement reactions have the same number of reactants and products. The oxidation number (O.N.) becomes more positive for the reducing agent and less positive for the oxidizing agent.

Solution **(a)** Combination: two substances form one. This reaction occurs, along with formation of magnesium oxide, when magnesium burns in air:

$$\overset{0}{3Mg}(s) + \overset{0}{N_2}(g) \longrightarrow \overset{+2\ -3}{Mg_3N_2}(s)$$

Mg is the reducing agent; N_2 is the oxidizing agent.

(b) Decomposition: one substance forms two. This reaction occurs within every bottle of this common household antiseptic. Hydrogen peroxide is very unstable and breaks down from heat, light, or just shaking:

$$\overset{+1-1}{2H_2O_2}(l) \longrightarrow \overset{+1-2}{2H_2O}(l) + \overset{0}{O_2}(g)$$

H_2O_2 is both the oxidizing *and* the reducing agent. The O.N. of O in peroxides is −1. It increases to 0 in O_2 and decreases to −2 in H_2O.

(c) Displacement: two substances form two others. As Figure 4.20 shows, Al is more active than Pb and, thus, displaces it from aqueous solution:

$$\overset{0}{2Al}(s) + \overset{+2\ +5\ -2}{3Pb(NO_3)_2}(aq) \longrightarrow \overset{+3\ +5\ -2}{2Al(NO_3)_3}(aq) + \overset{0}{3Pb}(s)$$

Al is the reducing agent; $Pb(NO_3)_2$ is the oxidizing agent.

The total ionic equation is

$$2Al(s) + 3Pb^{2+}(aq) + 6NO_3^-(aq) \longrightarrow 2Al^{3+}(aq) + 6NO_3^-(aq) + 3Pb(s)$$

The net ionic equation is

$$2Al(s) + 3Pb^{2+}(aq) \longrightarrow 2Al^{3+}(aq) + 3Pb(s)$$

FOLLOW-UP PROBLEM 4.10 Classify each of the following redox reactions as a combination, decomposition, or displacement reaction, write a balanced molecular equation for each, as well as total and net ionic equations for parts (b) and (c), and identify the oxidizing and reducing agents:

(a) $S_8(s) + F_2(g) \longrightarrow SF_4(g)$ **(b)** $CsI(aq) + Cl_2(aq) \longrightarrow CsCl(aq) + I_2(aq)$

(c) $Ni(NO_3)_2(aq) + Cr(s) \longrightarrow Ni(s) + Cr(NO_3)_3(aq)$

SECTION SUMMARY

Any reaction that includes a free element as reactant or product is a redox reaction. In combination reactions, elements combine to form a compound, or a compound and an element combine. Decomposition of compounds by absorption of heat or electricity can form elements or a compound and an element. In displacement reactions, one element displaces another from solution. Activity series rank elements in order of reactivity. The activity series of the metals ranks metals by their ability to displace H_2 from water, steam, acid or to displace one another from solution. Combustion typically releases heat and light energy through reaction of a substance with O_2.

4.7 REVERSIBLE REACTIONS: AN INTRODUCTION TO CHEMICAL EQUILIBRIUM

So far, we have viewed reactions as occurring from "left to right," from reactants to products and continuing until they are complete, that is, until the limiting reactant is used up. However, many reactions seem to stop before this happens. The reason is that two opposing reactions are taking place simultaneously. The forward (left-to-right) reaction has not stopped, but the reverse (right-to-left) reaction is occurring at the same rate. Therefore, *no further changes appear in the amounts of reactants or products*. At this point, the reaction mixture has reached **dynamic equilibrium.** On the macroscopic scale, the reaction is *static,* but it is *dynamic* on the molecular scale. In principle, all reactions are reversible and will eventually reach dynamic equilibrium as long as all products remain available for the reverse reaction.

Let's examine equilibrium with a particular set of substances. Calcium carbonate breaks down when heated to calcium oxide and carbon dioxide:

$$CaCO_3(s) \longrightarrow CaO(s) + CO_2(g) \quad \text{[breakdown]}$$

It also forms when calcium oxide and carbon dioxide react:

$$CaO(s) + CO_2(g) \longrightarrow CaCO_3(s) \quad \text{[formation]}$$

The formation is exactly the reverse of the breakdown. Suppose we place $CaCO_3$ in an *open* steel container and heat it to around 900°C, as shown in Figure 4.21A. The $CaCO_3$ starts breaking down to CaO and CO_2, and the CO_2 escapes from the open container. The reaction goes to completion because the reverse reaction (formation) can occur only if CO_2 is present.

In Figure 4.21B, we perform the same experiment in a *closed* container, so that the CO_2 remains in contact with the CaO. The breakdown (forward reaction) begins, but at first, when very little $CaCO_3$ has broken down, very little CO_2 and CaO are present; thus, the formation (reverse reaction) just barely begins. As the $CaCO_3$ continues to break down, the amounts of CO_2 and CaO increase. They react with each other more frequently, and the formation occurs a bit faster. As the amounts of CaO and CO_2 increase, the formation reaction gradually speeds up. Eventually, the reverse reaction (formation) happens just as fast as the forward reaction (breakdown), and the amounts of $CaCO_3$, CaO, and CO_2 no longer change: the system has reached equilibrium. We indicate this with a pair of arrows pointing in opposite directions:

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$$

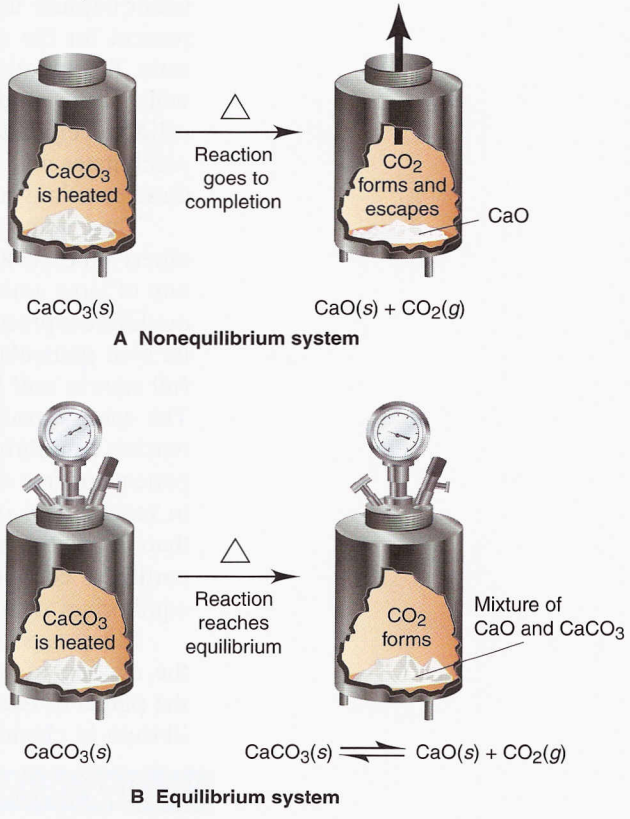

Figure 4.21 The equilibrium state. A, In an *open* steel reaction container, strong heating breaks down $CaCO_3$ completely because the product CO_2 escapes and is not present to react with the other product, CaO. **B,** When $CaCO_3$ breaks down in a *closed* container, the CO_2 *is* present to react with CaO and re-form $CaCO_3$ in a reaction that is the reverse of the breakdown. At a given temperature, no further change in the amounts of products and reactants means that the reaction has reached equilibrium.

Bear in mind that equilibrium can be established only when *all the substances involved are kept in contact with each other.* The breakdown of $CaCO_3$ goes to completion in the open container because the CO_2 escapes.

Reaction reversibility applies equally to the substances and reactions we discussed earlier. Weak acids and bases dissociate into ions only to a small extent because the dissociation quickly becomes balanced by reassociation. For example, when acetic acid dissolves in water, some of the CH_3COOH molecules transfer a proton to H_2O and form H_3O^+ and CH_3COO^- ions. As more of these ions form, they react with each other more often to re-form acetic acid and water:

$$CH_3COOH(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + CH_3COO^-(aq)$$

In 0.1 *M* CH_3COOH at 25°C, only about 1.3% of the acid molecules are dissociated at any given moment. Different weak acids dissociate to different extents. For example, under the same conditions, propanoic acid (CH_3CH_2COOH) is only 1.1% dissociated, but hydrofluoric acid (HF) is 8.6% dissociated.

Similarly, the weak base ammonia reacts with water to form NH_4^+ and OH^- ions. As the ions interact, they re-form ammonia and water, and the rates of the reverse and forward reactions soon balance:

$$NH_3(aq) + H_2O(l) \rightleftharpoons NH_4^+(aq) + OH^-(aq)$$

Another weak base, methylamine (CH_3NH_2), reacts with water to a greater extent before reaching equilibrium, while still another, aniline ($C_6H_5NH_2$), reacts less.

Aqueous acid-base reactions that form a gas go to completion in an open container because the gas escapes. But, if the container were closed and the gas were present for the reverse reaction to take place, the reaction would reach equilibrium. Precipitation and other acid-base reactions seem to "go to completion," even with all the products present, because the *ions* are tied up either as an insoluble solid (precipitation) or as water molecules (acid-base). In truth, however, ionic precipitates and water do dissociate, but to an extremely small extent. Therefore, these reactions also reach equilibrium, but with almost all product formed.

Thus, some reactions proceed very little before they reach equilibrium, while others proceed almost completely, and still others reach equilibrium with a mixture of large amounts of reactants *and* products. So, a fundamental question is why do different processes, even under the same conditions, each reach equilibrium with its own particular ratio of product concentrations to reactant concentrations? The full answer will have to wait until Chapter 20, but we can hint at the factors here. The energy available for a reaction to occur is called its *free energy*. A process reaches equilibrium when the reaction mixture has its lowest free energy. Two components of free energy are the heat a reaction releases (or absorbs) and the change in randomness of the particles—particles are dispersed more randomly in a gas than in a solid, more in a solution than in pure solute and solvent, and so forth. A particular combination of these factors determines the free energy and, thus, the equilibrium point for a given mixture of reactants and products.

Many aspects of dynamic equilibrium are relevant to natural systems, from the cycling of water in the environment to the balance of lion and antelope on the plains of Africa to the nuclear processes occurring in stars. We examine equilibrium in chemical and physical systems in Chapters 12, 13, and 17 through 21.

SECTION SUMMARY

Every reaction is reversible if all the substances are kept in contact with one another. As the amounts of products increase, the reactants begin to re-form. When the reverse reaction happens as rapidly as the forward reaction, the amounts of the substances no longer change, and the reaction mixture has reached dynamic equilibrium. Weak acids and bases reach equilibrium in water with a very small proportion of their molecules dissociated. A reaction "goes to completion" because a product is removed from the system (as a gas) or exists in a form that prevents it from reacting (precipitate or undissociated molecule).

Chapter Perspective

Classifying facts is the first step toward understanding them, and this chapter classified many of the most important facts of reaction chemistry into three major processes—precipitation, acid-base, and oxidation-reduction. We also examined the great influence that water has on reaction chemistry and introduced the state of dynamic equilibrium, which is related to the central question of why physical and chemical changes occur. All these topics appear again at many places in the text.

In the next chapter, our focus changes to the physical behavior of gases. You'll find that your growing appreciation of events on the molecular level has become indispensable for understanding the nature of this physical state.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. Why water is a polar molecule and how it dissolves ionic compounds and dissociates them into ions (4.1)
2. The difference between the species present when ionic and covalent compounds dissolve in water and that between strong and weak electrolytes (4.1)
3. The use of ionic equations to specify the essential nature of an aqueous reaction (4.2)
4. The driving force for aqueous ionic reactions (4.3, 4.4, 4.5)
5. How to decide whether a precipitation reaction occurs (4.3)
6. The main distinction between strong and weak aqueous acids and bases (4.4)
7. The essential character of aqueous acid-base reactions as proton-transfer processes (4.4)
8. The importance of net movement of electrons in the redox process (4.5)
9. The relation between change in oxidation number and identity of oxidizing and reducing agents (4.5)
10. The presence of elements in some important types of redox reactions: combination, decomposition, displacement (4.6)
11. The balance between forward and reverse rates of a chemical reaction that leads to dynamic equilibrium; why some acids and bases are weak (4.7)

Master These Skills

1. Using the formula of a compound to find the number of moles of ions in solution (SP 4.1)
2. Determining the concentration of H^+ ion in an aqueous acid solution (SP 4.2)
3. Predicting whether a precipitation reaction occurs (SP 4.3)
4. Writing ionic equations to describe precipitation and acid-base reactions (SPs 4.3 and 4.4)
5. Calculating an unknown concentration from an acid-base or redox titration (SPs 4.5 and 4.9)
6. Determining the oxidation number of any element in a compound (SP 4.6)
7. Identifying the oxidizing and reducing agents in a redox reaction (SP 4.7)
8. Balancing redox equations (SP 4.8)
9. Identifying combination, decomposition, and displacement redox reactions (SP 4.10)

Key Terms

Brief Solutions to Follow-up Problems

4.1 (a) $KClO_4(s) \xrightarrow{H_2O} K^+(aq) + ClO_4^-(aq)$;
2 mol of K^+ and 2 mol of ClO_4^-

(b) $Mg(C_2H_3O_2)_2(s) \xrightarrow{H_2O} Mg^{2+}(aq) + 2C_2H_3O_2^-(aq)$;
2.49 mol of Mg^{2+} and 4.97 mol of $C_2H_3O_2^-$

(c) $(NH_4)_2CrO_4(s) \xrightarrow{H_2O} 2NH_4^+(aq) + CrO_4^{2-}(aq)$;
6.24 mol of NH_4^+ and 3.12 mol of CrO_4^{2-}

(d) $NaHSO_4(s) \xrightarrow{H_2O} Na^+(aq) + HSO_4^-(aq)$;
0.73 mol of Na^+ and 0.73 mol of HSO_4^-

4.2 $$\text{Moles of } H^+ = 451 \text{ mL} \times \frac{1 \text{ L}}{10^3 \text{ mL}} \times \frac{3.20 \text{ mol HBr}}{1 \text{ L soln}} \times \frac{1 \text{ mol } H^+}{1 \text{ mol HBr}} = 1.44 \text{ mol } H^+$$

4.3 (a) $Fe^{3+}(aq) + 3Cl^-(aq) + 3Cs^+(aq) + PO_4^{3-}(aq) \longrightarrow FePO_4(s) + 3Cl^-(aq) + 3Cs^+(aq)$

$Fe^{3+}(aq) + PO_4^{3-}(aq) \longrightarrow FePO_4(s)$

(b) $2Na^+(aq) + 2OH^-(aq) + Cd^{2+}(aq) + 2NO_3^-(aq) \longrightarrow 2Na^+(aq) + 2NO_3^-(aq) + Cd(OH)_2(s)$

$2OH^-(aq) + Cd^{2+}(aq) \longrightarrow Cd(OH)_2(s)$

(c) No reaction occurs

(d) $2Ag^+(aq) + SO_4^{2-}(aq) + Ba^{2+}(aq) + 2Cl^-(aq) \longrightarrow 2AgCl(s) + BaSO_4(s)$

Total and net ionic equations are identical.

4.4 $Ca(OH)_2(aq) + 2HNO_3(aq) \longrightarrow Ca(NO_3)_2(aq) + 2H_2O(l)$

$Ca^{2+}(aq) + 2OH^-(aq) + 2H^+(aq) + 2NO_3^-(aq) \longrightarrow Ca^{2+}(aq) + 2NO_3^-(aq) + 2H_2O(l)$

$H^+(aq) + OH^-(aq) \longrightarrow H_2O(l)$

4.5 $Ba(OH)_2(aq) + 2HCl(aq) \longrightarrow BaCl_2(aq) + 2H_2O(l)$

$$\text{Volume (L) of soln} = 50.00 \text{ mL HCl soln} \times \frac{1 \text{ L}}{10^3 \text{ mL}} \times \frac{0.1016 \text{ mol HCl}}{1 \text{ L soln}} \times \frac{1 \text{ mol Ba(OH)}_2}{2 \text{ mol HCl}} \times \frac{1 \text{ L soln}}{0.1292 \text{ mol Ba(OH)}_2} = 0.01966 \text{ L}$$

4.6 (a) O.N. of Sc = +3; O.N. of O = −2
(b) O.N. of Ga = +3; O.N. of Cl = −1
(c) O.N. of H = +1; O.N. of P = +5; O.N. of O = −2
(d) O.N. of I = +3; O.N. of F = −1

4.7 (a) Fe is the reducing agent; Cl_2 is the oxidizing agent.
(b) C_2H_6 is the reducing agent; O_2 is the oxidizing agent.
(c) CO is the reducing agent; I_2O_5 is the oxidizing agent.

4.8 $K_2Cr_2O_7(aq) + 14HI(aq) \longrightarrow 2KI(aq) + 2CrI_3(aq) + 3I_2(s) + 7H_2O(l)$

4.9 (a) $$\text{Moles of } Ca^{2+} = 6.53 \text{ mL soln} \times \frac{1 \text{ L}}{10^3 \text{ mL}} \times \frac{4.56\times10^{-3} \text{ mol KMnO}_4}{1 \text{ L soln}} \times \frac{5 \text{ mol CaC}_2\text{O}_4}{2 \text{ mol KMnO}_4} \times \frac{1 \text{ mol } Ca^{2+}}{1 \text{ mol CaC}_2\text{O}_4} = 7.44\times10^{-5} \text{ mol } Ca^{2+}$$

$$\text{Molarity of } Ca^{2+} = \frac{7.44\times10^{-2} \text{ mol } Ca^{2+}}{2.50 \text{ mL milk}} \times \frac{10^3 \text{ mL}}{1 \text{ L}} = 2.98\times10^{-2} \, M \, Ca^{2+}$$

(b) $$\text{Conc. of } Ca^{2+} \text{ (g/L)} = \frac{2.98\times10^{-2} \text{ mol } Ca^{2+}}{1 \text{ L}} \times \frac{40.08 \text{ g } Ca^{2+}}{1 \text{ mol } Ca^{2+}} = \frac{1.19 \text{ g } Ca^{2+}}{1 \text{ L}}$$

4.10 (a) Combination:
$S_8(s) + 16F_2(g) \longrightarrow 8SF_4(g)$
S_8 is the reducing agent; F_2 is the oxidizing agent.

(b) Displacement:
$2CsI(aq) + Cl_2(aq) \longrightarrow 2CsCl(aq) + I_2(aq)$
Cl_2 is the oxidizing agent; CsI is the reducing agent.

$2Cs^+(aq) + 2I^-(aq) + Cl_2(aq) \longrightarrow 2Cs^+(aq) + 2Cl^-(aq) + I_2(aq)$

$2I^-(aq) + Cl_2(aq) \longrightarrow 2Cl^-(aq) + I_2(aq)$

(c) Displacement:
$3Ni(NO_3)_2(aq) + 2Cr(s) \longrightarrow 3Ni(s) + 2Cr(NO_3)_3(aq)$

$3Ni^{2+}(aq) + 6NO_3^-(aq) + 2Cr(s) \longrightarrow 3Ni(s) + 2Cr^{3+}(aq) + 6NO_3^-(aq)$

$3Ni^{2+}(aq) + 2Cr(s) \longrightarrow 3Ni(s) + 2Cr^{3+}(aq)$

Cr is the reducing agent; $Ni(NO_3)_2$ is the oxidizing agent.

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

The Role of Water as a Solvent

(Sample Problems 4.1 and 4.2)

Concept Review Questions

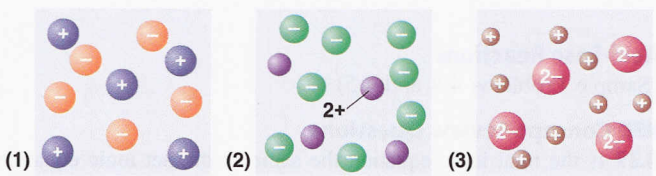
4.1 What two factors cause water to be polar?

4.2 What types of substances are most likely to be soluble in water?

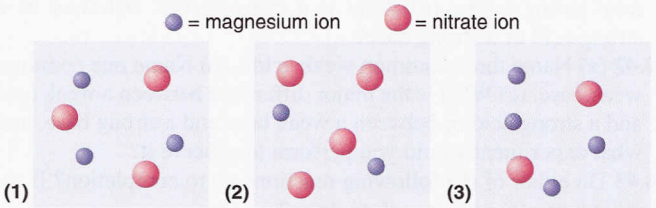
4.3 What must be present in an aqueous solution for it to conduct an electric current? What general classes of compounds form solutions that conduct?

4.4 What occurs on the molecular level when an ionic compound dissolves in water?

4.5 Examine each of the following aqueous solutions and determine which represents: (a) $CaCl_2$; (b) Li_2SO_4; (c) NH_4Br.



4.6 Which of the following best represents a volume from a solution of magnesium nitrate?



4.7 Why are some ionic compounds soluble in water and others are not?

4.8 Why are some covalent compounds soluble in water and others are not?

4.9 Some covalent compounds dissociate into ions when they dissolve in water. What atom do these compounds have in their structures? What type of aqueous solution do they form? Name three examples of such an aqueous solution.

Skill-Building Exercises *(grouped in similar pairs)*

4.10 State whether each of the following substances is likely to be very soluble in water. Explain.
(a) Benzene, C_6H_6 (b) Sodium hydroxide
(c) Ethanol, CH_3CH_2OH (d) Potassium acetate

4.11 State whether each of the following substances is likely to be very soluble in water. Explain.
(a) Lithium nitrate (b) Glycine, H_2NCH_2COOH
(c) Pentane (d) Ethylene glycol, $HOCH_2CH_2OH$

4.12 State whether an aqueous solution of each of the following substances conducts an electric current. Explain your reasoning.
(a) Cesium iodide (b) Hydrogen bromide

4.13 State whether an aqueous solution of each of the following substances conducts an electric current. Explain your reasoning.
(a) Potassium hydroxide (b) Glucose, $C_6H_{12}O_6$

4.14 How many total moles of ions are released when each of the following samples dissolves completely in water?
(a) 0.37 mol of NH_4Cl (b) 35.4 g of $Ba(OH)_2 \cdot 8H_2O$
(c) 3.55×10^{18} formula units of LiCl

4.15 How many total moles of ions are released when each of the following samples dissolves completely in water?
(a) 0.805 mol of Rb_2SO_4 (b) 3.85×10^{-3} g of $Ca(NO_3)_2$
(c) 4.03×10^{19} formula units of $Sr(HCO_3)_2$

4.16 How many total moles of ions are released when each of the following samples dissolves completely in water?
(a) 0.83 mol of K_3PO_4 (b) 8.11×10^{-3} g of $NiBr_2 \cdot 3H_2O$
(c) 1.23×10^{21} formula units of $FeCl_3$

4.17 How many total moles of ions are released when each of the following samples dissolves completely in water?
(a) 0.734 mol of Na_2HPO_4 (b) 3.86 g of $CuSO_4 \cdot 5H_2O$
(c) 8.66×10^{20} formula units of $NiCl_2$

4.18 How many moles and numbers of ions of each type are present in the following aqueous solutions?
(a) 100. mL of 2.45 *M* aluminum chloride
(b) 1.80 L of a solution containing 2.59 g lithium sulfate/L
(c) 225 mL of a solution containing 1.68×10^{22} formula units of potassium bromide per liter

4.19 How many moles and numbers of ions of each type are present in the following aqueous solutions?
(a) 88 mL of 1.75 *M* magnesium chloride
(b) 321 mL of a solution containing 0.22 g aluminum sulfate/L
(c) 1.65 L of a solution containing 8.83×10^{21} formula units of cesium nitrate per liter

4.20 How many moles of H^+ ions are present in the following aqueous solutions?
(a) 1.40 L of 0.25 *M* perchloric acid
(b) 1.8 mL of 0.72 *M* nitric acid
(c) 7.6 L of 0.056 *M* hydrochloric acid

4.21 How many moles of H^+ ions are present in the following aqueous solutions?
(a) 1.4 mL of 0.75 *M* hydrobromic acid
(b) 2.47 mL of 1.98 *M* hydriodic acid
(c) 395 mL of 0.270 *M* nitric acid

Problems in Context

4.22 To study a marine organism, a biologist prepares a 1.00-kg sample to simulate the ion concentrations in seawater. She mixes 26.5 g of NaCl, 2.40 g of $MgCl_2$, 3.35 g of $MgSO_4$, 1.20 g of $CaCl_2$, 1.05 g of KCl, 0.315 g of $NaHCO_3$, and 0.098 g of NaBr in distilled water. (a) If the density of this solution is 1.04 g/cm^3, what is the molarity of each ion? (b) What is the total molarity of alkali metal ions? (c) What is the total molarity of alkaline earth metal ions? (d) What is the total molarity of anions?

4.23 Water "softeners" remove metal ions such as Ca^{2+} and Fe^{3+} by replacing them with enough Na^+ ions to maintain the same number of positive charges in the solution. If 1.0×10^3 L of "hard" water is 0.015 *M* Ca^{2+} and 0.0010 *M* Fe^{3+}, how many moles of Na^+ are needed to replace these ions?

Writing Equations for Aqueous Ionic Reactions

Concept Review Questions

4.24 Which ions do not appear in a net ionic equation? Why?

4.25 Write two sets of equations (both molecular and total ionic) with different reactants that will give the same net ionic equation, as follows:

$$Ba(NO_3)_2(aq) + Na_2CO_3(aq) \longrightarrow BaCO_3(s) + 2NaNO_3(aq)$$

Precipitation Reactions

(Sample Problem 4.3)

Concept Review Questions

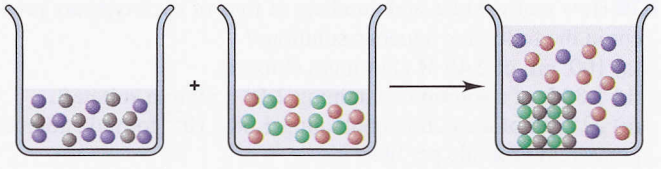
4.26 Why do some pairs of ions precipitate and others do not?

4.27 Use Table 4.1 to determine which of the following combinations leads to a reaction. How can you identify the spectator ions in the reaction?

(a) Calcium nitrate(aq) + sodium chloride(aq) $\longrightarrow$

(b) Potassium chloride(aq) + lead(II) nitrate(aq) $\longrightarrow$

4.28 The beakers represent the aqueous reaction of $AgNO_3$ and NaCl. Silver ions are gray. What colors are used to represent NO_3^-, Na^+, and Cl^-? Write molecular, total ionic, and net ionic equations for the reaction.



Skill-Building Exercises *(grouped in similar pairs)*

4.29 Complete the following precipitation reactions with balanced molecular, total ionic, and net ionic equations:

(a) $Hg_2(NO_3)_2(aq) + KI(aq) \longrightarrow$

(b) $FeSO_4(aq) + Ba(OH)_2(aq) \longrightarrow$

4.30 Complete the following precipitation reactions with balanced molecular, total ionic, and net ionic equations:

(a) $CaCl_2(aq) + Cs_3PO_4(aq) \longrightarrow$

(b) $Na_2S(aq) + ZnSO_4(aq) \longrightarrow$

4.31 When each of the following pairs of aqueous solutions is mixed, does a precipitation reaction occur? If so, write balanced molecular, total ionic, and net ionic equations:

(a) Sodium nitrate + copper(II) sulfate

(b) Ammonium iodide + silver nitrate

4.32 When each of the following pairs of aqueous solutions is mixed, does a precipitation reaction occur? If so, write balanced molecular, total ionic, and net ionic equations:

(a) Potassium carbonate + barium hydroxide

(b) Aluminum nitrate + sodium phosphate

4.33 When each of the following pairs of aqueous solutions is mixed, does a precipitation reaction occur? If so, write balanced molecular, total ionic, and net ionic equations:

(a) Potassium chloride + iron(II) nitrate

(b) Ammonium sulfate + barium chloride

4.34 When each of the following pairs of aqueous solutions is mixed, does a precipitation reaction occur? If so, write balanced molecular, total ionic, and net ionic equations:

(a) Sodium sulfide + nickel(II) sulfate

(b) Lead(II) nitrate + potassium bromide

4.35 If 35.0 mL of lead(II) nitrate solution reacts completely with excess sodium iodide solution to yield 0.628 g of precipitate, what is the molarity of lead(II) ion in the original solution?

4.36 If 25.0 mL of silver nitrate solution reacts with excess potassium chloride solution to yield 0.842 g of precipitate, what is the molarity of silver ion in the original solution?

Problems in Context

4.37 The mass percent of Cl^- in a seawater sample is determined by titrating 25.00 mL of seawater with $AgNO_3$ solution, causing a precipitation reaction. An indicator is used to detect the end point, which occurs when free Ag^+ ion is present in solution after all the Cl^- has reacted. If 43.63 mL of 0.3020 M $AgNO_3$ is required to reach the end point, what is the mass percent of Cl^- in the seawater (d of seawater = 1.04 g/mL)?

4.38 Aluminum sulfate, known as *cake alum*, has a wide range of uses, from dyeing leather and cloth to purifying sewage. In aqueous solution, it reacts with base to form a white precipitate. (a) Write balanced total and net ionic equations for its reaction with aqueous NaOH. (b) What mass of precipitate forms when 185.5 mL of 0.533 M NaOH is added to 627 mL of a solution that contains 15.8 g of aluminum sulfate per liter?

Acid-Base Reactions

(Sample Problems 4.4 and 4.5)

Concept Review Questions

4.39 Is the total ionic equation the same as the net ionic equation when $Sr(OH)_2(aq)$ and $H_2SO_4(aq)$ react? Explain.

4.40 State a general equation for a neutralization reaction.

4.41 (a) Name three common strong acids. (b) Name three common strong bases. (c) What is a characteristic behavior of a strong acid or a strong base?

4.42 (a) Name three common weak acids. (b) Name one common weak base. (c) What is the major difference between a weak acid and a strong acid or between a weak base and a strong base, and what experiment would you perform to observe it?

4.43 Do either of the following reactions go to completion? If so, what factor(s) causes each to do so?

(a) $MgSO_3(s) + 2HCl(aq) \longrightarrow MgCl_2(aq) + SO_2(g) + H_2O(l)$

(b) $3Ba(OH)_2(aq) + 2H_3PO_4(aq) \longrightarrow Ba_3(PO_4)_2(s) + 6H_2O(l)$

4.44 The net ionic equation for the aqueous neutralization reaction between acetic acid and sodium hydroxide is different from that for the reaction between hydrochloric acid and sodium hydroxide. Explain by writing balanced net ionic equations.

Skill-Building Exercises *(grouped in similar pairs)*

4.45 Complete the following acid-base reactions with balanced molecular, total ionic, and net ionic equations:

(a) Potassium hydroxide(aq) + hydriodic acid(aq) $\longrightarrow$

(b) Ammonia(aq) + hydrochloric acid(aq) $\longrightarrow$

4.46 Complete the following acid-base reactions with balanced molecular, total ionic, and net ionic equations:

(a) Cesium hydroxide(aq) + nitric acid(aq) $\longrightarrow$

(b) Calcium hydroxide(aq) + acetic acid(aq) $\longrightarrow$

4.47 Limestone (calcium carbonate) is insoluble in water but dissolves when a hydrochloric acid solution is added. Why? Write balanced total ionic and net ionic equations, showing hydro-

chloric acid as it actually exists in water and the reaction as a proton-transfer process.

4.48 Zinc hydroxide is insoluble in water but dissolves when a nitric acid solution is added. Why? Write balanced total ionic and net ionic equations, showing nitric acid as it actually exists in water and the reaction as a proton-transfer process.

4.49 If 25.98 mL of a standard 0.1180 *M* KOH solution reacts with 52.50 mL of CH_3COOH solution, what is the molarity of the acid solution?

4.50 If 36.25 mL of a standard 0.1750 *M* NaOH solution is required to neutralize 25.00 mL of H_2SO_4, what is the molarity of the acid solution?

Problems in Context

4.51 An auto mechanic spills 78 mL of 2.6 *M* H_2SO_4 solution from a rebuilt auto battery. How many milliliters of 1.5 *M* $NaHCO_3$ must be poured on the spill to react completely with the sulfuric acid?

4.52 Sodium hydroxide is used extensively in acid-base titrations because it is a strong, inexpensive base. A sodium hydroxide solution was standardized by titrating 25.00 mL of 0.1528 *M* standard hydrochloric acid. The initial buret reading of the sodium hydroxide was 2.24 mL, and the final reading was 39.21 mL. What was the molarity of the base solution?

4.53 One of the first steps in the enrichment of uranium for use in nuclear power plants involves a displacement reaction between UO_2 and aqueous HF:

$$UO_2(s) + 4HF(aq) \longrightarrow UF_4(s) + 2H_2O(l)$$

How many liters of 2.50 *M* HF will react with 2.25 kg of UO_2?

Oxidation-Reduction (Redox) Reactions

(Sample Problems 4.6 to 4.9)

Concept Review Questions

4.54 Describe how to determine the oxidation number of sulfur in (a) H_2S and (b) SO_3^{2-}.

4.55 Is the following a redox reaction? Explain.

$$NH_3(aq) + HCl(aq) \longrightarrow NH_4Cl(aq)$$

4.56 Explain why an oxidizing agent undergoes reduction.

4.57 Why must every redox reaction involve an oxidizing agent and a reducing agent?

4.58 In which of the following equations does sulfuric acid act as an oxidizing agent? In which does it act as an acid? Explain.

(a) $4H^+(aq) + SO_4^{2-}(aq) + 2NaI(s) \longrightarrow 2Na^+(aq) + I_2(s) + SO_2(g) + 2H_2O(l)$

(b) $BaF_2(s) + 2H^+(aq) + SO_4^{2-}(aq) \longrightarrow 2HF(aq) + BaSO_4(s)$

4.59 Identify the oxidizing agent and the reducing agent in the following reaction, and explain your answer:

$$8NH_3(g) + 6NO_2(g) \longrightarrow 7N_2(g) + 12H_2O(l)$$

Skill-Building Exercises *(grouped in similar pairs)*

4.60 Give the oxidation number of carbon in the following:
(a) CF_2Cl_2 (b) $Na_2C_2O_4$ (c) HCO_3^- (d) C_2H_6

4.61 Give the oxidation number of bromine in the following:
(a) KBr (b) BrF_3 (c) $HBrO_3$ (d) CBr_4

4.62 Give the oxidation number of nitrogen in the following:
(a) NH_2OH (b) N_2H_4 (c) NH_4^+ (d) HNO_2

4.63 Give the oxidation number of sulfur in the following:
(a) $SOCl_2$ (b) H_2S_2 (c) H_2SO_3 (d) Na_2S

4.64 Give the oxidation number of arsenic in the following:
(a) AsH_3 (b) H_3AsO_4 (c) $AsCl_3$

4.65 Give the oxidation number of phosphorus in the following:
(a) $H_2P_2O_7^{2-}$ (b) PH_4^+ (c) PCl_5

4.66 Give the oxidation number of manganese in the following:
(a) MnO_4^{2-} (b) Mn_2O_3 (c) $KMnO_4$

4.67 Give the oxidation number of chromium in the following:
(a) CrO_3 (b) $Cr_2O_7^{2-}$ (c) $Cr_2(SO_4)_3$

4.68 Identify the oxidizing and reducing agents in the following:

(a) $5H_2C_2O_4(aq) + 2MnO_4^-(aq) + 6H^+(aq) \longrightarrow 2Mn^{2+}(aq) + 10CO_2(g) + 8H_2O(l)$

(b) $3Cu(s) + 8H^+(aq) + 2NO_3^-(aq) \longrightarrow 3Cu^{2+}(aq) + 2NO(g) + 4H_2O(l)$

4.69 Identify the oxidizing and reducing agents in the following:

(a) $Sn(s) + 2H^+(aq) \longrightarrow Sn^{2+}(aq) + H_2(g)$

(b) $2H^+(aq) + H_2O_2(aq) + 2Fe^{2+}(aq) \longrightarrow 2Fe^{3+}(aq) + 2H_2O(l)$

4.70 Identify the oxidizing and reducing agents in the following:

(a) $8H^+(aq) + 6Cl^-(aq) + Sn(s) + 4NO_3^-(aq) \longrightarrow SnCl_6^{2-}(aq) + 4NO_2(g) + 4H_2O(l)$

(b) $2MnO_4^-(aq) + 10Cl^-(aq) + 16H^+(aq) \longrightarrow 5Cl_2(g) + 2Mn^{2+}(aq) + 8H_2O(l)$

4.71 Identify the oxidizing and reducing agents in the following:

(a) $8H^+(aq) + Cr_2O_7^{2-}(aq) + 3SO_3^{2-}(aq) \longrightarrow 2Cr^{3+}(aq) + 3SO_4^{2-}(aq) + 4H_2O(l)$

(b) $NO_3^-(aq) + 4Zn(s) + 7OH^-(aq) + 6H_2O(l) \longrightarrow 4Zn(OH)_4^{2-}(aq) + NH_3(aq)$

4.72 Discuss each conclusion from a study of redox reactions:
(a) The sulfide ion functions only as a reducing agent.
(b) The sulfate ion functions only as an oxidizing agent.
(c) Sulfur dioxide functions as an oxidizing or a reducing agent.

4.73 Discuss each conclusion from a study of redox reactions:
(a) The nitride ion functions only as a reducing agent.
(b) The nitrate ion functions only as an oxidizing agent.
(c) The nitrite ion functions as an oxidizing or a reducing agent.

4.74 Use the oxidation number method to balance the following equations by placing coefficients in the blanks. Identify the reducing and oxidizing agents:

(a) $__HNO_3(aq) + __K_2CrO_4(aq) + __Fe(NO_3)_2(aq) \longrightarrow __KNO_3(aq) + __Fe(NO_3)_3(aq) + __Cr(NO_3)_3(aq) + __H_2O(l)$

(b) $__HNO_3(aq) + __C_2H_6O(l) + __K_2Cr_2O_7(aq) \longrightarrow __KNO_3(aq) + __C_2H_4O(l) + __H_2O(l) + __Cr(NO_3)_3(aq)$

(c) $__HCl(aq) + __NH_4Cl(aq) + __K_2Cr_2O_7(aq) \longrightarrow __KCl(aq) + __CrCl_3(aq) + __N_2(g) + __H_2O(l)$

(d) $__KClO_3(aq) + __HBr(aq) \longrightarrow __Br_2(l) + __H_2O(l) + __KCl(aq)$

4.75 Use the oxidation number method to balance the following equations by placing coefficients in the blanks. Identify the reducing and oxidizing agents:

(a) $__HCl(aq) + __FeCl_2(aq) + __H_2O_2(aq) \longrightarrow __FeCl_3(aq) + __H_2O(l)$

(b) $__I_2(s) + __Na_2S_2O_3(aq) \longrightarrow __Na_2S_4O_6(aq) + __NaI(aq)$

(c) $_HNO_3(aq) + _KI(aq) \longrightarrow _NO(g) + _I_2(s) + _H_2O(l) + _KNO_3(aq)$

(d) $_PbO(s) + _NH_3(aq) \longrightarrow _N_2(g) + _H_2O(l) + _Pb(s)$

Problems in Context

4.76 The active agent in many hair bleaches is hydrogen peroxide. The amount of hydrogen peroxide in 13.8 g of hair bleach was determined by titration with a standard potassium permanganate solution:

$$2MnO_4^-(aq) + 5H_2O_2(aq) + 6H^+(aq) \longrightarrow 5O_2(g) + 2Mn^{2+}(aq) + 8H_2O(l)$$

(a) How many moles of MnO_4^- were required for the titration if 43.2 mL of 0.105 *M* $KMnO_4$ was needed to reach the end point? (b) How many moles of H_2O_2 were present in the 13.8-g sample of bleach? (c) How many grams of H_2O_2 were in the sample? (d) What is the mass percent of H_2O_2 in the sample? (e) What is the reducing agent in the redox reaction?

4.77 A person's blood alcohol (C_2H_5OH) level can be determined by titrating a sample of blood plasma with a potassium dichromate solution. The balanced equation is

$$16H^+(aq) + 2Cr_2O_7^{2-}(aq) + C_2H_5OH(aq) \longrightarrow 4Cr^{3+}(aq) + 2CO_2(g) + 11H_2O(l)$$

If 35.46 mL of 0.05961 *M* $Cr_2O_7^{2-}$ is required to titrate 28.00 g of plasma, what is the mass percent of alcohol in the blood?

Elements in Redox Reactions

(Sample Problem 4.10)

Concept Review Questions

4.78 Which type of redox reaction leads to the following?
(a) An increase in the number of substances
(b) A decrease in the number of substances
(c) No change in the number of substances

4.79 Why do decomposition reactions typically have compounds as reactants, whereas combination and displacement reactions have one or more elements?

4.80 Which of the three types of reactions discussed in this section commonly produce one or more compounds?

4.81 Give one example of a combination reaction that is a redox reaction and another that is not a redox reaction.

4.82 Are all combustion reactions redox reactions? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

4.83 Balance each of the following redox reactions and classify it as a combination, decomposition, or displacement reaction:
(a) $Ca(s) + H_2O(l) \longrightarrow Ca(OH)_2(aq) + H_2(g)$
(b) $NaNO_3(s) \longrightarrow NaNO_2(s) + O_2(g)$
(c) $C_2H_2(g) + H_2(g) \longrightarrow C_2H_6(g)$

4.84 Balance each of the following redox reactions and classify it as a combination, decomposition, or displacement reaction:
(a) $HI(g) \longrightarrow H_2(g) + I_2(g)$
(b) $Zn(s) + AgNO_3(aq) \longrightarrow Zn(NO_3)_2(aq) + Ag(s)$
(c) $NO(g) + O_2(g) \longrightarrow N_2O_4(l)$

4.85 Balance each of the following redox reactions and classify it as a combination, decomposition, or displacement reaction:
(a) $Sb(s) + Cl_2(g) \longrightarrow SbCl_3(s)$
(b) $AsH_3(g) \longrightarrow As(s) + H_2(g)$
(c) $Mn(s) + Fe(NO_3)_3(aq) \longrightarrow Mn(NO_3)_2(aq) + Fe(s)$

4.86 Balance each of the following redox reactions and classify it as a combination, decomposition, or displacement reaction:
(a) $Mg(s) + H_2O(g) \longrightarrow Mg(OH)_2(s) + H_2(g)$
(b) $Cr(NO_3)_3(aq) + Al(s) \longrightarrow Al(NO_3)_3(aq) + Cr(s)$
(c) $PF_3(g) + F_2(g) \longrightarrow PF_5(g)$

4.87 Predict the product(s) and write a balanced equation for each of the following redox reactions:
(a) $Ca(s) + Br_2(l) \longrightarrow$
(b) $Ag_2O(s) \xrightarrow{\Delta}$
(c) $Mn(s) + Cu(NO_3)_2(aq) \longrightarrow$

4.88 Predict the product(s) and write a balanced equation for each of the following redox reactions:
(a) $Mg(s) + HCl(aq) \longrightarrow$
(b) $LiCl(l) \xrightarrow{\text{electricity}}$
(c) $SnCl_2(aq) + Co(s) \longrightarrow$

4.89 Predict the product(s) and write a balanced equation for each of the following redox reactions:
(a) $N_2(g) + H_2(g) \longrightarrow$
(b) $NaClO_3(s) \xrightarrow{\Delta}$
(c) $Ba(s) + H_2O(l) \longrightarrow$

4.90 Predict the product(s) and write a balanced equation for each of the following redox reactions:
(a) $Fe(s) + HClO_4(aq) \longrightarrow$
(b) $S_8(s) + O_2(g) \longrightarrow$
(c) $BaCl_2(l) \xrightarrow{\text{electricity}}$

4.91 Predict the product(s) and write a balanced equation for each of the following redox reactions:
(a) Cesium + iodine $\longrightarrow$
(b) Aluminum + aqueous manganese(II) sulfate $\longrightarrow$
(c) Sulfur dioxide + oxygen $\longrightarrow$
(d) Propane and oxygen $\longrightarrow$
(e) Write a balanced net ionic equation for (b).

4.92 Predict the product(s) and write a balanced equation for each of the following redox reactions:
(a) Pentane (C_5H_{12}) + oxygen $\longrightarrow$
(b) Phosphorus trichloride + chlorine $\longrightarrow$
(c) Zinc + hydrobromic acid $\longrightarrow$
(d) Aqueous potassium iodide + bromine $\longrightarrow$
(e) Write a balanced net ionic equation for (d).

4.93 How many grams of O_2 can be prepared from the thermal decomposition of 4.27 kg of HgO? Name and calculate the mass (in kg) of the other product.

4.94 How many grams of chlorine gas can be produced from the electrolytic decomposition of 874 g of calcium chloride? Name and calculate the mass (in g) of the other product.

4.95 In a combination reaction, 1.62 g of lithium is mixed with 6.00 g of oxygen. (a) Which reactant is present in excess? (b) How many moles of product are formed? (c) After reaction, how many grams of each reactant and product are present?

4.96 In a combination reaction, 2.22 g of magnesium is heated with 3.75 g of nitrogen. (a) Which reactant is present in excess? (b) How many moles of product are formed? (c) After reaction, how many grams of each reactant and product are present?

4.97 A mixture of $KClO_3$ and KCl with a mass of 0.900 g was heated to produce O_2. After heating, the mass of residue was 0.700 g. Assuming all the $KClO_3$ decomposed to KCl and O_2, calculate the mass percent of $KClO_3$ in the original mixture.

4.98 A mixture of $CaCO_3$ and CaO weighing 0.693 g was heated to produce CO_2. After heating, the remaining solid weighed 0.508 g. Assuming all the $CaCO_3$ broke down to CaO and CO_2, calculate the mass percent of $CaCO_3$ in the original mixture.

Problems in Context

4.99 Before arc welding was developed, a displacement reaction involving aluminum and iron(III) oxide was commonly used to produce molten iron (the thermite process). This reaction was used, for example, to connect sections of iron railroad track. Calculate the mass of molten iron produced when 1.00 kg of aluminum reacts with 2.00 mol of iron(III) oxide.

4.100 Iron reacts rapidly with chlorine gas to form a reddish brown, ionic compound (A), which contains iron in the higher of its two common oxidation states. Strong heating decomposes compound A to compound B, another ionic compound, which contains iron in the lower of its two oxidation states. When compound A is formed by the reaction of 50.6 g of Fe and 83.8 g of Cl_2 and then heated, how much compound B forms?

Reversible Reactions: An Introduction to Chemical Equilibrium

Concept Review Questions

4.101 Why is the equilibrium state called "dynamic"?

4.102 In a decomposition reaction involving a gaseous product, what must be done for the reaction to reach equilibrium?

4.103 Describe what happens on the molecular level when acetic acid dissolves in water.

4.104 When either a mixture of NO and Br_2 or pure nitrosyl bromide (NOBr) is placed in a reaction vessel, the product mixture contains NO, Br_2, and NOBr. Explain.

Problems in Context

4.105 Ammonia is produced by the millions of tons annually for use as a fertilizer. It is commonly made from N_2 and H_2 by the Haber process. Because the reaction reaches equilibrium before going completely to product, the stoichiometric amount of ammonia is not obtained. At a particular temperature and pressure, 10.0 g of H_2 reacts with 20.0 g of N_2 to form ammonia. When equilibrium is reached, 15.0 g of NH_3 has formed.
(a) Calculate the percent yield.
(b) How many moles of N_2 and H_2 are present at equilibrium?

Comprehensive Problems

4.106 Nutritional biochemists have known for decades that acidic foods cooked in cast-iron cookware can supply significant amounts of dietary iron (ferrous ion).
(a) Write a balanced net ionic equation, with oxidation numbers, that supports this fact.
(b) Measurements show an increase from 3.3 mg of iron to 49 mg of iron per $\frac{1}{2}$-cup (125-g) serving during the slow preparation of tomato sauce in a cast-iron pot. How many ferrous ions are present in a 26-oz (737-g) jar of the tomato sauce?

4.107 Limestone ($CaCO_3$) is used to remove acidic pollutants from smokestack flue gases. It is heated to form lime (CaO), which reacts with sulfur dioxide to form calcium sulfite. Assuming a 70.% yield in the overall reaction, what mass of limestone is required to remove all the sulfur dioxide formed by the combustion of 8.5×10^4 kg of coal that is 0.33 mass % sulfur?

4.108 The brewing industry uses yeast microorganisms to convert glucose to ethanol for wine and beer. The baking industry uses the carbon dioxide produced to make bread rise:

$$C_6H_{12}O_6(s) \xrightarrow{\text{yeast}} 2C_2H_5OH(l) + 2CO_2(g)$$

How many grams of ethanol can be produced from 10.0 g of glucose? What volume of CO_2 is produced? (Assume 1 mol of gas occupies 22.4 L at the conditions used.)

4.109 A chemical engineer determines the mass percent of iron in an ore sample by converting the Fe to Fe^{2+} in acid and then titrating the Fe^{2+} with MnO_4^-. A 1.1081-g sample was dissolved in acid and then titrated with 39.32 mL of 0.03190 *M* $KMnO_4$. The balanced equation is

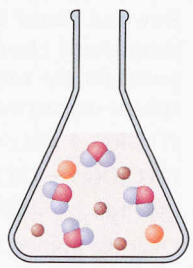
$$8H^+(aq) + 5Fe^{2+}(aq) + MnO_4^-(aq) \longrightarrow 5Fe^{3+}(aq) + Mn^{2+}(aq) + 4H_2O(l)$$

Calculate the mass percent of iron in the ore.

4.110 Mixtures of $CaCl_2$ and NaCl are used to melt ice on roads. A dissolved 1.9348-g sample of this mixture was analyzed by using excess $Na_2C_2O_4$ to precipitate the Ca^{2+} as CaC_2O_4. The CaC_2O_4 was dissolved in sulfuric acid, and the resulting $H_2C_2O_4$ was titrated with 37.68 mL of 0.1019 *M* $KMnO_4$ solution. (a) Write the balanced net ionic equation for the precipitation reaction. (b) Write the balanced net ionic equation for the titration reaction. (See Sample Problem 4.9.) (c) What is the oxidizing agent? (d) What is the reducing agent? (e) Calculate the mass percent of $CaCl_2$ in the original sample.

4.111 You are given solutions of HCl and NaOH and must determine their concentrations. You use 27.5 mL of NaOH to titrate 100. mL of HCl and 18.4 mL of NaOH to titrate 50.0 mL of 0.0782 *M* H_2SO_4. Find the unknown concentrations.

4.112 The flask *(right)* represents the products of the titration of 25 mL of sulfuric acid with 25 mL of sodium hydroxide.
(a) Write balanced molecular, total ionic, and net ionic equations for the reaction.
(b) If each orange sphere represents 0.010 mol of sulfate ion, how many moles of acid and of base reacted?
(c) What are the molarities of the acid and the base?



4.113 To find the mass percent of dolomite [$CaMg(CO_3)_2$] in a soil sample, a geochemist titrates 12.86 g of soil with 33.56 mL of 0.2516 *M* HCl. What is the mass percent of dolomite in the soil?

4.114 On a lab exam, you have to find the concentrations of the monoprotic (one proton per molecule) acids HA and HB. You are given 43.5 mL of HA solution in one flask. A second flask contains 37.2 mL of HA, and you add enough HB solution to it to reach a final volume of 50.0 mL. You titrate the first HA solution with 87.3 mL of 0.0906 *M* NaOH and the mixture of HA and HB in the second flask with 96.4 mL of the NaOH solution. Calculate the molarity of the HA and HB solutions.

4.115 Nitric acid, a major industrial and laboratory acid, is produced commercially by the multistep Ostwald process, which begins with the oxidation of ammonia:

Step 1. $4NH_3(g) + 5O_2(g) \longrightarrow 4NO(g) + 6H_2O(l)$
Step 2. $2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$
Step 3. $3NO_2(g) + H_2O(l) \longrightarrow 2HNO_3(l) + NO(g)$

(a) What are the oxidizing and reducing agents in each step?
(b) Assuming 100% yield in each step, what mass (in kg) of ammonia must be used to produce 3.0×10^4 kg of HNO_3?

4.116 For the following aqueous reactions, complete and balance the molecular equation and write a net ionic equation:
(a) Manganese(II) sulfide + hydrobromic acid
(b) Potassium carbonate + strontium nitrate
(c) Potassium nitrite + hydrochloric acid
(d) Calcium hydroxide + nitric acid
(e) Barium acetate + iron(II) sulfate
(f) Zinc carbonate + sulfuric acid
(g) Copper(II) nitrate + hydrosulfuric acid
(h) Magnesium hydroxide + chloric acid
(i) Potassium chloride + ammonium phosphate
(j) Barium hydroxide + hydrocyanic acid

4.117 Use the oxidation number method to balance the following equations by placing coefficients in the blanks. Identify the reducing and oxidizing agents:
(a) $_KOH(aq) + _H_2O_2(aq) + _Cr(OH)_3(s) \longrightarrow _K_2CrO_4(aq) + _H_2O(l)$
(b) $_MnO_4^-(aq) + _ClO_2^-(aq) + _H_2O(l) \longrightarrow _MnO_2(s) + _ClO_4^-(aq) + _OH^-(aq)$
(c) $_KMnO_4(aq) + _Na_2SO_3(aq) + _H_2O(l) \longrightarrow _MnO_2(s) + _Na_2SO_4(aq) + _KOH(aq)$
(d) $_CrO_4^{2-}(aq) + _HSnO_2^-(aq) + _H_2O(l) \longrightarrow _CrO_2^-(aq) + _HSnO_3^-(aq) + _OH^-(aq)$
(e) $_KMnO_4(aq) + _NaNO_2(aq) + _H_2O(l) \longrightarrow _MnO_2(s) + _NaNO_3(aq) + _KOH(aq)$
(f) $_I^-(aq) + _O_2(g) + _H_2O(l) \longrightarrow _I_2(s) + _OH^-(aq)$

4.118 In 1995, Mario Molina, Paul Crutzen, and F. Sherwood Rowland shared the Nobel Prize in chemistry for their work on atmospheric chemistry. One of several reaction sequences proposed for the role of chlorine in the decomposition of stratospheric ozone (we'll see another sequence in Chapter 16) is
(1) $Cl(g) + O_3(g) \longrightarrow ClO(g) + O_2(g)$
(2) $ClO(g) + ClO(g) \longrightarrow Cl_2O_2(g)$
(3) $Cl_2O_2(g) \xrightarrow{\text{light}} 2Cl(g) + O_2(g)$
Over the tropics, oxygen atoms are more common in the stratosphere, and ozone is also decomposed by reactions 1 and 4:
(4) $ClO(g) + O_3(g) \longrightarrow Cl(g) + O_2(g)$
(a) Which, if any, of the reactions are oxidation-reduction reactions?
(b) Write an overall equation combining reactions 1-3.

4.119 Sodium peroxide (Na_2O_2) is often used in self-contained breathing devices, such as those used in fire emergencies, because it reacts with exhaled CO_2 to form Na_2CO_3 and O_2. How many liters of respired air can react with 80.0 g of Na_2O_2 if each liter of respired air contains 0.0720 g of CO_2?

4.120 Magnesium is used in airplane bodies and other lightweight alloys. The metal is obtained from seawater in a process that includes precipitation, neutralization, evaporation, and electrolysis. How many kilograms of magnesium can be obtained from 1.00 km^3 of seawater if the initial Mg^{2+} concentration is 0.13% by mass (d of seawater = 1.04 g/mL)?

4.121 A typical formulation for window glass is 75% SiO_2, 15% Na_2O, and 10.% CaO by mass. What masses of sand (SiO_2), sodium carbonate, and calcium carbonate must be combined to produce 1.00 kg of glass after carbon dioxide is driven off by thermal decomposition of the carbonates?

4.122 Physicians who specialize in sports medicine routinely treat athletes and dancers. Ethyl chloride, a local anesthetic commonly used for simple injuries, is the product of the combination of ethylene with hydrogen chloride:

$$C_2H_4(g) + HCl(g) \longrightarrow C_2H_5Cl(g)$$

If 0.100 kg of C_2H_4 and 0.100 kg of HCl react:
(a) How many molecules of gas (reactants plus products) are present when the reaction is complete?
(b) How many moles of gas are present when half the product forms?

4.123 The *salinity* of a solution is defined as the grams of total salts per kilogram of solution. An agricultural chemist uses a solution whose salinity is 35.0 g/kg to test the effect of irrigating farmland with high-salinity river water. The two solutes are NaCl and $MgSO_4$, and there are twice as many moles of NaCl as $MgSO_4$. What masses of NaCl and $MgSO_4$ are contained in 1.00 kg of the solution?

4.124 Thyroxine ($C_{15}H_{11}I_4NO_4$) is a hormone synthesized by the thyroid gland and used to control many metabolic functions in the body. A physiologist determines the mass percent of thyroxine in a thyroid extract by igniting 0.4332 g of extract with sodium carbonate, which converts the iodine to iodide. The iodide is dissolved in water, and bromine and hydrochloric acid are added, which convert the iodide to iodate.
(a) How many moles of iodate form per mole of thyroxine?
(b) Excess bromine is boiled off and more iodide is added, which reacts as shown in the following *unbalanced* equation:

$$IO_3^-(aq) + H^+(aq) + I^-(aq) \longrightarrow I_2(aq) + H_2O(l)$$

How many moles of iodine are produced per mole of thyroxine? (*Hint:* Be sure to balance the charges as well as the atoms.) What are the oxidizing and reducing agents in the reaction?
(c) The iodine reacts completely with 17.23 mL of 0.1000 M thiosulfate as shown in the following *unbalanced* equation:

$$I_2(aq) + S_2O_3^{2-}(aq) \longrightarrow I^-(aq) + S_4O_6^{2-}(aq)$$

What is the mass percent of thyroxine in the thyroid extract?

4.125 Carbon dioxide is removed from the atmosphere of space capsules by reaction with a solid metal hydroxide. The products are water and the metal carbonate.
(a) Calculate the mass of CO_2 that can be removed by reaction with 3.50 kg of lithium hydroxide.
(b) How many grams of CO_2 can be removed by 1.00 g of each of the following: lithium hydroxide, magnesium hydroxide, and aluminum hydroxide?

4.126 Calcium dihydrogen phosphate, $Ca(H_2PO_4)_2$, and sodium hydrogen carbonate, $NaHCO_3$, are ingredients of baking powder that react with each other to produce CO_2, which causes dough or batter to rise:

$$Ca(H_2PO_4)_2(s) + NaHCO_3(s) \longrightarrow CO_2(g) + H_2O(g) + CaHPO_4(s) + Na_2HPO_4(s) \text{ [unbalanced]}$$

If the baking powder contains 31% $NaHCO_3$ and 35% $Ca(H_2PO_4)_2$ by mass:
(a) How many moles of CO_2 are produced from 1.00 g of baking powder?
(b) If 1 mol of CO_2 occupies 37.0 L at 350°F (a typical baking temperature), what volume of CO_2 is produced from 1.00 g of baking powder?

4.127 In a titration of HNO_3, you add a few drops of phenolphthalein indicator to 50.00 mL of acid in a flask. You quickly add 20.00 mL of 0.0502 *M* NaOH but overshoot the end point, and the solution turns deep pink. Instead of starting over, you add 30.00 mL of the acid, and the solution turns colorless. Then, it takes 3.22 mL of the NaOH to reach the end point. (a) What is the concentration of the HNO_3 solution? (b) How many moles of NaOH were in excess after the first addition?

4.128 The active compound in Pepto-Bismol contains C, H, O, and Bi.

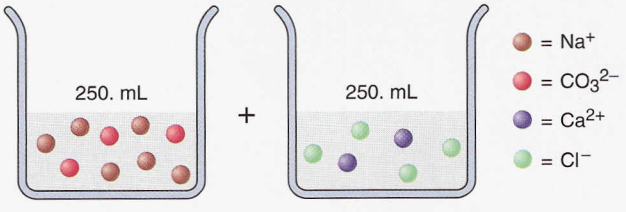
(a) When 0.22105 g of it was burned in excess O_2, 0.1422 g of bismuth(III) oxide, 0.1880 g of carbon dioxide, and 0.02750 g of water were formed. What is the empirical formula of this compound?

(b) Given a molar mass of 1086 g/mol, determine the molecular formula.

(c) Complete and balance the acid-base reaction between bismuth(III) hydroxide and salicylic acid ($HC_7H_5O_3$), which is used to form this compound.

(d) A dose of Pepto-Bismol contains 0.600 mg of the active ingredient. If the yield of the reaction in part (c) is 88.0%, what mass (in mg) of bismuth(III) hydroxide is required to prepare one dose?

4.129 Two aqueous solutions contain the ions indicated below.



(a) Write balanced molecular, total ionic, and net ionic equations for the reaction that occurs when the solutions are mixed. (b) If each sphere represents 0.050 mol of ion, what mass (in g) of precipitate forms, assuming 100% reaction. (c) What is the concentration of each ion in solution after reaction?

4.130 In 1997, at the United Nations Conference on Climate Change, the major industrial nations agreed to expand their research efforts to develop renewable sources of carbon-based fuels. For more than a decade, Brazil has been engaged in a program to replace gasoline with ethanol derived from the root crop manioc (cassava).

(a) Write separate balanced equations for the complete combustion of ethanol (C_2H_5OH) and of gasoline (represented by the formula C_8H_{18}).

(b) What mass of oxygen is required to burn completely 1.00 L of a mixture that is 90.0% gasoline (d = 0.742 g/mL) and 10.0% ethanol (d = 0.789 g/mL) by volume?

(c) If 1.00 mol of O_2 occupies 22.4 L, what volume of O_2 is needed to burn 1.00 L of the mixture?

(d) Air is 20.9% O_2 by volume. What volume of air is needed to burn 1.00 L of the mixture?

4.131 In a car engine, gasoline (represented by C_8H_{18}) does not burn completely, and some CO, a toxic pollutant, forms along with CO_2 and H_2O. If 5.0% of the gasoline forms CO:

(a) What is the ratio of CO_2 to CO molecules in the exhaust?

(b) What is the mass ratio of CO_2 to CO?

(c) What percentage of the gasoline must form CO for the mass ratio of CO_2 to CO to be exactly 1:1?

4.132 The amount of ascorbic acid (vitamin C; $C_6H_8O_6$) in tablets is determined by reaction with bromine and then titration of the hydrobromic acid with standard base:

$$C_6H_8O_6 + Br_2 \longrightarrow C_6H_6O_6 + 2HBr$$
$$HBr + NaOH \longrightarrow NaBr + H_2O$$

A certain tablet is advertised as containing 500 mg of vitamin C. One tablet was dissolved in water and reacted with Br_2. The solution was then titrated with 43.20 mL of 0.1350 *M* NaOH. Did the tablet contain the advertised quantity of vitamin C?

4.133 In the process of *salting-in*, protein solubility in a dilute salt solution is increased by adding more salt. Because the protein solubility depends on the total ion concentration as well as the ion charge, salts yielding divalent ions are often more effective than those yielding monovalent ions. (a) How many grams of $MgCl_2$ must dissolve to equal the ion concentration of 12.4 g of NaCl? (b) How many grams of CaS must dissolve? (c) Which of the three salt solutions would dissolve the most protein?

4.134 In the process of *pickling*, rust is removed from newly produced steel by washing the steel in hydrochloric acid:

$$(1)\ 6HCl(aq) + Fe_2O_3(s) \longrightarrow 2FeCl_3(aq) + 3H_2O(l)$$

During the process, some iron is lost as well:

$$(2)\ 2HCl(aq) + Fe(s) \longrightarrow FeCl_2(aq) + H_2(g)$$

(a) Which reaction, if either, is a redox process? (b) If reaction 2 did not occur and all the HCl were used, how many grams of Fe_2O_3 could be removed and $FeCl_3$ produced in a 2.50×10^3-L bath of 3.00 *M* HCl? (c) If reaction 1 did not occur and all the HCl were used, how many grams of Fe could be lost and $FeCl_2$ produced in a 2.50×10^3-L bath of 3.00 *M* HCl? (d) If 0.280 g of Fe is lost per gram of Fe_2O_3 removed, what is the mass ratio of $FeCl_2$ to $FeCl_3$?

4.135 At liftoff, the space shuttle uses a solid mixture of ammonium perchlorate and aluminum powder to obtain great thrust from the volume change of solid to gas. In the presence of a catalyst, the mixture forms solid aluminum oxide and aluminum trichloride and gaseous water and nitric oxide. (a) Write a balanced equation for the reaction, and identify the reducing and oxidizing agents. (b) How many total moles of gas (water vapor and nitric oxide) are produced when 50.0 kg of ammonium perchlorate reacts with a stoichiometric amount of Al? (c) What is the volume change from this reaction? (d of NH_4ClO_4 = 1.95 g/cc, Al = 2.70 g/cc, Al_2O_3 = 3.97 g/cc, and $AlCl_3$ = 2.44 g/cc; assume 1 mol of gas occupies 22.4 L.)

4.136 A *reaction cycle* for an element is a series of reactions beginning and ending with that element. In the following copper reaction cycle, copper has either a 0 or a +2 oxidation state. Write balanced molecular and net ionic equations for each step in the cycle.

(1) Copper metal reacts with aqueous bromine to produce a green-blue solution.

(2) Adding aqueous sodium hydroxide forms a blue precipitate.

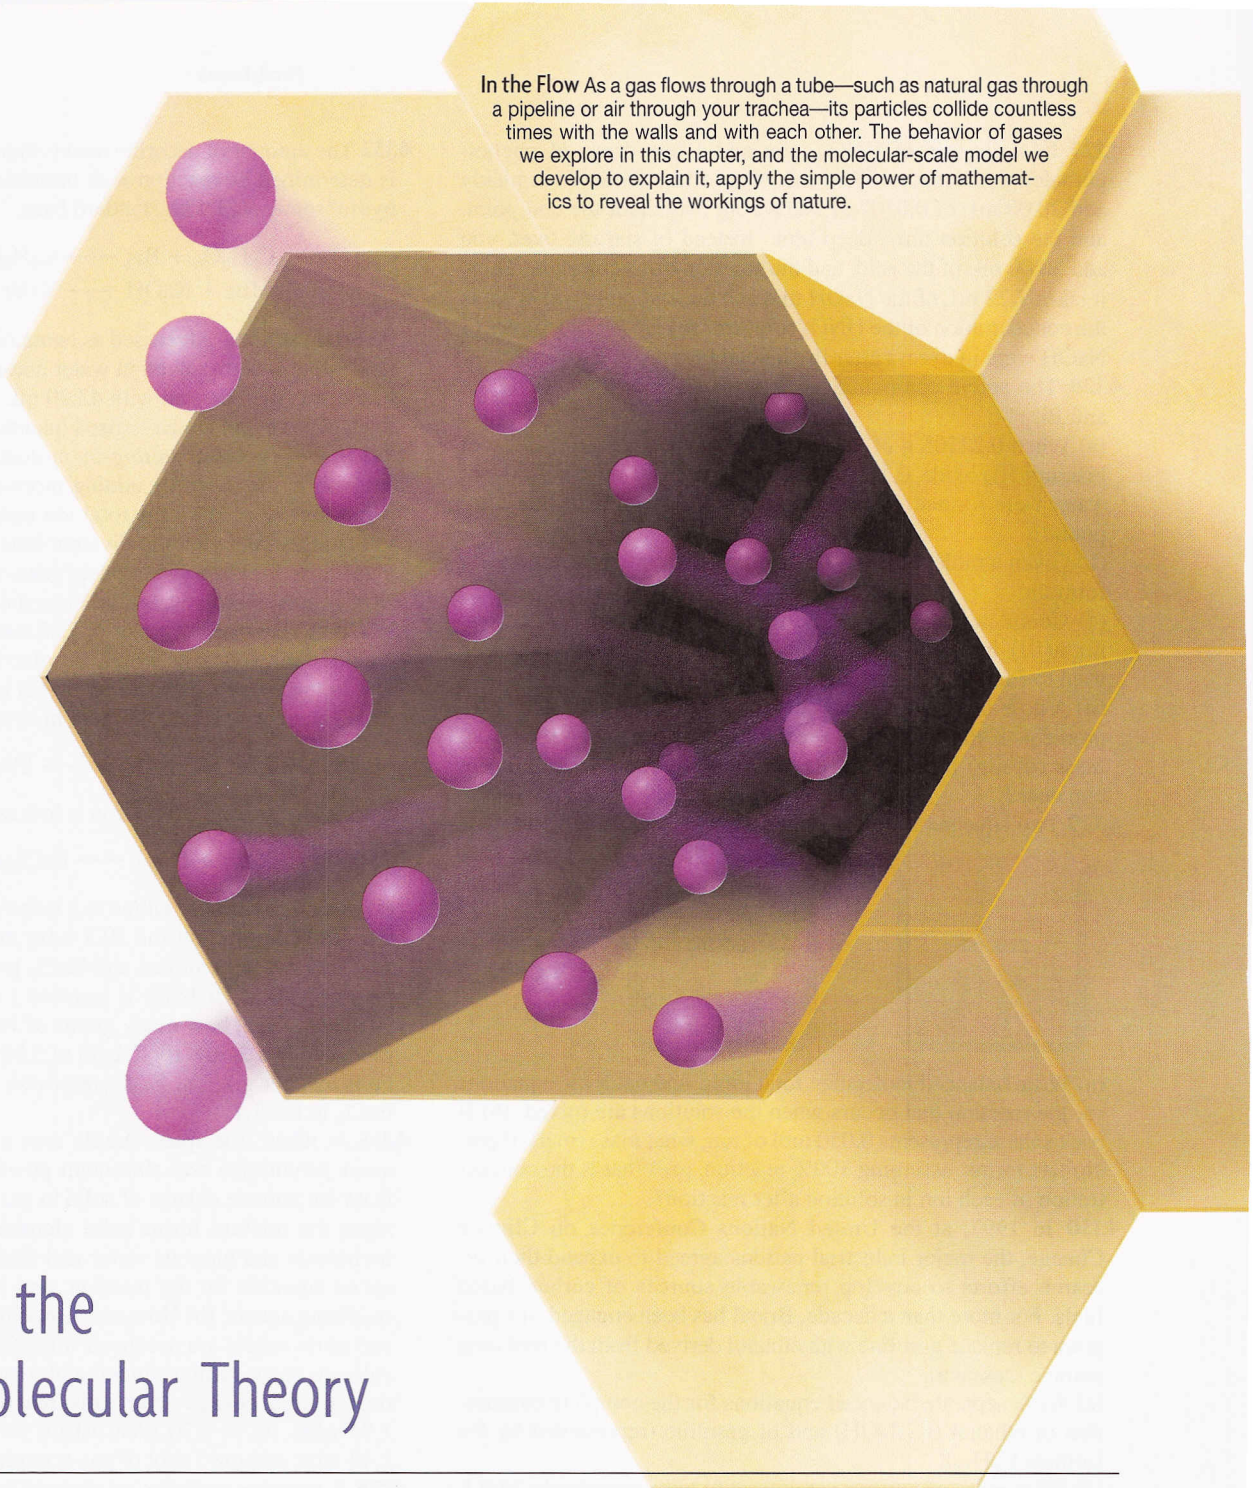
(3) The precipitate is heated and turns black (water is released).

(4) The black solid dissolves in nitric acid to give a blue solution.

(5) Adding aqueous sodium phosphate forms a green precipitate.

(6) The precipitate forms a blue solution in sulfuric acid.

(7) Copper metal is recovered from the blue solution when zinc metal is added.



In the Flow As a gas flows through a tube—such as natural gas through a pipeline or air through your trachea—its particles collide countless times with the walls and with each other. The behavior of gases we explore in this chapter, and the molecular-scale model we develop to explain it, apply the simple power of mathematics to reveal the workings of nature.

Effects of Extreme Conditions
The van der Waals Equation

Gases are everywhere. People have been observing their behavior, and that of matter in other states, throughout history—three of the four "elements" of the ancients were air (gas), water (liquid), and earth (solid). However, many questions remain. In this chapter and its companion, Chapter 12, we examine these states and their interrelations. Here, we highlight the gaseous state, the one we understand best.

Earth's atmosphere—the gaseous envelope that surrounds the planet—is a colorless, odorless mixture of nearly 20 elements and compounds that extends from the surface upward more than 500 km until it merges with outer space. Some components—O_2, N_2, H_2O vapor, and CO_2—take part in complex redox reaction cycles throughout the environment, and you participate in those cycles with every breath you take. Gases also have essential roles in industry (Table 5.1).

Concepts & Skills to Review
before you study this chapter

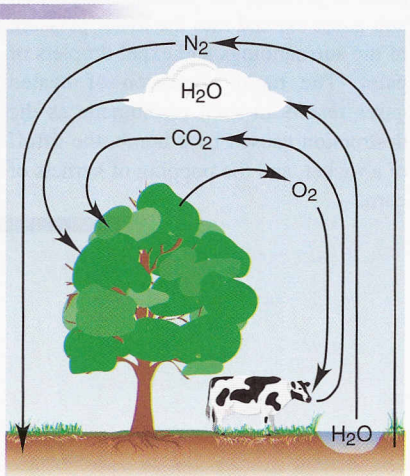
- physical states of matter (Section 1.1)
- SI unit conversions (Section 1.5)
- mole-mass-number conversions (Section 3.1)

Table 5.1 Some Important Industrial Gases

Name (Formula)	Origin; Use
Methane (CH_4)	Natural deposits; domestic fuel
Ammonia (NH_3)	From $N_2 + H_2$; fertilizers, explosives
Chlorine (Cl_2)	Electrolysis of seawater; bleaching and disinfecting
Oxygen (O_2)	Liquefied air; steelmaking
Ethylene (C_2H_4)	High-temperature decomposition of natural gas; plastics

Although the *chemical* behavior of a gas depends on its composition, all gases have remarkably similar *physical* behavior, which is the focus of this chapter. For instance, although the particular gases differ, the same physical behavior is at work in the operation of a car and in the baking of bread, in the thrust of a rocket engine and in the explosion of a kernel of popcorn. The process of breathing involves the same physical principles as the creation of thunder.

IN THIS CHAPTER . . . We first contrast gases with liquids and solids and then discuss gas pressure. We consider the mass laws, which describe gas behavior. We then examine the ideal gas law, which encompasses the other mass laws, and apply it to reaction stoichiometry. We explain the observable behavior of gases with the simple kinetic-molecular model. Then, we find that real gas behavior, especially under extreme conditions, requires refinements of the ideal gas law and the model. Finally, we apply these principles to the properties of planetary atmospheres.



Atmosphere-Biosphere Redox Interconnections The diverse organisms that make up the biosphere interact intimately with the gases of the atmosphere. Powered by solar energy, green plants reduce atmospheric CO_2 and incorporate the C atoms into their own substance. In the process, O atoms in H_2O are oxidized and released to the air as O_2. Certain microbes that live on plant roots reduce N_2 to NH_3 and form compounds that the plant uses to make its proteins. Other microbes that feed on dead plants (and animals) oxidize the proteins and release N_2 again. Animals eat plants and other animals, use O_2 to oxidize their food, and return CO_2 and H_2O to the air.

5.1 AN OVERVIEW OF THE PHYSICAL STATES OF MATTER

Under appropriate conditions of pressure and temperature, most substances can exist as a solid, a liquid, or a gas. In Chapter 1 we described these physical states in terms of how each fills a container and began to develop a molecular view that explains this macroscopic behavior: a solid has a fixed shape regardless of the container shape because its particles are held rigidly in place; a liquid conforms to the container shape but has a definite volume and a surface because its particles are close together but free to move around each other; and a gas fills the container because its particles are far apart and moving randomly. Several other aspects of their behavior distinguish gases from liquids and solids:

1. *Gas volume changes greatly with pressure.* When a sample of gas is confined to a container of variable volume, such as the piston-cylinder assembly of a car engine, an external force can compress the gas. Removing the external force allows the gas volume to increase again. In contrast, a liquid or solid resists significant changes in volume.

2. *Gas volume changes greatly with temperature.* When a gas sample at constant pressure is heated, its volume increases; when it is cooled, its volume decreases. This volume change is 50 to 100 times greater for gases than for liquids or solids.
3. *Gases have relatively low viscosity.* Gases flow much more freely than liquids and solids. Low viscosity allows gases to be transported through pipes over long distances but also to leak rapidly out of small holes.
4. *Most gases have relatively low densities* under normal conditions. Gas density is usually tabulated in units of grams per *liter,* whereas liquid and solid densities are in grams per *milliliter,* about 1000 times as dense (see Table 1.5, p. 21). For example, at 20°C and normal atmospheric pressure, the density of $O_2(g)$ is 1.3 g/**L,** whereas the density of $H_2O(l)$ is 1.0 g/**mL** and that of NaCl(*s*) is 2.2 g/**mL.** When a gas is cooled, its density increases because its volume decreases: at 0°C, the density of $O_2(g)$ increases to 1.4 g/L.
5. *Gases are miscible. Miscible* substances mix with one another in any proportion to form a solution. Clean dry air, for example, is a solution of about 18 gases. Two liquids, however, may or may not be miscible: water and ethanol are, but water and gasoline are not. Two solids generally do not form a solution unless they are mixed as molten liquids and then allowed to solidify.

Each of these observable properties offers a clue to the molecular properties of gases. For example, consider these density data. At 20°C and normal atmospheric pressure, gaseous N_2 has a density of 1.25 g/L. If cooled below −196°C, it condenses to liquid N_2 and its density becomes 0.808 g/mL. (Note the change in units.) The same amount of nitrogen occupies less than $\frac{1}{600}$ as much space! Further cooling to below −210°C yields solid N_2 (d = 1.03 g/mL), which is only somewhat more dense than the liquid. These values show again that *the molecules are much farther apart in the gas than in either the liquid or the solid.* Moreover, a large amount of space between molecules is consistent with gases' miscibility, low viscosity, and compressibility. Figure 5.1 compares macroscopic and atomic-scale views of the physical states of a real substance.

POW! P-s-s-s-t! POP! A jackhammer uses the force of rapidly expanding compressed air to break through rock and cement. When the nozzle on a can of spray paint is pressed, the pressurized propellant gases expand into the lower pressure of the surroundings and expel droplets of paint. The rapid expansion of heated gases results in such phenomena as the destruction caused by a bomb, the liftoff of a rocket, and the popping of kernels of corn.

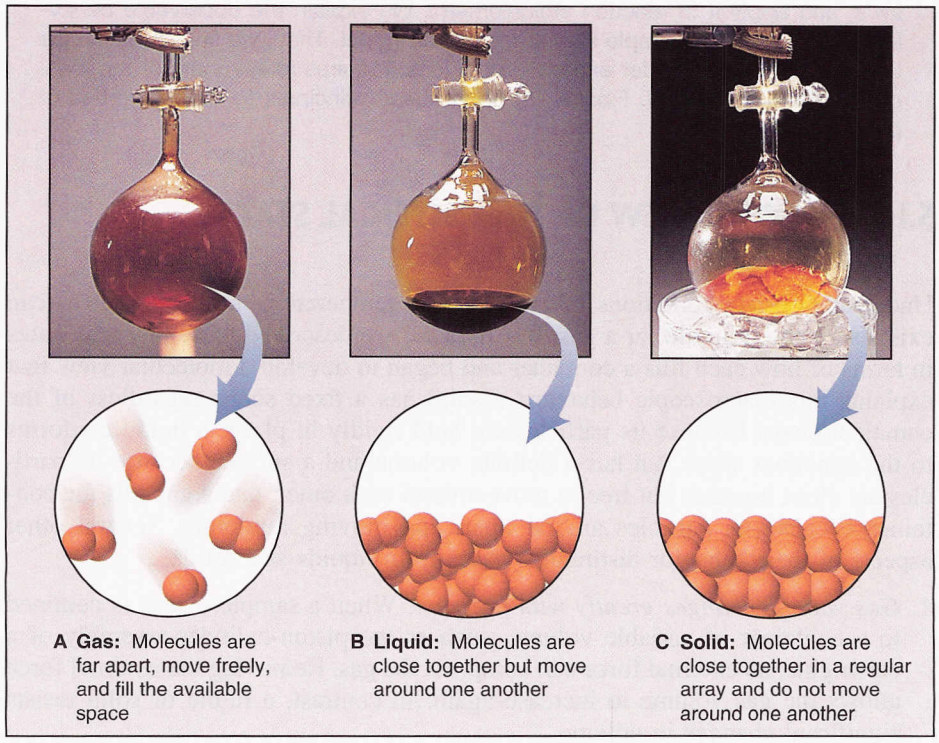


Figure 5.1 The three states of matter. Many pure substances, such as bromine (Br_2), can exist under appropriate conditions of pressure and temperature as **A,** a gas; **B,** a liquid; or **C,** a solid. The atomic-scale views show that molecules are much farther apart in a gas than in a liquid or solid.

SECTION SUMMARY

The volume of a gas can be altered significantly by changing the applied external force or the temperature. The corresponding volume changes for liquids and solids are much smaller. Gases flow more freely and have lower densities than liquids and solids, and they mix in any proportion to form solutions. The major reason for these differences in properties is the greater distance between particles in a gas than in a liquid or a solid.

5.2 GAS PRESSURE AND ITS MEASUREMENT

Blowing up a balloon provides clear evidence that a gas exerts pressure on the walls of its container. **Pressure** (*P*) is defined as the force exerted per unit of surface area:

$$\text{Pressure} = \frac{\text{force}}{\text{area}}$$

Earth's gravitational attraction pulls the atmospheric gases toward its surface, where they exert a force on all objects. The force, or weight, of these gases creates a pressure of about 14.7 pounds per square inch (lb/in^2; psi) of surface.

As we'll discuss later, the molecules in a gas are moving in every direction, so the pressure of the atmosphere is exerted uniformly on the floor, walls, ceiling, and every object in a room. The pressure on the outside of your body is equalized by the pressure on the inside, so there is no net pressure on your body's outer surface. What would happen if this were not the case? As an analogy, consider the empty metal can attached to a vacuum pump in Figure 5.2. With the pump off, the can maintains its shape because the pressure on the outside is equal to the pressure on the inside. With the pump on, the internal pressure decreases greatly, and the ever-present external pressure easily crushes the can. A vacuum-filtration flask (and tubing), which you may have used in the lab, has thick walls that can withstand the external pressure when the flask is evacuated.

Snowshoes and the Meaning of Pressure Snowshoes allow you to walk on powdery snow without sinking because they distribute your weight over a much larger area than a boot does, thereby greatly decreasing your weight per square inch. The area of a snowshoe is typically about 10 times as large as that of a boot sole, so the snowshoe exerts only about one-tenth as much pressure as the boot. The wide, padded paws of snow leopards accomplish this, too. For the same reason, high-heeled shoes exert much more pressure than flat shoes.

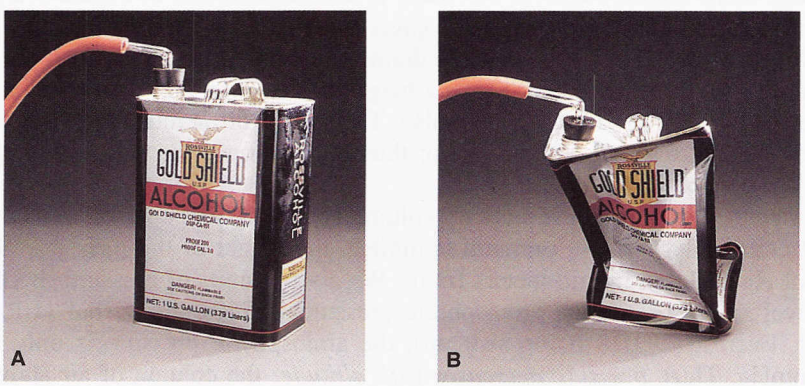

Figure 5.2 Effect of atmospheric pressure on objects at Earth's surface.
A, A metal can filled with air has equal pressure on the inside and outside.
B, When the air inside the can is removed, the atmospheric pressure crushes the can.

Laboratory Devices for Measuring Gas Pressure

The **barometer** is a common device used to measure atmospheric pressure. Invented in 1643 by Evangelista Torricelli, the barometer is still basically just a tube about 1 m long, closed at one end, filled with mercury, and inverted into a dish containing more mercury. When the tube is inverted, some of the mercury flows out into the dish, and a vacuum forms above the mercury remaining in the

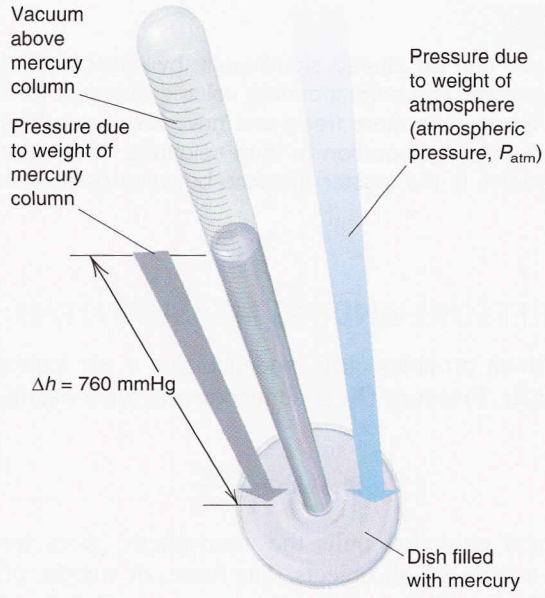

Figure 5.3 A mercury barometer. (See text for explanation.)

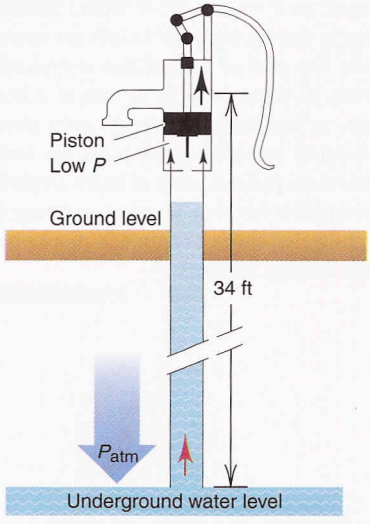

The Mystery of the Suction Pump

When you drink through a straw, you create lower pressure above the liquid, and the atmosphere pushes the liquid up. Similarly, a "suction" pump is a tube dipping into a water source, with a piston and handle that lower the air pressure above the water level. The pump can raise water from a well no deeper than 34 ft. This depth limit was a mystery until the great 17th-century Italian scientist Galileo showed that the atmosphere pushes the water up into the tube and that its pressure can support only a 34-ft column of water. Modern pumps that draw water from deeper sources use compressed air to increase the pressure exerted on the water.

tube, as shown in Figure 5.3. At sea level under ordinary atmospheric conditions, the outward flow of mercury stops when the surface of the mercury in the tube is about 760 mm above the surface of the mercury in the dish. It stops at 760 mm because at that point the column of mercury in the tube exerts the same pressure (weight/area) on the mercury surface in the dish as does the column of air that extends from the dish to the outer reaches of the atmosphere. The air pushing down keeps any more of the mercury in the tube from flowing out. Likewise, if you place an evacuated tube into a dish filled with mercury, the mercury rises about 760 mm into the tube because the atmosphere pushes the mercury up to that height.

Several centuries ago, people ascribed mysterious "suction" forces to a vacuum. We know now that a vacuum does not suck up mercury into the barometer tube any more than it sucks in the walls of the crushed can in Figure 5.2. Only matter—in this case, the atmospheric gases—can exert a force.

Notice that we did not specify the diameter of the barometer tube. If the mercury in a 1-cm diameter tube rises to a height of 760 mm, the mercury in a 2-cm diameter tube will rise to that height also. The *weight* of mercury is greater in the wider tube, but the area is larger also; thus the *pressure*, the *ratio* of weight to area, is the same.

Since the pressure of the mercury column is directly proportional to its height, a unit commonly used for pressure is mmHg, the height of the mercury (atomic symbol Hg) column in millimeters (mm). We discuss units of pressure shortly. At sea level and 0°C, normal atmospheric pressure is 760 mmHg, but at the top of Mt. Everest (29,028 ft, or 8848 m), the atmospheric pressure is only about 270 mmHg. Thus, *pressure decreases with altitude:* the column of air above sea level is taller and weighs more than the column of air above Mt. Everest.

Laboratory barometers contain mercury rather than some other liquid because its high density allows the barometer to be a convenient size. For example, the pressure of the atmosphere would equal the pressure of a column of water about 10,300 mm, almost 34 ft, high. Note that, for a given pressure, the ratio of heights (h) of the liquid columns is inversely related to the ratio of the densities (d) of the liquids:

$$\frac{h_{H_2O}}{h_{Hg}} = \frac{d_{Hg}}{d_{H_2O}}$$

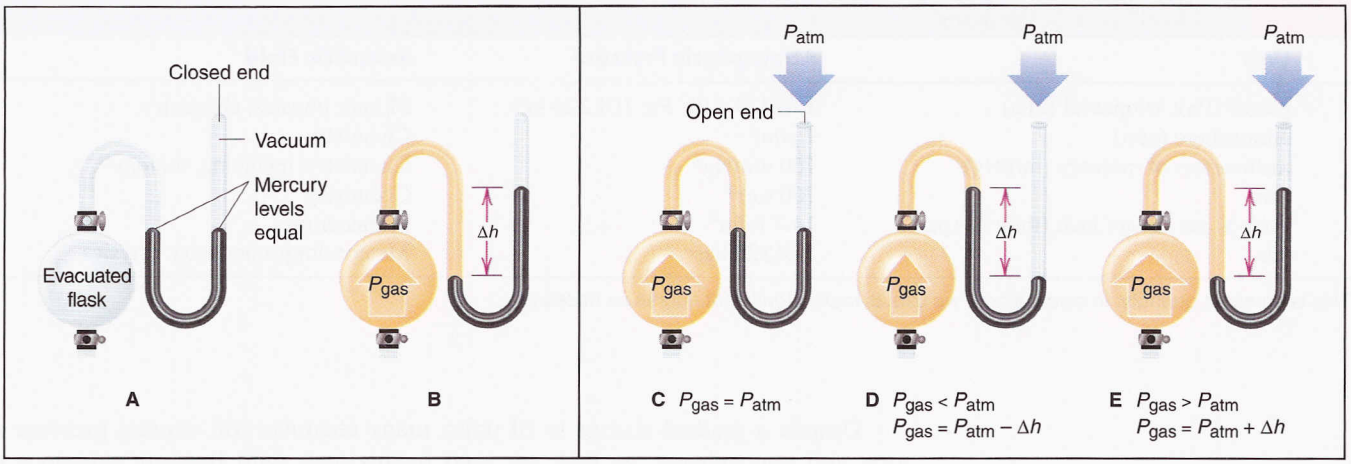

Figure 5.4 Two types of manometer. A, A closed-end manometer with an evacuated flask attached has the mercury levels equal. **B,** A gas exerts pressure on the mercury in the arm closer to the flask. The difference in heights (Δh) equals the gas pressure. **C–E,** An open-end manometer is shown with gas pressure equal to atmospheric pressure, **(C),** gas pressure lower than atmospheric pressure **(D),** and gas pressure higher than atmospheric pressure **(E).**

Manometers are devices used to measure the pressure of a gas in an experiment. Figure 5.4 shows two types of manometer. Part A shows a *closed-end manometer,* a mercury-filled, curved tube, *closed* at one end and attached to a flask at the other. When the flask is evacuated, the mercury levels in the two arms of the tube are the same because no gas exerts pressure on either mercury surface. When a gas is in the flask (part B), it pushes down the mercury level in the near arm, so the level rises in the far arm. The *difference* in column heights (Δh) equals the gas pressure. Note that if we open the lower stopcock of the evacuated flask in part A, air rushes in, Δh equals atmospheric pressure, and the closed-end manometer becomes a barometer.

The *open-end manometer,* shown in parts C–E, also consists of a curved tube filled with mercury, but one end of the tube is *open* to the atmosphere and the other is connected to the gas sample. The atmosphere pushes on one mercury level and the gas pushes on the other. Since Δh equals the difference between two pressures, to calculate the gas pressure with an open-end manometer, we must measure the atmospheric pressure separately with a barometer.

Units of Pressure

Pressure results from a force exerted on an area. The SI unit of force is the newton (N): $1\ \text{N} = 1\ \text{kg·m/s}^2$. The SI unit of pressure is the **pascal (Pa),** which equals a force of one newton exerted on an area of one square meter:

$$1\ \text{Pa} = 1\ \text{N/m}^2$$

A much larger unit is the **standard atmosphere (atm),** the average atmospheric pressure measured at sea level and 0°C. It is defined in terms of the pascal:

$$1\ \text{atm} = 101.325\ \text{kilopascals (kPa)} = 1.01325\times10^5\ \text{Pa}$$

Another common pressure unit is the **millimeter of mercury (mmHg),** which is based on measurement with a barometer or manometer. In honor of Torricelli, this unit has been named the **torr:**

$$1\ \text{torr} = 1\ \text{mmHg} = \frac{1}{760}\ \text{atm} = \frac{101.325}{760}\ \text{kPa} = 133.322\ \text{Pa}$$

The *bar* is coming into more common use in chemistry:

$$1\ \text{bar} = 1\times10^2\ \text{kPa} = 1\times10^5\ \text{Pa}$$

Table 5.2 Common Units of Pressure

Unit	Atmospheric Pressure	Scientific Field
pascal (Pa); kilopascal (kPa)	1.01325×10^5 Pa; 101.325 kPa	SI unit; physics, chemistry
atmosphere (atm)	1 atm*	Chemistry
millimeters of mercury (mmHg)	760 mmHg*	Chemistry, medicine, biology
torr	760 torr*	Chemistry
pounds per square inch (lb/in^2 or psi)	14.7 lb/in^2	Engineering
bar	1.01325 bar	Meteorology, chemistry, physics

*This is an exact quantity; in calculations, we use as many significant figures as necessary.

Despite a gradual change to SI units, many chemists still express pressure in torrs and atmospheres, so they are used in this text, with frequent reference to pascals. Table 5.2 lists some important pressure units used in various scientific fields.

SAMPLE PROBLEM 5.1 Converting Units of Pressure

Problem A geochemist heats a limestone ($CaCO_3$) sample and collects the CO_2 released in an evacuated flask attached to a closed-end manometer (see Figure 5.4B). After the system comes to room temperature, Δh = 291.4 mmHg. Calculate the CO_2 pressure in torrs, atmospheres, and kilopascals.

Plan The CO_2 pressure is given in units of mmHg, so we construct conversion factors from Table 5.2 to find the pressure in the other units.

Solution Converting from mmHg to torr:

$$P_{CO_2}(\text{torr}) = 291.4\ \cancel{\text{mmHg}} \times \frac{1\ \text{torr}}{1\ \cancel{\text{mmHg}}} = 291.4\ \text{torr}$$

Converting from torr to atm:

$$P_{CO_2}(\text{atm}) = 291.4\ \cancel{\text{torr}} \times \frac{1\ \text{atm}}{760\ \cancel{\text{torr}}} = 0.3834\ \text{atm}$$

Converting from atm to kPa:

$$P_{CO_2}(\text{kPa}) = 0.3834\ \cancel{\text{atm}} \times \frac{101.325\ \text{kPa}}{1\ \cancel{\text{atm}}} = 38.85\ \text{kPa}$$

Check There are 760 torr in 1 atm, so ~300 torr should be <0.5 atm. There are ~100 kPa in 1 atm, so <0.5 atm should be <50 kPa.

Comment **1.** In the conversion from torr to atm, we retained four significant figures because this unit conversion factor involves *exact* numbers; that is, 760 torr has as many significant figures as the calculation requires.

2. From here on, except in particularly complex situations, *the canceling of units in calculations is no longer shown.*

FOLLOW-UP PROBLEM 5.1 The CO_2 released from another mineral sample was collected in an evacuated flask connected to an open-end manometer (see Figure 5.4D). If the barometer reading is 753.6 mmHg and Δh is 174.0 mmHg, calculate P_{CO_2} in torrs, pascals, and lb/in^2.

SECTION SUMMARY

Gases exert pressure (force/area) on all surfaces with which they make contact. A barometer measures atmospheric pressure in terms of the height of the mercury column that the atmosphere can support (760 mmHg at sea level and 0°C). Both closed-end and open-end manometers are used to measure the pressure of a gas sample. Chemists measure pressure in units of atmospheres (atm), torr (equivalent to mmHg), or pascals (Pa, the SI unit).

5.3 THE GAS LAWS AND THEIR EXPERIMENTAL FOUNDATIONS

The physical behavior of a sample of gas can be described completely by four variables: pressure (P), volume (V), temperature (T), and amount (number of moles, n). The variables are interdependent: *any one of them can be determined by measuring the other three.* We know now that this quantitatively predictable behavior is a direct outcome of the structure of gases on the molecular level. Yet, it was discovered, for the most part, before Dalton's atomic theory was published!

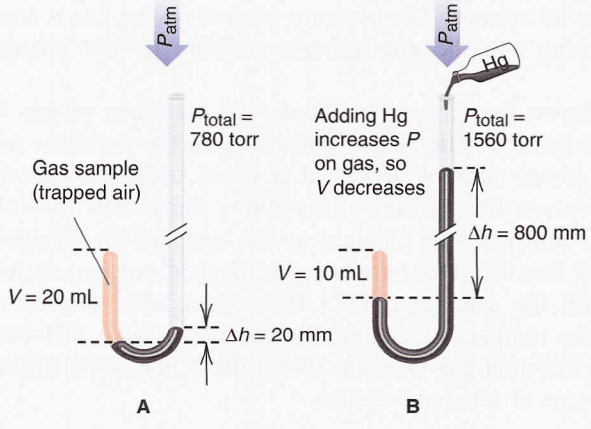
Three key relationships exist among the four gas variables—Boyle's, Charles's, and Avogadro's laws. Each of these gas laws expresses the effect of one variable on another, with the remaining two variables held constant. Since the volume occupied by a gas is so easy to measure, the laws are traditionally expressed as the effect on gas volume of changing the pressure, temperature, or amount of gas.

These three laws are special cases of an all-encompassing relationship among gas variables called the *ideal gas law.* This unifying observation quantitatively describes the state of a so-called **ideal gas,** one that exhibits simple linear relationships among volume, pressure, temperature, and amount. Although no ideal gas actually exists, most simple gases, such as N_2, O_2, H_2, and the noble gases, show nearly ideal behavior at ordinary temperatures and pressures. We discuss the ideal gas law after the three special cases.

The Relationship Between Volume and Pressure: Boyle's Law

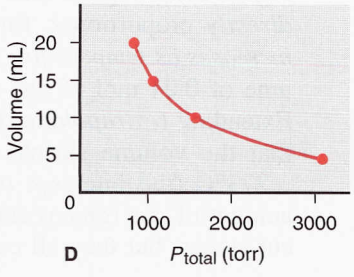
Following Torricelli's invention of the barometer, the great English chemist Robert Boyle performed a series of experiments that led him to conclude that at a given temperature, *the volume occupied by a gas is inversely related to its pressure.* Figure 5.5 shows Boyle's experiment and some typical data he might have collected. Boyle fashioned a J-shaped glass tube, sealed the shorter end, and poured mercury into the longer end, thereby trapping some air, the gas in the experiment. From the height of the trapped air column and the diameter of the tube, he calculated the air volume. The total pressure applied to the trapped air was the pressure of the atmosphere (measured with a barometer) plus that of the mercury column (part A). By adding mercury, Boyle increased the total pressure exerted on the air, and the air volume decreased (part B). Since the temperature and amount of air were constant, Boyle could directly measure the effect of the applied pressure on the volume of air.

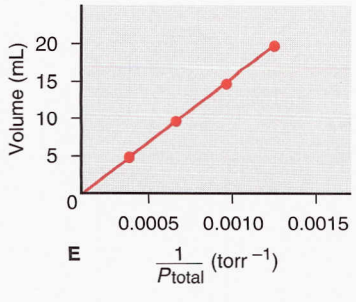
Figure 5.5 The relationship between the volume and pressure of a gas. A, A small amount of air (the gas) is trapped in the short arm of a J tube; n and T are fixed. The total pressure on the gas (P_{total}) is the sum of the pressure due to the difference in heights of the mercury columns (Δh) and the pressure of the atmosphere (P_{atm}). If P_{atm} = 760 torr, P_{total} = 780 torr. **B,** As mercury is added, the total pressure on the gas increases and its volume (V) decreases. Note that if P_{total} is doubled (to 1560 torr), V is halved (not drawn to scale). **C,** Some typical pressure-volume data from the experiment. **D,** A plot of V vs. P_{total} shows that V is inversely proportional to P. **E,** A plot of V vs. $1/P_{total}$ is a straight line whose slope is a constant characteristic of *any* gas that behaves ideally.



C

V (mL)	P (torr) Δh	+ P_{atm} =	P_{total}	$\frac{1}{P_{total}}$	PV (torr•mL)
20.0	20.0	760	780	0.00128	1.56×10^4
15.0	278	760	1038	0.000963	1.56×10^4
10.0	800	760	1560	0.000641	1.56×10^4
5.0	2352	760	3112	0.000321	1.56×10^4





Note the following results (Figure 5.5):

- The product of corresponding P and V values is a constant (part C, rightmost column)
- V is *inversely* proportional to P (part D)
- V is *directly* proportional to $1/P$ (part E) and generates a linear plot of V against $1/P$. This *linear relationship between two gas variables* is a hallmark of ideal gas behavior.

The generalization of Boyle's observations is known as **Boyle's law:** *at constant temperature, the volume occupied by a fixed amount of gas is inversely proportional to the applied (external) pressure,* or

$$V \propto \frac{1}{P} \qquad [T \text{ and } n \text{ fixed}] \tag{5.1}$$

This relationship can also be expressed as

$$PV = \text{constant} \qquad \text{or} \qquad V = \frac{\text{constant}}{P} \qquad [T \text{ and } n \text{ fixed}]$$

The constant is the same for the great majority of gases. Thus, tripling the external pressure reduces the volume to one-third its initial value; halving the external pressure doubles the volume; and so forth.

The wording of Boyle's law focuses on *external* pressure. In his experiment, however, adding more mercury caused the mercury level to rise until the pressure of the trapped air stopped the rise at some new level. At that point, the pressure exerted *on* the gas equaled the pressure exerted *by* the gas. In other words, by measuring the applied pressure, Boyle was also measuring the gas pressure. Thus, when gas volume doubles, gas pressure is halved. In general, if V_{gas} increases, P_{gas} decreases, and vice versa.

The Relationship Between Volume and Temperature: Charles's Law

One question raised by Boyle's work was why the pressure-volume relationship holds only at constant temperature. Experience had shown that gas volume depends on temperature, but it was not until the early 19th century, through the separate work of the French scientists J. A. C. Charles and J. L. Gay-Lussac, that the relationship was clearly understood.

Let's examine this relationship by measuring the volume of a fixed amount of a gas under constant pressure but at different temperatures. A straight tube, closed at one end, traps a fixed amount of air under a small mercury plug. The tube is immersed in a water bath that can be warmed with a heater or cooled with ice. After each change of water temperature, we measure the length of the air column, which is proportional to its volume. The pressure exerted on the gas is constant because the mercury plug and the atmospheric pressure do not change (Figure 5.6A and B).

Some typical data are shown for different amounts and pressures of gas in Figure 5.6C. Again, note the linear relationships, but this time the variables are *directly* proportional: for a given amount of gas at a given pressure, *volume increases as temperature increases*. For example, the red line shows how the volume of 0.04 mol of gas at 1 atm pressure changes as the temperature changes. Extending (*extrapolating*) the line to lower temperatures (dashed portion) shows that the volume shrinks until the gas occupies a theoretical zero volume at $-273°C$ (the intercept on the temperature axis). Similar plots for a different amount of gas (green) and a different gas pressure (blue) show lines with different slopes, but they all converge at this temperature.

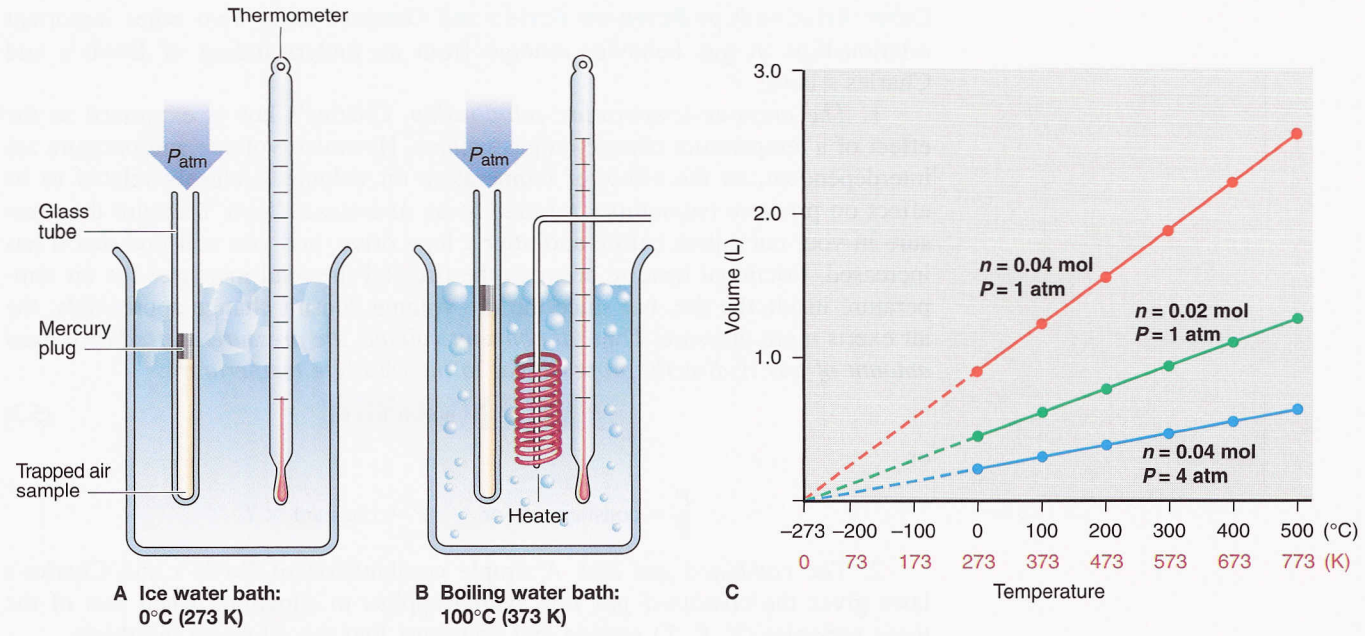


Figure 5.6 The relationship between the volume and temperature of a gas. At constant P, the volume of a given amount of gas is *directly* proportional to the absolute temperature. A fixed amount of gas (air) is trapped under a small plug of mercury at a fixed pressure. **A,** The sample is in an ice water bath. **B,** The sample is in a boiling water bath. As the temperature increases, the volume of the gas increases. **C,** The three lines show the effect of amount (n) of gas (compare red and green) and pressure (P) of gas (compare red and blue). The dashed lines extrapolate the data to lower temperatures. For any amount of an ideal gas at any pressure, the volume is theoretically zero at −273.15°C (0 K).

A half-century after Charles's and Gay-Lussac's work, William Thomson (Lord Kelvin) used this linear relation between gas volume and temperature to devise the absolute temperature scale (Section 1.5). In this scale, absolute zero (0 K or −273.15°C) is the temperature at which an ideal gas would have zero volume. (Absolute zero has never been reached, but physicists have attained temperatures as low as 10^{-9} K.) Of course, no sample of matter can have zero volume, and every real gas condenses to a liquid at some temperature higher than 0 K. Nevertheless, *this linear dependence of volume on absolute temperature holds for most common gases over a wide temperature range.*

The modern statement of the volume-temperature relationship is known as **Charles's law:** *at constant pressure, the volume occupied by a fixed amount of gas is directly proportional to its absolute temperature,* or

$$V \propto T \qquad [P \text{ and } n \text{ fixed}] \tag{5.2}$$

This relationship can also be expressed as

$$\frac{V}{T} = \text{constant} \qquad \text{or} \qquad V = \text{constant} \times T \qquad [P \text{ and } n \text{ fixed}]$$

If T increases, V increases, and vice versa. Once again, for any given P and n, the constant is the same for the great majority of gases.

The dependence of gas volume on *absolute* temperature means that you must *use the Kelvin scale in gas law calculations.* For instance, if the temperature changes from 200 K to 400 K, the volume of 1 mol of gas doubles. But, if the temperature changes from 200°C to 400°C, the volume increases by a factor of 1.42; that is, $\left(\dfrac{400°\text{C} + 273.15}{200°\text{C} + 273.15}\right) = \dfrac{673}{473} = 1.42.$

Other Relationships Based on Boyle's and Charles's Laws Two other important relationships in gas behavior emerge from an understanding of Boyle's and Charles's laws:

1. *The pressure-temperature relationship.* Charles's law is expressed as the effect of a temperature change on gas *volume*. However, volume and pressure are interdependent, so the effect of temperature on volume is closely related to its effect on pressure (sometimes referred to as *Amontons's law*). Measure the pressure in your car's tires before and after a long drive, and you will find that it has increased. Frictional heating between the tire and the road increases the air temperature inside the tire, but since the tire volume doesn't change appreciably, the air exerts more pressure. Thus, *at constant volume, the pressure exerted by a fixed amount of gas is directly proportional to the absolute temperature:*

$$P \propto T \qquad [V \text{ and } n \text{ fixed}] \tag{5.3}$$

or

$$\frac{P}{T} = \text{constant} \qquad \text{or} \qquad P = \text{constant} \times T$$

2. *The combined gas law.* A simple combination of Boyle's and Charles's laws gives the *combined gas law,* which applies to situations when two of the three variables (V, P, T) change and you must find the effect on the third:

$$V \propto \frac{T}{P} \qquad \text{or} \qquad V = \text{constant} \times \frac{T}{P} \qquad \text{or} \qquad \frac{PV}{T} = \text{constant}$$

The Relationship Between Volume and Amount: Avogadro's Law

Boyle's and Charles's laws both specify a fixed amount of gas. Let's see why. Figure 5.7 shows an experiment that involves two small test tubes, each fitted with a piston-cylinder assembly. We add 0.10 mol (4.4 g) of dry ice (frozen CO_2) to the first (tube A) and 0.20 mol (8.8 g) to the second (tube B). As the solid warms, it changes directly to gaseous CO_2, which expands into the cylinder and pushes up the piston. When all the solid has changed to gas and the temperature is constant, we find that cylinder A has half the volume of cylinder B. (We can neglect the volume of the tube because it is so much smaller than the volume of the cylinder.)

This experimental result shows that twice the amount (mol) of gas occupies twice the volume. Notice that, for both cylinders, the T of the gas equals room temperature and the P of the gas equals atmospheric pressure. Thus, *at fixed tem-*

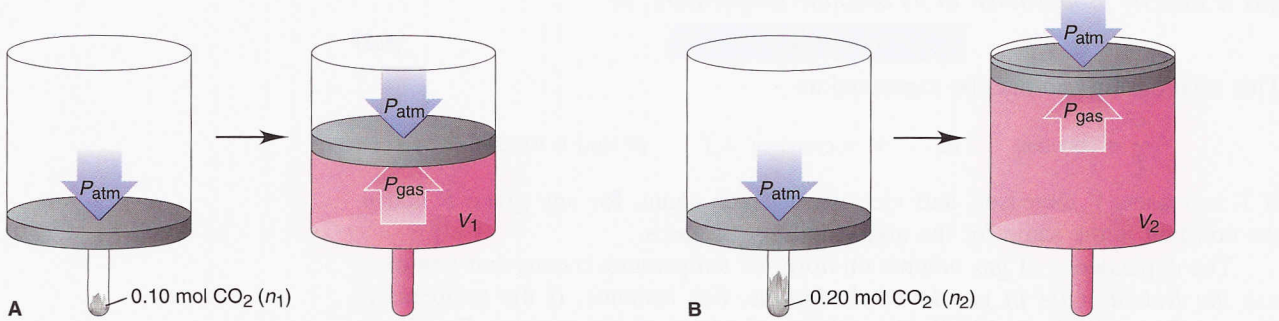

Figure 5.7 An experiment to study the relationship between the volume and amount of a gas. A, At a given external P and T, a given amount (n_1) of $CO_2(s)$ is put into the tube. When the CO_2 changes from solid to gas, it pushes up the piston until $P_{gas} = P_{atm}$, at which point it occupies a given volume of the cylinder. **B,** When twice the amount (n_2) of $CO_2(s)$ is used, twice the volume of the cylinder becomes occupied. Thus, at fixed P and T, the volume (V) of a gas is directly proportional to the amount of gas (n).

perature and pressure, the volume occupied by a gas is directly proportional to the amount (mol) of gas:

$$V \propto n \quad [P \text{ and } T \text{ fixed}] \tag{5.4}$$

As n increases, V increases, and vice versa. This relationship is also expressed as

$$\frac{V}{n} = \text{constant} \quad \text{or} \quad V = \text{constant} \times n$$

The constant is the same for all gases at a given temperature and pressure. This relationship is another way of expressing **Avogadro's law,** which states that *at fixed temperature and pressure, equal volumes of* ***any*** *ideal gas contain equal numbers of particles (or moles).*

Many familiar phenomena are based on the relationships among volume, temperature, and amount of gas. For example, in a car engine, a reaction occurs in which fewer moles of gasoline and O_2 form more moles of CO_2 and H_2O vapor, which expand as a result of the released heat and push back the piston. Dynamite explodes because a solid decomposes rapidly to form hot gases. Dough rises in a warm room because yeast forms CO_2 bubbles in the dough, which expand during baking to give the bread a still larger volume.

Breathing and the Gas Laws Taking a deep breath is a combined application of the gas laws. When you inhale, muscles are coordinated such that your diaphragm moves down and your rib cage moves out. This movement increases the volume of the lungs, which decreases the pressure of the air inside them relative to that outside, so air rushes in (Boyle's). The greater amount of air stretches the elastic tissue of the lungs and expands the volume further (Avogadro's). The air also expands slightly as it warms to body temperature (Charles's). When you exhale, the diaphragm relaxes and moves up, the rib cage moves in, and the lung volume decreases. The inside air pressure becomes greater than the outside pressure, and air rushes out.

Gas Behavior at Standard Conditions

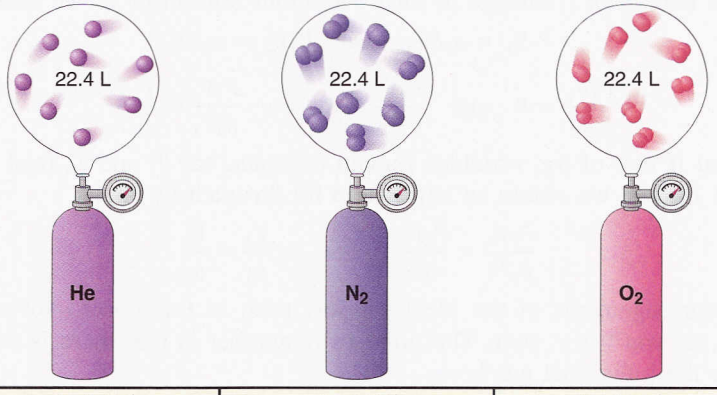
To better understand the factors that influence gas behavior, chemists use a set of *standard conditions* called **standard temperature and pressure (STP):**

$$\text{STP:} \quad 0°\text{C (273.15 K) and 1 atm (760 torr)} \tag{5.5}$$

Under these conditions, the volume of 1 mol of an ideal gas is called the **standard molar volume:**

$$\text{Standard molar volume} = 22.4141 \text{ L} \text{ or } 22.4 \text{ L [to 3 sf]} \tag{5.6}$$

Figure 5.8 compares the properties of three simple gases at STP.



n = 1 mol	n = 1 mol	n = 1 mol
P = 1 atm (760 torr)	P = 1 atm (760 torr)	P = 1 atm (760 torr)
T = 0°C (273 K)	T = 0°C (273 K)	T = 0°C (273 K)
V = 22.4 L	V = 22.4 L	V = 22.4 L
Number of gas particles = 6.022×10^{23}	Number of gas particles = 6.022×10^{23}	Number of gas particles = 6.022×10^{23}
Mass = 4.003 g	Mass = 28.02 g	Mass = 32.00 g
d = 0.179 g/L	d = 1.25 g/L	d = 1.43 g/L

Figure 5.8 Standard molar volume. One mole of an ideal gas occupies 22.4 L at STP (0°C and 1 atm). At STP, helium, nitrogen, oxygen, and most other simple gases behave ideally. Note that the *mass* of a gas, and thus its density (d), depends on its molar mass.

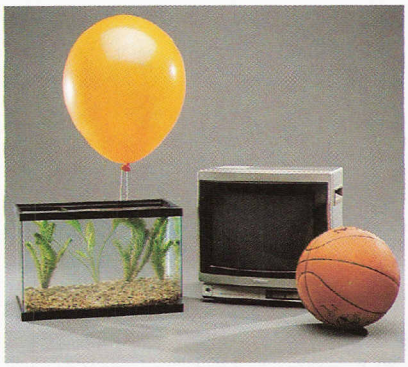


Figure 5.9 The volumes of 1 mol of an ideal gas and some familiar objects. A basketball (7.5 L), 5-gal fish tank (18.9 L), 13-in television (21.6 L), and 22.4 L of He gas in a balloon.

Figure 5.9 compares the volumes of some familiar objects with the standard molar volume of an ideal gas.

The Ideal Gas Law

Each of the gas laws focuses on the effect that changes in one variable have on gas volume:

- Boyle's law focuses on pressure ($V \propto 1/P$).
- Charles's law focuses on temperature ($V \propto T$).
- Avogadro's law focuses on amount (mol) of gas ($V \propto n$).

We can combine these individual effects into one relationship, called the **ideal gas law** (or *ideal gas equation*):

$$V \propto \frac{nT}{P} \quad \text{or} \quad PV \propto nT \quad \text{or} \quad \frac{PV}{nT} = R$$

where R is a proportionality constant known as the **universal gas constant.** Rearranging gives the most common form of the ideal gas law:

$$PV = nRT \tag{5.7}$$

We can obtain a value of R by measuring the volume, temperature, and pressure of a given amount of gas and substituting the values into the ideal gas law. For example, using standard conditions for the gas variables, we have

$$R = \frac{PV}{nT} = \frac{1 \text{ atm} \times 22.4141 \text{ L}}{1 \text{ mol} \times 273.15 \text{ K}} = 0.082058 \frac{\text{atm·L}}{\text{mol·K}} = 0.0821 \frac{\text{atm·L}}{\text{mol·K}} \quad [3 \text{ sf}] \tag{5.8}$$

This numerical value of R corresponds to the gas variables P, V, and T expressed *in these units*. R has a different numerical value when different units are used. For example, later in this chapter, R has the value 8.314 J/mol·K (J stands for joule, the SI unit of energy).

Figure 5.10 makes a central point: the ideal gas law *becomes* one of the individual gas laws when two of the four variables are kept constant. When initial conditions (subscript $_1$) change to final conditions (subscript $_2$), we have

$$P_1V_1 = n_1RT_1 \quad \text{and} \quad P_2V_2 = n_2RT_2$$

Thus,

$$\frac{P_1V_1}{n_1T_1} = R \quad \text{and} \quad \frac{P_2V_2}{n_2T_2} = R, \quad \text{so} \quad \frac{P_1V_1}{n_1T_1} = \frac{P_2V_2}{n_2T_2}$$

Notice that if two of the variables remain constant, say P and T, then $P_1 = P_2$ and $T_1 = T_2$, and we obtain an expression for Avogadro's law:

$$\frac{P_1V_1}{n_1T_1} = \frac{P_2V_2}{n_2T_2} \quad \text{or} \quad \frac{V_1}{n_1} = \frac{V_2}{n_2}$$

We use rearrangements of the ideal gas law such as this one to solve gas law problems, as you'll see next. The point to remember is that there is no need to memorize the individual gas laws.

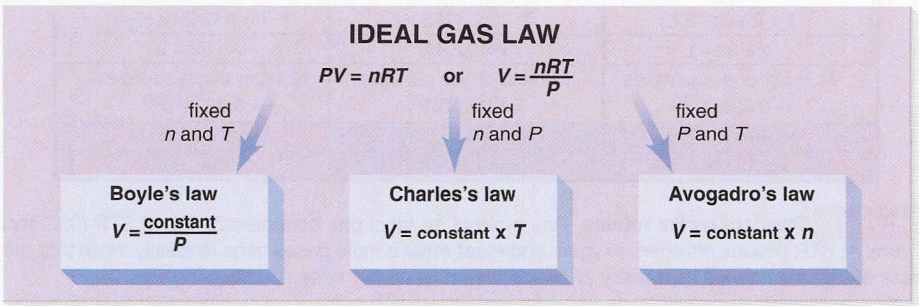

Figure 5.10 Relationship between the ideal gas law and the individual gas laws. Boyle's, Charles's, and Avogadro's laws are contained within the ideal gas law.

Solving Gas Law Problems

Animation: Properties of Gases
Online Learning Center

Gas law problems are phrased in many ways, but they can usually be grouped into two main types:

1. *A change in one of the four variables causes a change in another, while the two remaining variables remain constant.* In this type, the ideal gas law reduces to one of the individual gas laws, and you solve for the new value of the variable. Units must be consistent, T must always be in kelvins, but R is not involved. Sample Problems 5.2 to 5.4 and 5.6 are of this type. [A variation on this type involves the combined gas law (p. 186) for simultaneous changes in two of the variables that cause a change in a third.]

2. *One variable is unknown, but the other three are known and no change occurs.* In this type, exemplified by Sample Problem 5.5, the ideal gas law is applied directly to find the unknown, and the units must conform to those in R.

These problems are far easier to solve if you follow a systematic approach:

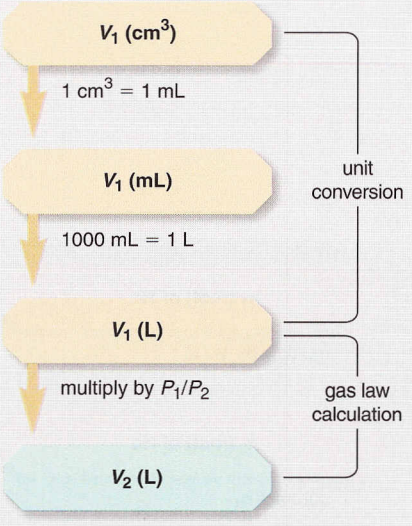
- Summarize the information: identify the changing gas variables—knowns and unknown—and those held constant.
- Predict the direction of the change, and later check your answer against the prediction.
- Perform any necessary unit conversions.
- Rearrange the ideal gas law to obtain the appropriate relationship of gas variables, and solve for the unknown variable.

The following series of sample problems applies the various gas behaviors.

SAMPLE PROBLEM 5.2 Applying the Volume-Pressure Relationship

Problem Boyle's apprentice finds that the air trapped in a J tube occupies 24.8 cm^3 at 1.12 atm. By adding mercury to the tube, he increases the pressure on the trapped air to 2.64 atm. Assuming constant temperature, what is the new volume of air (in L)?

Plan We must find the final volume (V_2) in liters, given the initial volume (V_1), initial pressure (P_1), and final pressure (P_2). The temperature and amount of gas are fixed. We convert the units of V_1 from cm^3 to mL and then to L, rearrange the ideal gas law to the appropriate form, and solve for V_2. We can predict the direction of the change: since P increases, V will decrease; thus, $V_2 < V_1$. (Note that the roadmap has two parts.)



Solution Summarizing the gas variables:

$P_1 = 1.12$ atm $\quad P_2 = 2.64$ atm

$V_1 = 24.8\ cm^3$ (convert to L) $\quad V_2 =$ unknown $\quad T$ and n remain constant

Converting V_1 from cm^3 to L:

$$V_1 = 24.8\ cm^3 \times \frac{1\ mL}{1\ cm^3} \times \frac{1\ L}{1000\ mL} = 0.0248\ L$$

Arranging the ideal gas law and solving for V_2: At fixed n and T, we have

$$\frac{P_1V_1}{\cancel{n_1T_1}} = \frac{P_2V_2}{\cancel{n_2T_2}} \quad \text{or} \quad P_1V_1 = P_2V_2$$

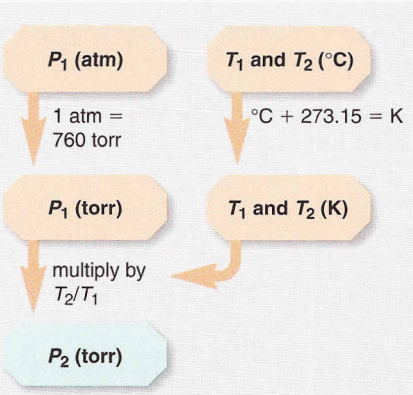
$$V_2 = V_1 \times \frac{P_1}{P_2} = 0.0248\ L \times \frac{1.12\ atm}{2.64\ atm} = 0.0105\ L$$

Check As we predicted, $V_2 < V_1$. Let's think about the relative values of P and V as we check the math. P more than doubled, so V_2 should be less than $\frac{1}{2}V_1$ ($0.0105/0.0248 < \frac{1}{2}$).

Comment Predicting the direction of the change provides another check on the problem setup: To make $V_2 < V_1$, we must multiply V_1 by a number *less than* 1. This means the ratio of pressures must be *less than* 1, so the larger pressure (P_2) must be in the denominator, P_1/P_2.

FOLLOW-UP PROBLEM 5.2 A sample of argon gas occupies 105 mL at 0.871 atm. If the temperature remains constant, what is the volume (in L) at 26.3 kPa?

SAMPLE PROBLEM 5.3 Applying the Pressure-Temperature Relationship



Problem A steel tank used for fuel delivery is fitted with a safety valve that opens if the internal pressure exceeds 1.00×10^3 torr. It is filled with methane at 23°C and 0.991 atm and placed in boiling water at exactly 100°C. Will the safety valve open?

Plan The question "Will the safety valve open?" translates into "Is P_2 greater than 1.00×10^3 torr at T_2?" Thus, P_2 is the unknown, and T_1, T_2, and P_1 are given, with V (steel tank) and n fixed. We convert both T values to kelvins and P_1 to torrs in order to compare P_2 with the safety-limit pressure. We rearrange the ideal gas law to the appropriate form and solve for P_2. Since $T_2 > T_1$, we predict that $P_2 > P_1$.

Solution Summary of gas variables:

$P_1 = 0.991$ atm (convert to torr) $\quad P_2 =$ unknown

$T_1 = 23$°C (convert to K) $\quad T_2 = 100$°C (convert to K)

V and n remain constant

Converting T from °C to K:

$$T_1\text{ (K)} = 23°\text{C} + 273.15 = 296\text{ K} \qquad T_2\text{ (K)} = 100°\text{C} + 273.15 = 373\text{ K}$$

Converting P from atm to torr:

$$P_1\text{ (torr)} = 0.991\text{ atm} \times \frac{760\text{ torr}}{1\text{ atm}} = 753\text{ torr}$$

Arranging the ideal gas law and solving for P_2: At fixed n and V, we have

$$\frac{P_1\cancel{V_1}}{\cancel{n_1}T_1} = \frac{P_2\cancel{V_2}}{\cancel{n_2}T_2} \quad \text{or} \quad \frac{P_1}{T_1} = \frac{P_2}{T_2}$$

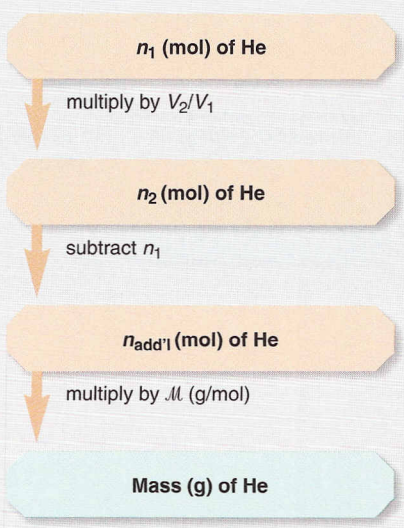
$$P_2 = P_1 \times \frac{T_2}{T_1} = 753\text{ torr} \times \frac{373\text{ K}}{296\text{ K}} = 949\text{ torr}$$

P_2 is less than 1.00×10^3 torr, so the valve will *not* open.

Check Our prediction is correct: because $T_2 > T_1$, we have $P_2 > P_1$. Thus, the temperature ratio should be >1 (T_2 in the numerator). The T ratio is about 1.25 (373/296), so the P ratio should also be about 1.25 (950/750 ≈ 1.25).

FOLLOW-UP PROBLEM 5.3 An engineer pumps air at 0°C into a newly designed piston-cylinder assembly. The volume measures 6.83 cm^3. At what temperature (in K) will the volume be 9.75 cm^3?

SAMPLE PROBLEM 5.4 Applying the Volume-Amount Relationship



Problem A scale model of a blimp rises when it is filled with helium to a volume of 55.0 dm^3. When 1.10 mol of He is added to the blimp, the volume is 26.2 dm^3. How many more grams of He must be added to make it rise? Assume constant T and P.

Plan We are given the initial amount of helium (n_1), the initial volume of the blimp (V_1), and the volume needed for it to rise (V_2), and we need the additional mass of helium to make it rise. So we first need to find n_2. We rearrange the ideal gas law to the appropriate form, solve for n_2, subtract n_1 to find the additional amount ($n_{add'l}$), and then convert moles to grams. We predict that $n_2 > n_1$ because $V_2 > V_1$.

Solution Summary of gas variables:

$n_1 = 1.10$ mol $\quad n_2 =$ unknown (find, and then subtract n_1)

$V_1 = 26.2\text{ dm}^3 \quad V_2 = 55.0\text{ dm}^3$

P and T remain constant

Arranging the ideal gas law and solving for n_2: At fixed P and T, we have

$$\frac{\cancel{P_1}V_1}{n_1\cancel{T_1}} = \frac{\cancel{P_2}V_2}{n_2\cancel{T_2}} \quad \text{or} \quad \frac{V_1}{n_1} = \frac{V_2}{n_2}$$

$$n_2 = n_1 \times \frac{V_2}{V_1} = 1.10\text{ mol He} \times \frac{55.0\text{ dm}^3}{26.2\text{ dm}^3} = 2.31\text{ mol He}$$

Finding the additional amount of He:

$$n_{add'l} = n_2 - n_1 = 2.31 \text{ mol He} - 1.10 \text{ mol He} = 1.21 \text{ mol He}$$

Converting moles of He to grams:

$$\text{Mass (g) of He} = 1.21 \text{ mol He} \times \frac{4.003 \text{ g He}}{1 \text{ mol He}}$$

$$= 4.84 \text{ g He}$$

Check Since V_2 is about twice V_1 (55/26 ≈ 2), n_2 should be about twice n_1 (2.3/1.1 ≈ 2). Since $n_2 > n_1$, we were right to multiply n_1 by a number >1 (that is, V_2/V_1). About 1.2 mol × 4 g/mol ≈ 4.8 g.

Comment **1.** A different sequence of steps will give you the same answer: first find the additional volume ($V_{add'l} = V_2 - V_1$), and then solve directly for $n_{add'l}$. Try it for yourself.

2. You saw that Charles's law ($V \propto T$ at fixed P and n) translates into a similar relationship between P and T at fixed V and n. The follow-up problem demonstrates that Avogadro's law ($V \propto n$ at fixed P and T) translates into an analogous relationship at fixed V and T.

FOLLOW-UP PROBLEM 5.4 A rigid plastic container holds 35.0 g of ethylene gas (C_2H_4) at a pressure of 793 torr. What is the pressure if 5.0 g of ethylene is removed at constant temperature?

SAMPLE PROBLEM 5.5 Solving for an Unknown Gas Variable at Fixed Conditions

Problem A steel tank has a volume of 438 L and is filled with 0.885 kg of O_2. Calculate the pressure of O_2 at 21°C.

Plan We are given V, T, and the mass of O_2, and we must find P. Since conditions are not changing, we apply the ideal gas law without rearranging it. We use the given V in liters, convert T to kelvins and mass of O_2 to moles, and solve for P.

Solution Summary of gas variables:

V = 438 L	T = 21°C (convert to K)
n = 0.885 kg O_2 (convert to mol)	P = unknown

Converting T from °C to K:

$$T \text{ (K)} = 21°C + 273.15 = 294 \text{ K}$$

Converting from mass of O_2 to moles:

$$n = \text{mol of } O_2 = 0.885 \text{ kg } O_2 \times \frac{1000 \text{ g}}{1 \text{ kg}} \times \frac{1 \text{ mol } O_2}{32.00 \text{ g } O_2} = 27.7 \text{ mol } O_2$$

Solving for P (note the unit canceling here):

$$P = \frac{nRT}{V} = \frac{27.7 \text{ mol} \times 0.0821 \dfrac{\text{atm·L}}{\text{mol·K}} \times 294 \text{ K}}{438 \text{ L}}$$

$$= 1.53 \text{ atm}$$

Check The amount of O_2 seems correct: ~900 g/(30 g/mol) = 30 mol. To check the approximate size of the final calculation, round off the values, including that for R:

$$P = \frac{30 \text{ mol } O_2 \times 0.1 \dfrac{\text{atm·L}}{\text{mol·K}} \times 300 \text{ K}}{450 \text{ L}} = 2 \text{ atm}$$

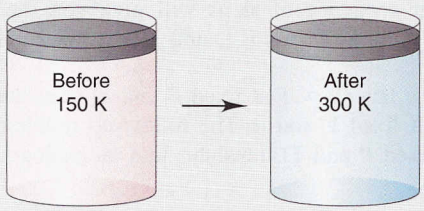
which is reasonably close to 1.53 atm.

FOLLOW-UP PROBLEM 5.5 The tank in the sample problem develops a slow leak that is discovered and sealed. The new measured pressure is 1.37 atm. How many grams of O_2 remain?

Finally, in a slightly different type of problem that depicts a simple laboratory scene, we apply the gas laws to determine the correct balanced equation for a process.

SAMPLE PROBLEM 5.6 Using Gas Laws to Determine a Balanced Equation

Problem The piston-cylinders below depict a gaseous reaction carried out at constant pressure. Before the reaction, the temperature is 150 K; when it is complete, the temperature is 300 K.



Which of the following balanced equations describes the reaction?

(1) $A_2 + B_2 \longrightarrow 2AB$ (2) $2AB + B_2 \longrightarrow 2AB_2$

(3) $A + B_2 \longrightarrow AB_2$ (4) $2AB_2 \longrightarrow A_2 + 2B_2$

Plan We are shown a depiction of a gaseous reaction and must choose the balanced equation. The problem says that P is constant, and the pictures show that T doubles and V stays the same. If n were also constant, the gas laws tell us that V should double when T doubles. Therefore, n cannot be constant, and the only way to maintain V with P constant and T doubling is for n to be halved. So we examine the four balanced equations and count the number of moles on each side to see in which equation n is halved.

Solution In equation (1), n does not change, so doubling T would double V.

In equation (2), n decreases from 3 mol to 2 mol, so doubling T would increase V by one-third.

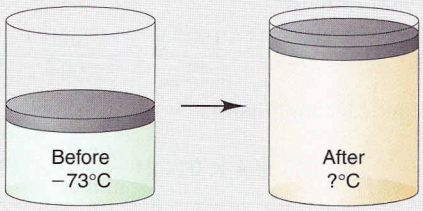
In equation (3), n decreases from 2 mol to 1 mol. Doubling T would exactly balance the decrease from halving n, so V would stay the same.

In equation (4), n increases, so doubling T would more than double V.

Equation (3) is correct:

$$A + B_2 \longrightarrow AB_2$$

FOLLOW-UP PROBLEM 5.6 The gaseous reaction depicted below is carried out at constant pressure and an initial temperature of −73°C:



The *unbalanced* equation is $CD \longrightarrow C_2 + D_2$. What is the final temperature (in °C)?

SECTION SUMMARY

Four variables define the physical behavior of an ideal gas: volume (V), pressure (P), temperature (T), and amount (number of moles, n). Most simple gases display nearly ideal behavior at ordinary temperatures and pressures. Boyle's, Charles's, and Avogadro's laws relate volume to pressure, to temperature, and to amount of gas, respectively. At STP (0°C and 1 atm), 1 mol of an ideal gas occupies 22.4 L. The ideal gas law incorporates the individual gas laws into one equation: $PV = nRT$, where R is the universal gas constant.

5.4 FURTHER APPLICATIONS OF THE IDEAL GAS LAW

The ideal gas law can be recast in additional ways to determine other properties of gases. In this section, we use it to find gas density, molar mass, and the partial pressure of each gas in a mixture.

The Density of a Gas

One mole of any gas occupies nearly the same volume at a given temperature and pressure, so differences in gas density ($d = m/V$) depend on differences in molar mass (see Figure 5.8). For example, at STP, 1 mol of O_2 occupies the same volume as 1 mol of N_2, but since each O_2 molecule has a greater mass than each N_2 molecule, O_2 is denser.

All gases are miscible when thoroughly mixed, but in the absence of mixing, a less dense gas will lie above a more dense one. There are many familiar examples of this phenomenon. Some types of fire extinguishers release CO_2 because it is denser than air and will sink onto the fire, preventing more O_2 from reaching the burning material. Enormous air masses of different densities and temperatures moving past each other around the globe give rise to much of our weather.

We can rearrange the ideal gas law to calculate the density of a gas from its molar mass. Recall that the number of moles (n) is the mass (m) divided by the molar mass ($\mathcal{M}$), $n = m/\mathcal{M}$. Substituting for n in the ideal gas law gives

$$PV = \frac{m}{\mathcal{M}}RT$$

Rearranging to isolate m/V gives

$$\frac{m}{V} = d = \frac{\mathcal{M} \times P}{RT} \qquad (5.9)$$

Two important ideas are expressed by Equation 5.9:

- *The density of a gas is directly proportional to its molar mass* because a given amount of a heavier gas occupies the same volume as that amount of a lighter gas (Avogadro's law).
- *The density of a gas is inversely proportional to the temperature.* As the volume of a gas increases with temperature (Charles's law), the same mass occupies more space; thus, the density is lower.

Architectural designers and heating engineers apply the second idea when they place heating ducts near the floor of a room: the less dense warm air from the ducts rises and heats the room air. Safety experts recommend staying near the floor when escaping from a fire to avoid the hot, and therefore less dense, noxious gases. We use Equation 5.9 to find the density of a gas at any temperature and pressure near standard conditions.

Gas Density and Human Disasters Many gases that are denser than air have been involved in natural and human-caused disasters. The dense gases in smog that blanket urban centers, such as Los Angeles (see photo), contribute greatly to respiratory illness. On a far more horrific scale, in World War I, phosgene ($COCl_2$) was used against ground troops as they lay in trenches. More recently, the unintentional release of methylisocyanate from a Union Carbide India Ltd. chemical plant in Bhopal, India, killed thousands of people as vapors spread from the outskirts into the city. In 1986 in Cameroon, CO_2 released naturally from Lake Nyos suffocated thousands as it flowed down valleys into villages. Some paleontologists suggest that a similar process in volcanic lakes may have contributed to dinosaur kills.

SAMPLE PROBLEM 5.7 Calculating Gas Density

Problem To apply a green chemistry approach, a chemical engineer uses waste CO_2 from a manufacturing process, instead of chlorofluorocarbons, as a "blowing agent" in the production of polystyrene containers. Find the density (in g/L) of CO_2 and the number of molecules per liter **(a)** at STP (0°C and 1 atm) and **(b)** at room conditions (20.°C and 1.00 atm).

Plan We must find the density (d) and number of molecules of CO_2, given the two sets of P and T data. We find $\mathcal{M}$, convert T to kelvins, and calculate d with Equation 5.9. Then we convert the mass per liter to molecules per liter with Avogadro's number.

Solution **(a)** Density and molecules per liter of CO_2 at STP. Summary of gas properties:

$$T = 0°C + 273.15 = 273\ K \qquad P = 1\ atm \qquad \mathcal{M}\ of\ CO_2 = 44.01\ g/mol$$

Calculating density (note the unit canceling here):

$$d = \frac{\mathcal{M} \times P}{RT} = \frac{44.01\ g/\cancel{mol} \times 1.00\ \cancel{atm}}{0.0821\ \frac{\cancel{atm}\cdot L}{\cancel{mol}\cdot\cancel{K}} \times 273\ \cancel{K}} = 1.96\ g/L$$

Converting from mass/L to molecules/L:

$$\text{Molecules } CO_2/L = \frac{1.96\ g\ CO_2}{1\ L} \times \frac{1\ mol\ CO_2}{44.01\ g\ CO_2} \times \frac{6.022\times10^{23}\ \text{molecules } CO_2}{1\ mol\ CO_2}$$
$$= 2.68\times10^{22}\ \text{molecules } CO_2/L$$

(b) Density and molecules of CO_2 per liter at room conditions. Summary of gas properties:

$$T = 20.°C + 273.15 = 293\ K \qquad P = 1.00\ atm \qquad \mathcal{M}\ of\ CO_2 = 44.01\ g/mol$$

Calculating density:

$$d = \frac{\mathcal{M} \times P}{RT} = \frac{44.01\ g/mol \times 1.00\ atm}{0.0821\ \frac{atm\cdot L}{mol\cdot K} \times 293\ K} = 1.83\ g/L$$

Converting from mass/L to molecules/L:

$$\text{Molecules } CO_2/L = \frac{1.83\ g\ CO_2}{1\ L} \times \frac{1\ mol\ CO_2}{44.01\ g\ CO_2} \times \frac{6.022\times10^{23}\ \text{molecules } CO_2}{1\ mol\ CO_2}$$
$$= 2.50\times10^{22}\ \text{molecules } CO_2/L$$

Check Round off to check the density values; for example, in (a), at STP:

$$\frac{50\ g/mol \times 1\ atm}{0.1\ \frac{atm\cdot L}{mol\cdot K} \times 250\ K} = 2\ g/L \approx 1.96\ g/L$$

At the higher temperature in (b), the density should decrease, which can happen only if there are fewer molecules per liter, so the answer is reasonable.

Comment **1.** An *alternative approach* for finding the density of most simple gases, but *at STP only,* is to divide the molar mass by the standard molar volume, 22.4 L:

$$d = \frac{\mathcal{M}}{V} = \frac{44.01\ g/mol}{22.4\ L/mol} = 1.96\ g/L$$

Then, since you know the density at one temperature (0°C), you can find it at any other temperature with the following relationship: $d_1/d_2 = T_2/T_1$.

2. Note that we have different numbers of significant figures for the pressure values. In (a), "1 atm" is part of the definition of STP, so it is an exact number. In (b), we specified "1.00 atm" to allow three significant figures in the answer.

3. Hot-air balloonists have always applied the change in density with temperature.

FOLLOW-UP PROBLEM 5.7 Compare the density of CO_2 at 0°C and 380 torr with its density at STP.

Up, Up, and Away! When the gas in a hot-air balloon is heated, its volume increases and the balloon inflates. Further heating causes some of the gas to escape. By these means, the gas density decreases and the balloon rises. Two pioneering hot-air balloonists used their knowledge of gas behavior to excel at their hobby. Jacques Charles (of Charles's law) made one of the first balloon flights in 1783. Twenty years later, Joseph Gay-Lussac (who studied the pressure-temperature relationship) set a solo altitude record that held for 50 years.

The Molar Mass of a Gas

Through another simple rearrangement of the ideal gas law, we can determine the molar mass of an unknown gas or volatile liquid (one that is easily vaporized):

$$n = \frac{m}{\mathcal{M}} = \frac{PV}{RT} \quad \text{so} \quad \mathcal{M} = \frac{mRT}{PV} \quad \text{or} \quad \mathcal{M} = \frac{dRT}{P} \qquad (5.10)$$

Notice that this equation is just a rearrangement of Equation 5.9.

The French chemist J. B. A. Dumas (1800–1884) pioneered an ingenious method for finding the molar mass of a volatile liquid. Figure 5.11 shows the apparatus. Place a small volume of the liquid in a preweighed flask of known volume. Close the flask with a stopper that contains a narrow tube and immerse it

in a water bath whose fixed temperature exceeds the liquid's boiling point. As the liquid vaporizes, the gas fills the flask and some flows out the tube. When the liquid is gone, the pressure of the gas filling the flask equals the atmospheric pressure. Remove the flask from the water bath and cool it, and the gas condenses to a liquid. Reweigh the flask to obtain the mass of the liquid, *which equals the mass of gas* that remained in the flask.

By this procedure, you have directly measured all the variables needed to calculate the molar mass of the gas: the mass of gas (m) occupies the flask volume (V) at a pressure (P) equal to the barometric pressure and at the temperature (T) of the water bath.

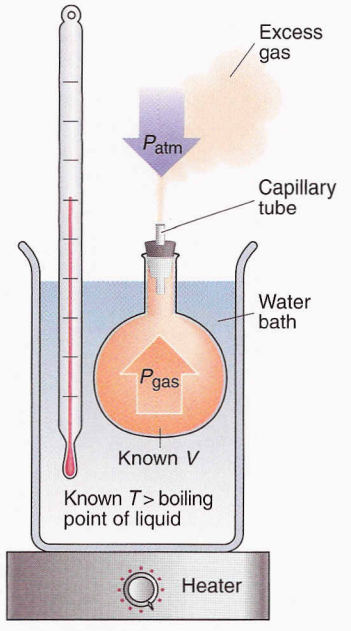


Figure 5.11 Determining the molar mass of an unknown volatile liquid. A small amount of unknown liquid is vaporized, and the gas fills the flask of known volume at the known temperature of the bath. Excess gas escapes through the capillary tube until $P_{gas} = P_{atm}$. When the flask is cooled, the gas condenses, the liquid is weighed, and the ideal gas law is used to calculate $\mathcal{M}$ (see text).

SAMPLE PROBLEM 5.8 Finding the Molar Mass of a Volatile Liquid

Problem An organic chemist isolates a colorless liquid from a petroleum sample. She uses the Dumas method and obtains the following data:

Volume (V) of flask = 213 mL T = 100.0°C P = 754 torr
Mass of flask + gas = 78.416 g Mass of flask = 77.834 g

Calculate the molar mass of the liquid.

Plan We are given V, T, P, and mass data and must find the molar mass ($\mathcal{M}$) of the liquid. We convert V to liters, T to kelvins, and P to atmospheres, find the mass of gas by subtracting the mass of the empty flask, and use Equation 5.10 to solve for $\mathcal{M}$.

Solution Summary of gas variables:

$$m = 78.416\text{ g} - 77.834\text{ g} = 0.582\text{ g} \qquad P\text{ (atm)} = 754\text{ torr} \times \frac{1\text{ atm}}{760\text{ torr}} = 0.992\text{ atm}$$

$$V\text{ (L)} = 213\text{ mL} \times \frac{1\text{ L}}{1000\text{ mL}} = 0.213\text{ L} \qquad T\text{ (K)} = 100.0°\text{C} + 273.15 = 373.2\text{ K}$$

Solving for $\mathcal{M}$:

$$\mathcal{M} = \frac{mRT}{PV} = \frac{0.582\text{ g} \times 0.0821\dfrac{\text{atm·L}}{\text{mol·K}} \times 373.2\text{ K}}{0.992\text{ atm} \times 0.213\text{ L}} = 84.4\text{ g/mol}$$

Check Rounding to check the arithmetic, we have

$$\frac{0.6\text{ g} \times 0.08\dfrac{\text{atm·L}}{\text{mol·K}} \times 375\text{ K}}{1\text{ atm} \times 0.2\text{ L}} = 90\text{ g/mol}$$ which is close to 84.4 g/mol

FOLLOW-UP PROBLEM 5.8 At 10.0°C and 102.5 kPa, the density of dry air is 1.26 g/L. What is the average "molar mass" of dry air at these conditions?

The Partial Pressure of a Gas in a Mixture of Gases

All of the behaviors we've discussed so far were observed from experiments with air, which is a complex mixture of gases. The ideal gas law holds for virtually any gas, whether pure or a mixture, at ordinary conditions for two reasons:

- Gases mix homogeneously (form a solution) in any proportions.
- Each gas in a mixture behaves as if it were the only gas present (assuming no chemical interactions).

Dalton's Law of Partial Pressures The second point above was discovered by John Dalton in his studies of humidity. He observed that when water vapor is added to dry air, the total air pressure increases by an increment equal to the pressure of the water vapor:

$$P_{\text{humid air}} = P_{\text{dry air}} + P_{\text{added water vapor}}$$

In other words, each gas in the mixture exerts a **partial pressure,** a portion of the total pressure of the mixture, that is the same as the pressure it would exert

by itself. This observation is formulated as **Dalton's law of partial pressures:** *in a mixture of unreacting gases, the total pressure is the sum of the partial pressures of the individual gases:*

$$P_{total} = P_1 + P_2 + P_3 + \cdots \tag{5.11}$$

As an example, suppose you have a tank of fixed volume that contains nitrogen gas at a certain pressure, and you introduce a sample of hydrogen gas into the tank. Each gas behaves independently, so we can write an ideal gas law expression for each:

$$P_{N_2} = \frac{n_{N_2}RT}{V} \quad \text{and} \quad P_{H_2} = \frac{n_{H_2}RT}{V}$$

Because each gas occupies the same total volume and is at the same temperature, the pressure of each gas depends only on its amount, n. Thus, the total pressure is

$$P_{total} = P_{N_2} + P_{H_2} = \frac{n_{N_2}RT}{V} + \frac{n_{H_2}RT}{V} = \frac{(n_{N_2} + n_{H_2})RT}{V} = \frac{n_{total}RT}{V}$$

where $n_{total} = n_{N_2} + n_{H_2}$.

Each component in a mixture contributes a fraction of the total number of moles in the mixture, which is the **mole fraction** (X) of that component. Multiplying X by 100 gives the mole percent. Keep in mind that the sum of the mole fractions of all components in any mixture must be 1, and the sum of the mole percents must be 100%. For N_2, the mole fraction is

$$X_{N_2} = \frac{n_{N_2}}{n_{total}} = \frac{n_{N_2}}{n_{N_2} + n_{H_2}}$$

Since the total pressure is due to the total number of moles, the partial pressure of gas A is the total pressure multiplied by the mole fraction of A, X_A:

$$P_A = X_A \times P_{total} \tag{5.12}$$

Equation 5.12 is a very important result. To see that it is valid for the mixture of N_2 and H_2, we recall that $X_{N_2} + X_{H_2} = 1$ and obtain

$$P_{total} = P_{N_2} + P_{H_2} = (X_{N_2} \times P_{total}) + (X_{H_2} \times P_{total}) = (X_{N_2} + X_{H_2})P_{total} = 1 \times P_{total}$$

SAMPLE PROBLEM 5.9 Applying Dalton's Law of Partial Pressures

Problem In a study of O_2 uptake by muscle at high altitude, a physiologist prepares an atmosphere consisting of 79 mole % N_2, 17 mole % $^{16}O_2$, and 4.0 mole % $^{18}O_2$. (The isotope ^{18}O will be measured to determine O_2 uptake.) The total pressure is 0.75 atm to simulate high altitude. Calculate the mole fraction and partial pressure of $^{18}O_2$ in the mixture.

Plan We must find $X_{^{18}O_2}$ and $P_{^{18}O_2}$ from P_{total} (0.75 atm) and the mole % of $^{18}O_2$ (4.0). Dividing the mole % by 100 gives the mole fraction, $X_{^{18}O_2}$. Then, using Equation 5.12, we multiply $X_{^{18}O_2}$ by P_{total} to find $P_{^{18}O_2}$.

Mole % of $^{18}O_2$
↓ divide by 100
Mole fraction, $X_{^{18}O_2}$
↓ multiply by P_{total}
Partial pressure, $P_{^{18}O_2}$

Solution Calculating the mole fraction of $^{18}O_2$:

$$X_{^{18}O_2} = \frac{4.0 \text{ mol \% } ^{18}O_2}{100} = 0.040$$

Solving for the partial pressure of $^{18}O_2$:

$$P_{^{18}O_2} = X_{^{18}O_2} \times P_{total} = 0.040 \times 0.75 \text{ atm} = 0.030 \text{ atm}$$

Check $X_{^{18}O_2}$ is small because the mole % is small, so $P_{^{18}O_2}$ should be small also.

Comment At high altitudes, specialized brain cells that are sensitive to O_2 and CO_2 levels in the blood trigger an increase in rate and depth of breathing for several days, until a person becomes acclimated.

FOLLOW-UP PROBLEM 5.9 To prevent the presence of air, noble gases are placed over highly reactive chemicals to act as inert "blanketing" gases. A chemical engineer places a mixture of noble gases consisting of 5.50 g of He, 15.0 g of Ne, and 35.0 g of Kr in a piston-cylinder assembly at STP. Calculate the partial pressure of each gas.

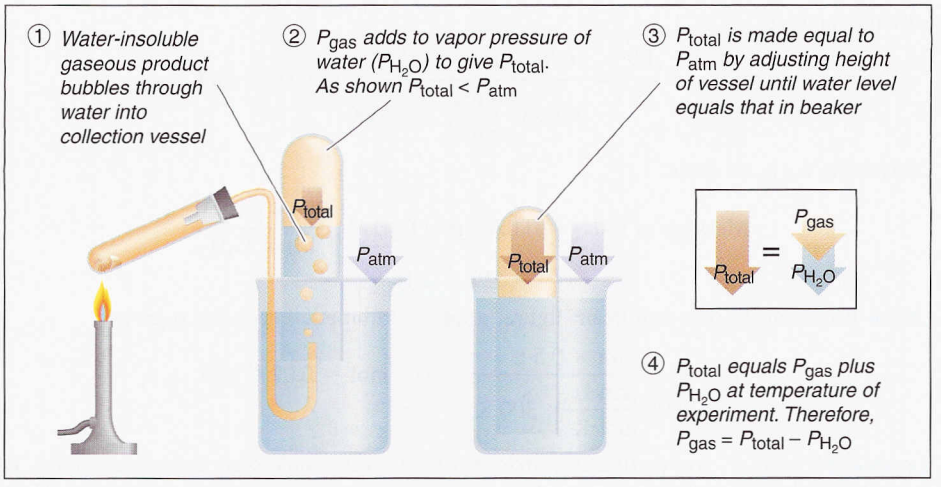

Figure 5.12 Collecting a water-insoluble gaseous product and determining its pressure.

40	55.3
45	71.9
50	92.5
55	118.0
60	149.4
65	187.5
70	233.7
75	289.1
80	355.1
85	433.6
90	525.8
95	633.9
100	760.0

Collecting a Gas over Water The law of partial pressures is frequently used to determine the yield of a water-insoluble gas formed in a reaction. The gaseous product bubbles through water and is collected into an inverted container, as shown in Figure 5.12. The water vapor that mixes with the gas contributes a portion of the total pressure, called the *vapor pressure,* which depends only on the water temperature.

In order to determine the yield of gaseous product, we find the appropriate vapor pressure value from a list, such as the one in Table 5.3, and subtract it from the total gas pressure (corrected to barometric pressure) to get the partial pressure of the gaseous product. With V and T known, we can calculate the amount of product.

SAMPLE PROBLEM 5.10 Calculating the Amount of Gas Collected over Water

Problem Acetylene (C_2H_2), an important fuel in welding, is produced in the laboratory when calcium carbide (CaC_2) reacts with water:

$$CaC_2(s) + 2H_2O(l) \longrightarrow C_2H_2(g) + Ca(OH)_2(aq)$$

For a sample of acetylene collected over water, total gas pressure (adjusted to barometric pressure) is 738 torr and the volume is 523 mL. At the temperature of the gas (23°C), the vapor pressure of water is 21 torr. How many grams of acetylene are collected?

Plan In order to find the mass of C_2H_2, we first need to find the number of moles of C_2H_2, $n_{C_2H_2}$, which we can obtain from the ideal gas law by calculating $P_{C_2H_2}$. The barometer reading gives us P_{total}, which is the sum of $P_{C_2H_2}$ and P_{H_2O}, and we are given P_{H_2O}, so we subtract to find $P_{C_2H_2}$. We are also given V and T, so we convert to consistent units, and find $n_{C_2H_2}$ from the ideal gas law. Then we convert moles to grams using the molar mass from the formula.

Solution Summary of gas variables:

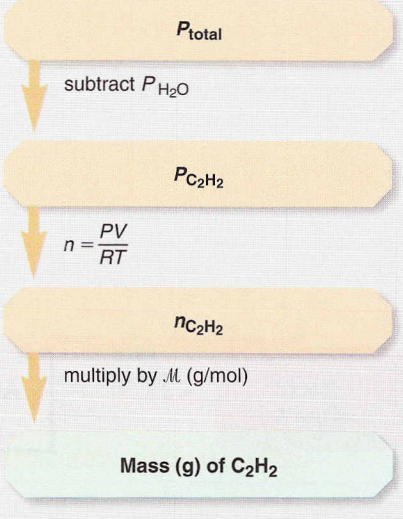
$$P_{C_2H_2}\,(\text{torr}) = P_{total} - P_{H_2O} = 738\text{ torr} - 21\text{ torr} = 717\text{ torr}$$

$$P_{C_2H_2}\,(\text{atm}) = 717\text{ torr} \times \frac{1\text{ atm}}{760\text{ torr}} = 0.943\text{ atm}$$

$$V\,(\text{L}) = 523\text{ mL} \times \frac{1\text{ L}}{1000\text{ mL}} = 0.523\text{ L}$$

$$T\,(\text{K}) = 23°\text{C} + 273.15 = 296\text{ K}$$

$$n_{C_2H_2} = \text{unknown}$$



Solving for $n_{C_2H_2}$:

$$n_{C_2H_2} = \frac{PV}{RT} = \frac{0.943 \text{ atm} \times 0.523 \text{ L}}{0.0821 \dfrac{\text{atm·L}}{\text{mol·K}} \times 296 \text{ K}} = 0.0203 \text{ mol}$$

Converting $n_{C_2H_2}$ to mass:

$$\text{Mass (g) of } C_2H_2 = 0.0203 \text{ mol } C_2H_2 \times \frac{26.04 \text{ g } C_2H_2}{1 \text{ mol } C_2H_2}$$

$$= 0.529 \text{ g } C_2H_2$$

Check Rounding to one significant figure, a quick arithmetic check for n gives

$$n \approx \frac{1 \text{ atm} \times 0.5 \text{ L}}{0.08 \dfrac{\text{atm·L}}{\text{mol·K}} \times 300 \text{ K}} = 0.02 \text{ mol} \approx 0.0203 \text{ mol}$$

Comment The C_2^{2-} ion (called the *carbide*, or *acetylide, ion*) is an interesting anion. It is simply $^-C{\equiv}C^-$, which acts as a base in water, removing an H^+ ion from two H_2O molecules to form acetylene, H—C≡C—H.

FOLLOW-UP PROBLEM 5.10 A small piece of zinc reacts with dilute HCl to form H_2, which is collected over water at 16°C into a large flask. The total pressure is adjusted to barometric pressure (752 torr), and the volume is 1495 mL. Use Table 5.3 to help calculate the partial pressure and mass of H_2.

Online Learning Center

SECTION SUMMARY

The ideal gas law can be rearranged to calculate the density and molar mass of a gas. In a mixture of gases, each component contributes its own partial pressure to the total pressure (Dalton's law of partial pressures). The mole fraction of each component is the ratio of its partial pressure to the total pressure. When a gas is in contact with water, the total pressure is the sum of the gas pressure and the vapor pressure of water at the given temperature.

5.5 THE IDEAL GAS LAW AND REACTION STOICHIOMETRY

In Chapters 3 and 4, we encountered many reactions that involved gases as reactants (e.g., combustion with O_2) or as products (e.g., acid treatment of a carbonate). From the balanced equation, we used stoichiometrically equivalent molar ratios to calculate the amounts (moles) of reactants and products and converted these quantities into masses, numbers of molecules, or solution volumes (see Figures 3.12, p. 117, and 3.15, p. 122). Figure 5.13 shows how you can expand your problem-solving repertoire by using the ideal gas law to convert between gas variables (P, T, and V) and amounts (moles) of gaseous reactants and products. In effect, you combine a gas law problem with a stoichiometry problem; it is more realistic to measure the volume, pressure, and temperature of a gas than its mass.

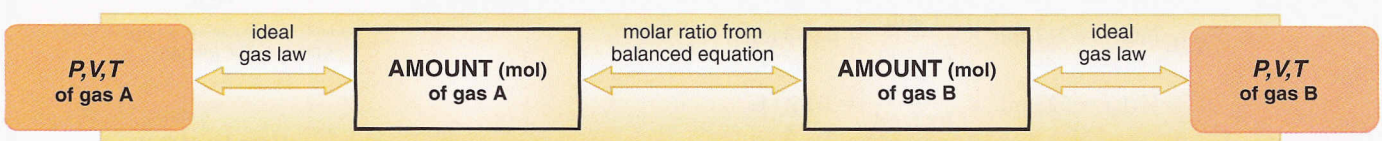

Figure 5.13 **Summary of the stoichiometric relationships among the amount (mol, *n*) of gaseous reactant or product and the gas variables pressure (*P*), volume (*V*), and temperature (*T*).**

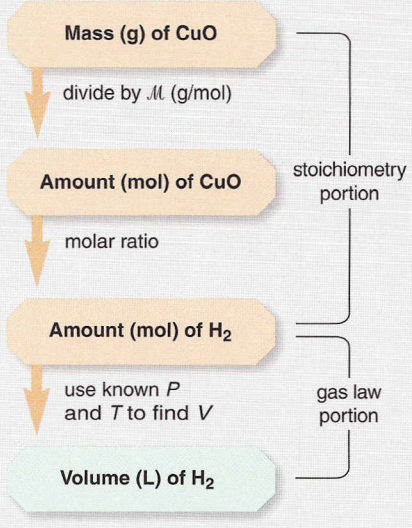
SAMPLE PROBLEM 5.11 Using Gas Variables to Find Amounts of Reactants or Products

Problem Copper dispersed in absorbent beds is used to react with oxygen impurities in the ethylene used for producing polyethylene. The beds are regenerated when hot H_2 reduces the metal oxide, forming the pure metal and H_2O. On a laboratory scale, what volume of H_2 at 765 torr and 225°C is needed to reduce 35.5 g of copper(II) oxide?

Plan This is a stoichiometry *and* gas law problem. To find V_{H_2}, we first need n_{H_2}. We write and balance the equation. Next, we convert the given mass of CuO (35.5 g) to amount (mol) and use the molar ratio to find moles of H_2 needed (stoichiometry portion). Then, we use the ideal gas law to convert moles of H_2 to liters (gas law portion). A roadmap is shown, but you are familiar with all the steps.



Solution Writing the balanced equation:

$$CuO(s) + H_2(g) \longrightarrow Cu(s) + H_2O(g)$$

Calculating n_{H_2}:

$$n_{H_2} = 35.5 \text{ g CuO} \times \frac{1 \text{ mol CuO}}{79.55 \text{ g CuO}} \times \frac{1 \text{ mol } H_2}{1 \text{ mol CuO}} = 0.446 \text{ mol } H_2$$

Summary of other gas variables:

$$V = \text{unknown} \qquad P \text{ (atm)} = 765 \text{ torr} \times \frac{1 \text{ atm}}{760 \text{ torr}} = 1.01 \text{ atm}$$

$$T \text{ (K)} = 225°C + 273.15 = 498 \text{ K}$$

Solving for V_{H_2}:

$$V = \frac{nRT}{P} = \frac{0.446 \text{ mol} \times 0.0821 \dfrac{\text{atm·L}}{\text{mol·K}} \times 498 \text{ K}}{1.01 \text{ atm}} = 18.1 \text{ L}$$

Check One way to check the answer is to compare it with the molar volume of an ideal gas at STP (22.4 L at 273.15 K and 1 atm). One mole of H_2 at STP occupies about 22 L, so less than 0.5 mol occupies less than 11 L. T is less than twice 273 K, so V should be less than twice 11 L. In this case, the decrease in n and the increase in T nearly cancel each other.

Comment The main point here is that the stoichiometry provides one gas variable (n), two more are given, and the ideal gas law is used to find the fourth.

FOLLOW-UP PROBLEM 5.11 Sulfuric acid reacts with sodium chloride to form aqueous sodium sulfate and hydrogen chloride gas. How many milliliters of gas form at STP when 0.117 kg of sodium chloride reacts with excess sulfuric acid?

SAMPLE PROBLEM 5.12 Using the Ideal Gas Law in a Limiting-Reactant Problem

Problem The alkali metals [Group 1A(1)] react with the halogens [Group 7A(17)] to form ionic metal halides. What mass of potassium chloride forms when 5.25 L of chlorine gas at 0.950 atm and 293 K reacts with 17.0 g of potassium (see photo)?

Plan The only difference between this and previous limiting-reactant problems (see Sample Problem 3.11, p. 113) is that here we use the ideal gas law to find the amount (n) of gaseous reactant from the known V, P, and T. We first write the balanced equation and then use it to find the limiting reactant and the amount of product.

Solution Writing the balanced equation:

$$2K(s) + Cl_2(g) \longrightarrow 2KCl(s)$$

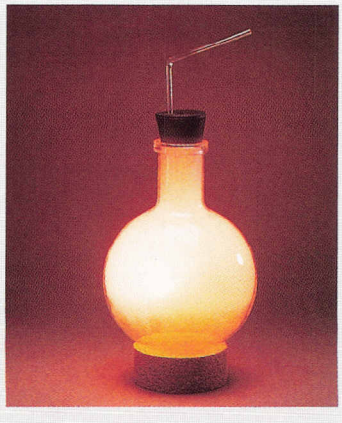
Summary of gas variables:

$$P = 0.950 \text{ atm} \qquad V = 5.25 \text{ L}$$

$$T = 293 \text{ K} \qquad n = \text{unknown}$$

Solving for n_{Cl_2}:

$$n_{Cl_2} = \frac{PV}{RT} = \frac{0.950 \text{ atm} \times 5.25 \text{ L}}{0.0821 \dfrac{\text{atm·L}}{\text{mol·K}} \times 293 \text{ K}} = 0.207 \text{ mol}$$



Chlorine gas reacting with potassium.

Converting from grams of potassium (K) to moles:

$$\text{Moles of K} = 17.0 \text{ g K} \times \frac{1 \text{ mol K}}{39.10 \text{ g K}} = 0.435 \text{ mol K}$$

Determining the limiting reactant: If Cl_2 is limiting,

$$\text{Moles of KCl} = 0.207 \text{ mol } Cl_2 \times \frac{2 \text{ mol KCl}}{1 \text{ mol } Cl_2} = 0.414 \text{ mol KCl}$$

If K is limiting,

$$\text{Moles of KCl} = 0.435 \text{ mol K} \times \frac{2 \text{ mol KCl}}{2 \text{ mol K}} = 0.435 \text{ mol KCl}$$

Cl_2 is the limiting reactant because it forms less KCl.
Converting from moles of KCl to grams:

$$\text{Mass (g) of KCl} = 0.414 \text{ mol KCl} \times \frac{74.55 \text{ g KCl}}{1 \text{ mol KCl}} = 30.9 \text{ g KCl}$$

Check The gas law calculation seems correct. At STP, 22 L of Cl_2 gas contains about 1 mol, so a 5-L volume would contain a bit less than 0.25 mol of Cl_2. Moreover, since P (in numerator) is slightly lower than STP and T (in denominator) is slightly higher, these should lower the calculated n further below the ideal value. The mass of KCl seems correct: less than 0.5 mol of KCl gives $<0.5 \times \mathcal{M}$ (30.9 g $< 0.5 \times 75$ g).

FOLLOW-UP PROBLEM 5.12 Ammonia and hydrogen chloride gases react to form solid ammonium chloride. A 10.0-L reaction flask contains ammonia at 0.452 atm and 22°C, and 155 mL of hydrogen chloride gas at 7.50 atm and 271 K is introduced. After the reaction occurs and the temperature returns to 22°C, what is the pressure inside the flask? (Neglect the volume of the solid product.)

SECTION SUMMARY

By expressing the amount (mol) of gaseous reactant or product in terms of the other gas variables, we can solve stoichiometry problems for reactions involving gases.

5.6 THE KINETIC-MOLECULAR THEORY: A MODEL FOR GAS BEHAVIOR

So far we have discussed observations of macroscopic samples of gas: decreasing cylinder volume, increasing tank pressure, and so forth. This section presents the central model that explains macroscopic gas behavior at the level of individual particles: the **kinetic-molecular theory.** The theory draws conclusions through mathematical derivations, but here our discussion will be largely qualitative.

How the Kinetic-Molecular Theory Explains the Gas Laws

Developed by some of the great scientists of the 19th century, most notably James Clerk Maxwell and Ludwig Boltzmann, the kinetic-molecular theory was able to explain the gas laws that some of the great scientists of the century before had arrived at empirically.

Questions Concerning Gas Behavior To model gas behavior, we must rationalize certain questions at the molecular level:

1. *Origin of pressure.* Pressure is a measure of the force a gas exerts on a surface. How do individual gas particles create this force?
2. *Boyle's law.* A change in gas pressure in one direction causes a change in gas volume in the other. What happens to the particles when external pressure compresses the gas volume? And why aren't liquids and solids compressible?

3. *Dalton's law.* The pressure of a gas mixture is the sum of the pressures of the individual gases. Why does each gas contribute to the total pressure in proportion to its mole fraction?
4. *Charles's law.* A change in temperature is accompanied by a corresponding change in volume. What effect does higher temperature have on gas particles that increases the volume—or increases the pressure if volume is fixed? This question raises a more fundamental one: what does temperature measure on the molecular scale?
5. *Avogadro's law.* Gas volume (or pressure) depends on the number of moles present, not on the nature of the particular gas. But shouldn't 1 mol of larger molecules occupy more space than 1 mol of smaller molecules? And why doesn't 1 mol of heavier molecules exert more pressure than 1 mol of lighter molecules?

Postulates of the Kinetic-Molecular Theory The theory is based on three postulates (assumptions):

Postulate 1. *Particle volume.* A gas consists of a large collection of individual particles. The volume of an individual particle is *extremely* small compared with the volume of the container. In essence, the model pictures gas particles as having mass but no volume.

Postulate 2. *Particle motion.* Gas particles are in constant, random, straight-line motion, except when they collide with the container walls or with each other.

Postulate 3. *Particle collisions.* Collisions are *elastic,* which means that, somewhat like minute billiard balls, the colliding molecules exchange energy but they do not lose any energy through friction. Thus, their total kinetic energy (E_k) is constant. Between collisions, the molecules do not influence each other at all.

Picture the scene envisioned by the postulates: Countless particles moving in every direction, smashing into the container walls and one another. Any given particle changes its speed with each collision, perhaps one instant standing nearly still from a head-on crash and the next instant zooming away from a smash on the side. Thus, *the particles have an average speed*, with most moving near the average speed, some moving faster, and some slower.

Figure 5.14 depicts the distribution of molecular speeds (u) for N_2 gas at three temperatures. The curves flatten and spread at higher temperatures. Note especially that the *most probable speed (the peak of each curve) increases as the temperature increases*. This increase occurs because the average kinetic energy of the molecules ($\overline{E_k}$: the overbar indicates the average value of a quantity), which incorporates the most probable speed, is proportional to the absolute temperature: $\overline{E_k} \propto T$, or $\overline{E_k} = c \times T$, where c is a constant that is the same for any gas. (We'll return to this equation shortly.) Thus, a major conclusion based on the distribution of speeds, which arises directly from postulate 3, is that *at a given temperature, all gases have the same average kinetic energy.*

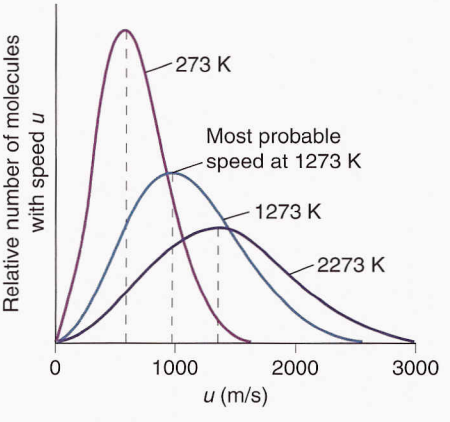


Figure 5.14 Distribution of molecular speeds at three temperatures. At a given temperature, a plot of the relative number of N_2 molecules vs. molecular speed (u) results in a skewed bell-shaped curve, with the most probable speed at the peak. Note that the curves spread at higher temperatures and the most probable speed is directly proportional to the temperature.

A Molecular View of the Gas Laws Let's continue visualizing the particles to see how the theory explains the macroscopic behavior of gases and answers the questions posed above:

1. *Origin of pressure.* When a moving object collides with a surface, it exerts a force. We conclude from postulate 2, which describes particle motion, that when a particle collides with the container wall, it too exerts a force. Many such collisions result in the observed pressure. The greater the number of molecules in a given container, the more frequently they collide with the walls, and the greater the pressure is.

2. *Boyle's law* ($V \propto 1/P$). Gas molecules are points of mass with empty space between them (postulate 1), so as the pressure exerted *on* the sample increases at constant temperature, the distance between molecules decreases, and the sample volume decreases. The pressure exerted *by* the gas increases simultaneously because in a smaller volume of gas, there are shorter distances between gas molecules and the walls and between the walls themselves; thus, collisions are more frequent (Figure 5.15). The fact that liquids and solids cannot be compressed means there is little, if any, free space between the molecules.

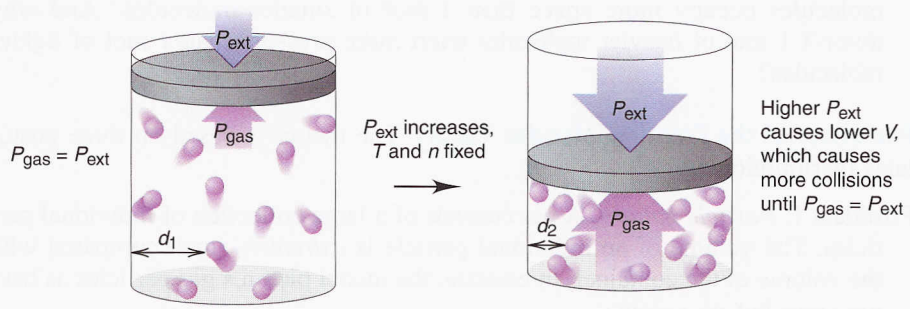

Figure 5.15 A molecular description of Boyle's law. At a given T, gas molecules collide with the walls across an average distance (d_1) and give rise to a pressure (P_{gas}) that equals the external pressure (P_{ext}). If P_{ext} increases, V decreases, and so the average distance between a molecule and the walls is shorter ($d_2 < d_1$). Molecules strike the walls more often, and P_{gas} increases until it again equals P_{ext}. Thus, V decreases when P increases.

3. *Dalton's law of partial pressures* ($P_{total} = P_A + P_B$). Adding a given amount of gas A to a given amount of gas B causes an increase in the total number of molecules in proportion to the amount of A that is added. This increase causes a corresponding increase in the number of collisions per second with the walls (postulate 2), which causes a corresponding increase in the pressure (Figure 5.16). Thus, each gas exerts a fraction of the total pressure based on the fraction of molecules (or fraction of moles; that is, the mole fraction) of that gas in the mixture.

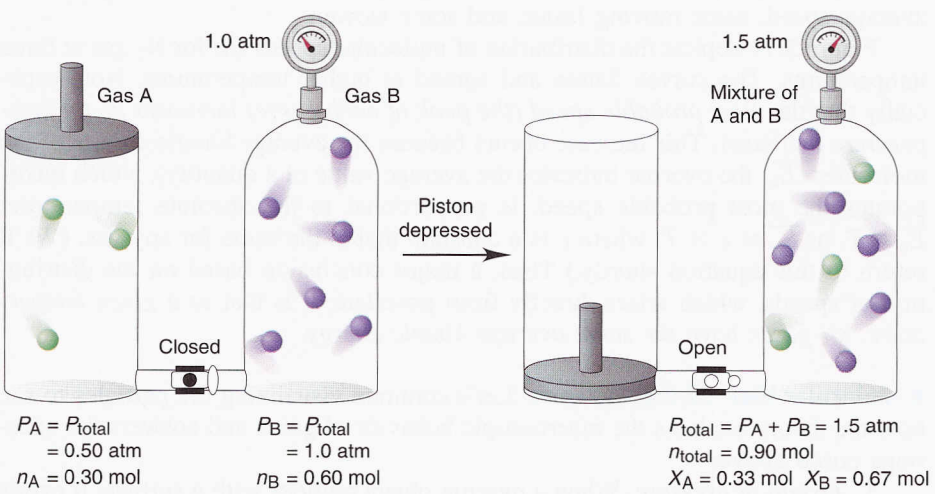

Figure 5.16 A molecular description of Dalton's law of partial pressures. A piston-cylinder assembly containing 0.30 mol of gas A at 0.50 atm is connected to a tank of fixed volume containing 0.60 mol of gas B at 1.0 atm. When the piston is depressed at fixed temperature, gas A is forced into the tank of gas B and the gases mix. The new total pressure, 1.5 atm, equals the sum of the partial pressures, which is related to the new total amount of gas, 0.90 mol. Thus, each gas undergoes a fraction of the total collisions related to its fraction of the total number of molecules (moles), which is equal to its mole fraction.

4. *Charles's law* ($V \propto T$). As the temperature increases, the most probable molecular speed and the average kinetic energy increase (postulate 3). Thus, the molecules hit the walls more frequently *and* more energetically. A higher frequency of collisions causes higher internal pressure. As a result, the walls move outward, which increases the volume and restores the starting pressure (Figure 5.17).

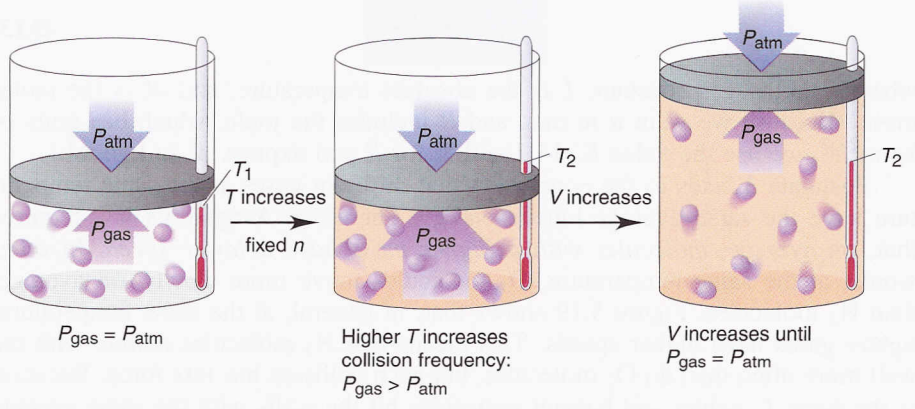

Figure 5.17 A molecular description of Charles's law. At a given temperature (T_1), $P_{gas} = P_{atm}$. When the gas is heated to T_2, the molecules move faster and collide with the walls more often, which increases P_{gas}. This increases V, and so the molecules collide less often until P_{gas} again equals P_{atm}. Thus, V increases when T increases.

5. *Avogadro's law* ($V \propto n$). Adding more molecules to a container increases the total number of collisions with the walls and, therefore, the internal pressure. As a result, the volume expands until the number of collisions per unit of wall area is the same as it was before the addition (Figure 5.18).

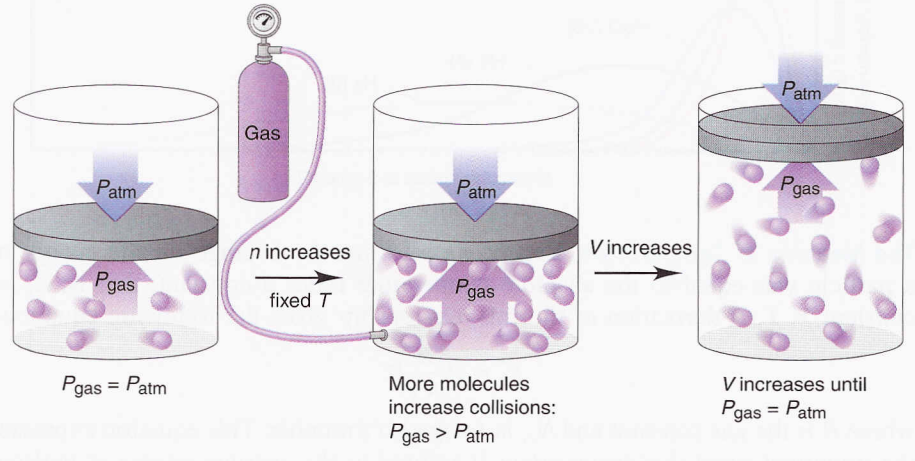

Figure 5.18 A molecular description of Avogadro's law. At a given T, a certain amount (n) of gas gives rise to a pressure (P_{gas}) equal to P_{atm}. When more gas is added, n increases. Collisions with the walls become more frequent, and P_{gas} increases. This leads to an increase in V until $P_{gas} = P_{atm}$ again. Thus, V increases when n increases.

Relation Between Molecular Speed and Mass We still need to explain why equal numbers of molecules of two different gases, such as O_2 and H_2, occupy the same volume. Let's first see why heavier O_2 particles *do not* hit the container walls with more energy than lighter H_2 particles. Recall that the kinetic energy of an object is the energy associated with its motion (Chapter 1). This energy is related to the mass *and* the speed of the object:

$$E_k = \tfrac{1}{2}\,\text{mass} \times \text{speed}^2$$

This equation shows that if a heavy object and a light object have the same kinetic energy, *the heavy object must be moving more slowly.* For a large population of molecules, the average kinetic energy is

$$\overline{E_k} = \tfrac{1}{2}m\overline{u^2}$$

where m is the molecular mass and $\overline{u^2}$ is the average of the squares of the molecular speeds. The square root of $\overline{u^2}$ is called the root-mean-square speed, or **rms speed (u_{rms}).** *A molecule moving at this speed has the average kinetic energy.* The rms speed is somewhat higher than the most probable speed, but the speeds are proportional to each other and we will use them interchangeably. The rms speed is related to the temperature and the molar mass as follows:

$$u_{rms} = \sqrt{\frac{3RT}{\mathcal{M}}} \tag{5.13}$$

where R is the gas constant, T is the absolute temperature, and $\mathcal{M}$ is the molar mass. (Because we want u in m/s, and R includes the joule, which has units of kg·m^2/s^2, we use the value 8.314 J/mol·K for R and express $\mathcal{M}$ in kg/mol.)

Postulate 3 leads to the conclusion that different gases at the same temperature have the same average kinetic energy. Therefore, Avogadro's law requires that, on average, *molecules with a higher mass have a lower speed.* In other words, at the same temperature, O_2 molecules move more slowly, on average, than H_2 molecules. Figure 5.19 shows that, in general, at the same temperature, lighter gases have higher speeds. This means that H_2 molecules collide with the wall more often than do O_2 molecules, but each collision has less force. Because, at the same T, lighter and heavier molecules hit the walls with the same average kinetic energy, lighter and heavier gases have the same pressure and, thus, the same volume.

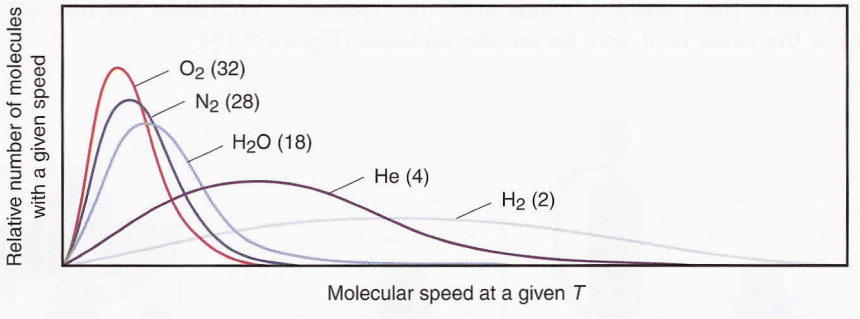

Figure 5.19 Relationship between molar mass and molecular speed. At a given temperature, gases with lower molar masses (numbers in parentheses) have higher most probable speeds (peak of each curve).

The Meaning of Temperature Earlier we said that the average kinetic energy of a particle was equal to the absolute temperature times a constant, that is, $\overline{E_k}$ = constant × T. A derivation of the full relationship gives the following equation:

$$\overline{E_k} = \tfrac{3}{2}\left(\frac{R}{N_A}\right)T$$

where R is the gas constant and N_A is Avogadro's number. This equation expresses the important point that *temperature is related to the average energy of molecular motion.* Note that it is not related to the *total* energy, which depends on the size of the sample, but to the *average* energy: as T increases, $\overline{E_k}$ increases. What occurs when, say, a beaker of water containing a thermometer is heated over a flame? The rapidly moving gas particles in the flame collide more energetically with the atoms of the beaker, transferring some of their kinetic energy. The atoms vibrate faster and transfer kinetic energy to the molecules of water, which move faster and transfer kinetic energy to the atoms in the thermometer bulb. These, in turn, transfer kinetic energy to the atoms of mercury. They collide with each other more frequently and more energetically, which causes the mercury volume to expand and the level to rise. In the macroscopic world, we see this as a temperature increase; in the molecular world, it is a sequence of kinetic energy transfers from higher energy particles to lower energy particles, such that each group of particles increases its average kinetic energy.

Effusion and Diffusion

The movement of gases, either through one another or into regions of very low pressure, has many important applications.

The Process of Effusion One of the early triumphs of the kinetic-molecular theory was an explanation of **effusion,** the process by which a gas escapes from its container through a tiny hole into an evacuated space. In 1846, Thomas Graham studied this process and concluded that the effusion rate was inversely proportional to the square root of the gas density. The effusion rate is the number of moles (or molecules) of gas effusing per unit time. Since density is directly proportional to molar mass, we state **Graham's law of effusion** as follows: *the rate of effusion of a gas is inversely proportional to the square root of its molar mass,*

$$\text{Rate of effusion} \propto \frac{1}{\sqrt{\mathcal{M}}}$$

Argon (Ar) is lighter than krypton (Kr), so it effuses faster, assuming equal pressures of the two gases. Thus, the ratio of the rates is

$$\frac{\text{Rate}_{Ar}}{\text{Rate}_{Kr}} = \frac{\sqrt{\mathcal{M}_{Kr}}}{\sqrt{\mathcal{M}_{Ar}}} \quad \text{or, in general,} \quad \frac{\text{rate}_A}{\text{rate}_B} = \frac{\sqrt{\mathcal{M}_B}}{\sqrt{\mathcal{M}_A}} = \sqrt{\frac{\mathcal{M}_B}{\mathcal{M}_A}} \qquad (5.14)$$

The kinetic-molecular theory explains that, at a given temperature and pressure, *the gas with the lower molar mass effuses faster because the most probable speed of its molecules is higher; therefore, more molecules escape per unit time.*

Preparing Nuclear Fuel One of the most important applications of Graham's law is the *enrichment* of nuclear reactor fuel: separating nonfissionable, more abundant ^{238}U from fissionable ^{235}U to increase the proportion of ^{235}U in the mixture. Since the two isotopes have identical chemical properties, they are separated by differences in the effusion rates of their gaseous compounds. Uranium ore is converted to gaseous UF_6 (a mixture of $^{238}UF_6$ and $^{235}UF_6$), which is pumped through a series of chambers with porous barriers. Because they move very slightly faster, molecules of $^{235}UF_6$ ($\mathcal{M}$ = 349.03) effuse through each barrier 1.0043 times faster than do molecules of $^{238}UF_6$ ($\mathcal{M}$ = 352.04). Many passes are made, each increasing the fraction of $^{235}UF_6$ until a mixture is obtained that contains enough $^{235}UF_6$. This isotope-enrichment process was developed during the latter years of World War II and produced enough ^{235}U for two of the world's first three atomic bombs.

SAMPLE PROBLEM 5.13 Applying Graham's Law of Effusion

Problem Calculate the ratio of the effusion rates of helium and methane (CH_4).

Plan The effusion rate is inversely proportional to $\sqrt{\mathcal{M}}$, so we find the molar mass of each substance from the formula and take its square root. The inverse of the ratio of the square roots is the ratio of the effusion rates.

Solution

$$\mathcal{M} \text{ of } CH_4 = 16.04 \text{ g/mol} \qquad \mathcal{M} \text{ of He} = 4.003 \text{ g/mol}$$

Calculating the ratio of the effusion rates:

$$\frac{\text{Rate}_{He}}{\text{Rate}_{CH_4}} = \sqrt{\frac{\mathcal{M}_{CH_4}}{\mathcal{M}_{He}}} = \sqrt{\frac{16.04 \text{ g/mol}}{4.003 \text{ g/mol}}} = \sqrt{4.007} = 2.002$$

Check A ratio >1 makes sense because the lighter He should effuse faster than the heavier CH_4. Because the molar mass of He is about one-fourth that of CH_4, He should effuse about twice as fast (the inverse of $\sqrt{\frac{1}{4}}$).

FOLLOW-UP PROBLEM 5.13 If it takes 1.25 min for 0.010 mol of He to effuse, how long will it take for the same amount of ethane (C_2H_6) to effuse?

Graham's law is also used to determine the molar mass of an unknown gas, X, by comparing its effusion rate with that of a known gas, such as He:

$$\frac{\text{Rate}_X}{\text{Rate}_{He}} = \sqrt{\frac{\mathcal{M}_{He}}{\mathcal{M}_X}}$$

Squaring both sides and solving for the molar mass of X gives

$$\mathcal{M}_X = \mathcal{M}_{He} \times \left(\frac{\text{rate}_{He}}{\text{rate}_X}\right)^2$$

The Process of Diffusion Closely related to effusion is the process of gaseous **diffusion,** the movement of one gas through another. Diffusion rates are also described generally by Graham's law:

$$\text{Rate of diffusion} \propto \frac{1}{\sqrt{\mathcal{M}}}$$

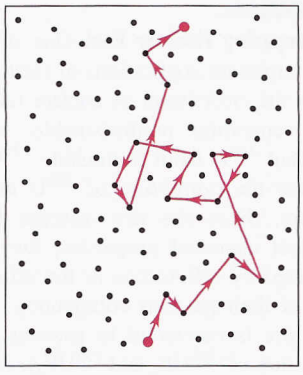

Figure 5.20 Diffusion of a gas particle through a space filled with other particles. In traversing a space, a gas molecule collides with many other molecules, which gives it a tortuous path. For clarity, the path of only one particle *(red dot)* is shown *(red lines)*.

For two gases at equal pressures, such as NH_3 and HCl, moving through another gas or a mixture of gases, such as air, we find

$$\frac{\text{Rate}_{NH_3}}{\text{Rate}_{HCl}} = \sqrt{\frac{\mathcal{M}_{HCl}}{\mathcal{M}_{NH_3}}}$$

The reason for this dependence on molar mass is the same as for effusion rates: lighter molecules have higher molecular speeds than heavier molecules, so they move farther in a given amount of time.

If gas molecules move at hundreds of meters per second at ordinary temperatures (see Figure 5.14), why does it take a second or two after you open a bottle of perfume to smell the fragrance? Although convection plays an important role, a molecule moving by diffusion does not travel very far before it collides with a molecule in the air. As you can see from Figure 5.20, the path of each molecule is tortuous. Imagine walking through an empty room, and then imagine walking through a room crowded with other moving people.

Diffusion also occurs in liquids (and even to a small extent in solids). However, because the distances between molecules are much shorter in a liquid than in a gas, collisions are much more frequent; thus, diffusion is *much* slower. Diffusion of a gas through a liquid is a vital process in biological systems. For example, it plays a key part in the movement of O_2 from lungs to blood. Many organisms have evolved elaborate ways to speed the diffusion of nutrients (for example, sugar and metal ions) through their cell membranes and to slow, or even stop, the diffusion of toxins.

The Chaotic World of Gases: Mean Free Path and Collision Frequency

Refinements of the basic kinetic-molecular theory provide a view into the amazing, chaotic world of gas molecules. Let's follow an "average" N_2 molecule in a room at 20°C and 1 atm pressure—perhaps the room you are in now.

Distribution of Molecular Speeds Our molecule is hurtling through the room at an average speed of 0.47 km/s, or nearly 1100 mi/h (rms speed = 0.51 km/s), and continually changing speed as it collides with other molecules. At any instant, it may be traveling at 2500 mi/h or standing still as it collides head on, but these extreme speeds are *much* less likely than the most probable one (see Figure 5.19).

Mean Free Path From a molecule's diameter, we can use the kinetic-molecular theory to obtain the **mean free path,** the average distance the molecule travels between collisions at a given temperature and pressure. Our average N_2 molecule (3.7×10^{-10} m in diameter) travels 6.6×10^{-8} m before smashing into a fellow traveler, which means it travels about 180 molecular diameters between collisions. (An analogy in the macroscopic world would be an N_2 molecule the size of a billiard ball traveling about 30 ft before colliding with another.) Therefore, even though gas molecules are *not* points of mass, a gas sample *is* mostly empty space. Mean free path is a key factor in the rate of diffusion and the rate of heat flow through a gas.

Collision Frequency Divide the most probable speed (distance per second) by the mean free path (distance per collision) and you obtain the **collision frequency,** the average number of collisions per second that each molecule undergoes:

$$\text{Collision frequency} = \frac{4.7\times10^{2}\ \text{m/s}}{6.6\times10^{-8}\ \text{m/collision}} = 7.1\times10^{9}\ \text{collisions/s}$$

Distribution of speed (and kinetic energy) and collision frequency are essential ideas for understanding the speed of a chemical reaction, as you'll see in Chapter 16. As the upcoming Chemical Connections essay shows, the kinetic-molecular theory applies directly to the behavior of our planet's atmosphere.

Danger on Molecular Highways To give you some idea of how astounding events are in the molecular world, we can express the collision frequency of a molecule in terms of a common experience in the macroscopic world: driving a compact car on the highway. Since a car is much larger than an N_2 molecule, to match the collision frequency of the molecule you would have to travel at 2.8 billion mi/s (an impossibility, given that it is much faster than the speed of light) and would smash into another car every 700 yd!

Structure and Composition of Earth's Atmosphere

An **atmosphere** is the envelope of gases that extends continuously from a planet's surface outward, eventually thinning to a point at which it is indistinguishable from interplanetary space. On Earth, complex changes in pressure, temperature, and composition occur within this mixture of gases, and the present atmosphere is very different from the one that existed during our planet's early history.

Variation in Pressure

Since gases are compressible (Boyle's law), the pressure of the atmosphere *decreases* smoothly with distance from the surface, with a more rapid decrease at lower altitudes (Figure B5.1). Although no specific boundary delineates the outermost fringe of the atmosphere, the density and composition at around 10,000 km from the surface are identical with those of outer space. About 99% of the atmosphere's mass lies within 30 km of the surface, and 75% lies within the lowest 11 km.

Variation in Temperature

Unlike the change in pressure, temperature does *not* decrease smoothly with altitude, and the atmosphere is usually classified into regions based on the direction of temperature change (Figure B5.1). In the *troposphere,* which includes the region from the surface to around 11 km, temperatures *drop* 7°C per kilometer to −55°C (218 K). All our weather occurs in the troposphere, and all but a few aircraft fly there. Temperatures then *rise* through the *stratosphere* from −55°C to about 7°C (280 K) at 50 km; we'll discuss the reason shortly.

In the *mesosphere,* temperatures *drop* smoothly again to −93°C (180 K) at around 80 km. Within the *thermosphere,* which extends to around 500 km, temperatures *rise* again, but vary between 700 and 2000 K, depending on the intensity of solar radiation and sunspot activity.

The *exosphere,* the outermost region, maintains these temperatures and merges with outer space.

(continued)

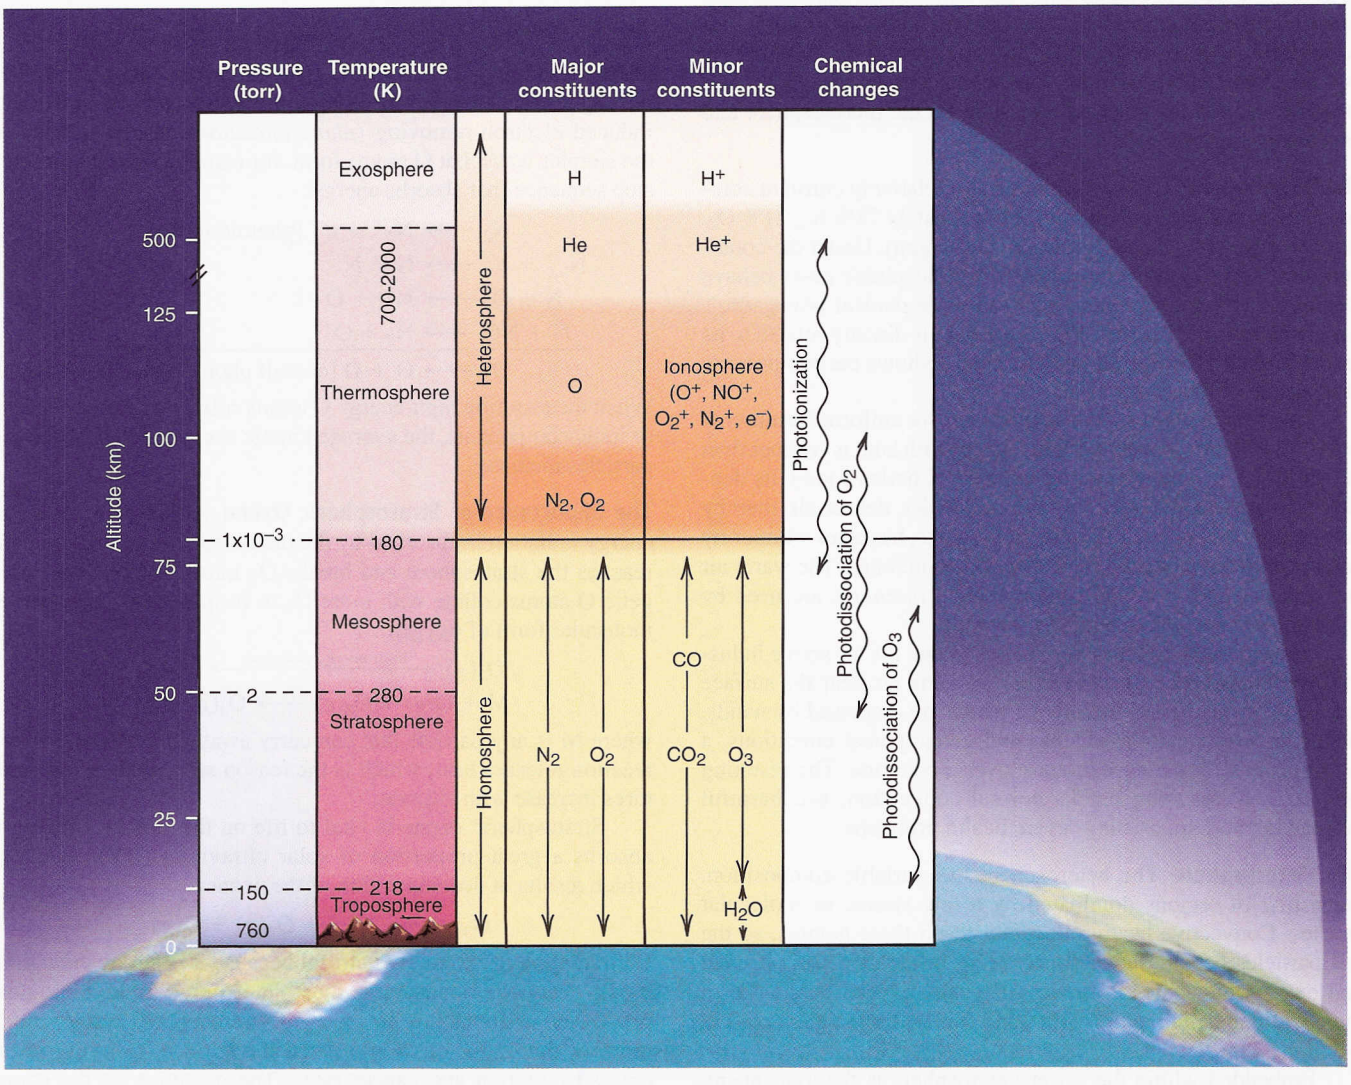

Figure B5.1 Variations in pressure, temperature, and composition of Earth's atmosphere.

What does it actually mean to have a temperature of 2000 K at 500 km (300 mi) above Earth's surface? Would a piece of iron (melting point ≈ 1700 K) glow red-hot and melt in the thermosphere? Our everyday use of the words "hot" and "cold" refers to measurements near the surface, where the density of the atmosphere is 10^6 times greater than in the thermosphere. At an altitude of 500 km, where collision frequency is extremely low, a thermometer, or any other object, experiences *very little transfer of kinetic energy.* Thus, the object does not become "hot" in the usual sense; in fact, it is very "cold." Recall that absolute temperature is proportional to the average kinetic energy of the particles. The high-energy solar radiation reaching these outer regions is transferred to relatively few particles, so their average kinetic energy becomes extremely high, as indicated by the high temperature. For this reason, supersonic aircraft do not reach maximum speed until they reach maximum altitude, where the air is less dense, so that collisions with gas molecules are less frequent and the aircraft material becomes less hot.

Variation in Composition

In terms of chemical composition, the atmosphere is usually classified into two major regions, *homosphere* and *heterosphere.* Superimposing the regions defined by temperature on these shows that the homosphere includes the troposphere, stratosphere, and mesosphere, and the heterosphere includes the thermosphere and exosphere (Figure B5.1).

The Homosphere The homosphere has a relatively constant composition, containing, by volume, approximately 78% N_2, 21% O_2, and 1% a mixture of other gases (mostly argon). Under the conditions that occur in the homosphere, the atmospheric gases behave ideally, so volume percent is equal to mole percent (Avogadro's law), and the mole fraction of a component is directly related to its partial pressure (Dalton's law). Table B5.1 shows the components of a sample of clean, dry air at sea level.

The composition of the homosphere is uniform because of *convective mixing.* Air directly in contact with land is warmer than the air above it. The warmer air expands (Charles's law), its density decreases, and it rises through the cooler, denser air, thereby mixing the components. The cooler air sinks, becomes warmer by contact with the land, and the convection continues. The warm air currents that rise from the ground, called *thermals,* are used by soaring birds and glider pilots to stay aloft.

An important effect of convection is that the air above industrialized areas becomes cleaner as the rising air near the surface carries up ground-level pollutants, which are dispersed by winds. However, under certain weather and geographical conditions, a warm air mass remains stationary over a cool one. The resulting *temperature inversion* blocks normal convection, and harmful pollutants build up, causing severe health problems.

The Heterosphere The heterosphere has variable composition, consisting of regions dominated by a few atomic or molecular species. Convective heating does not reach these heights, so the gas particles become layered according to molar mass: nitrogen and oxygen molecules in the lower levels, oxygen atoms (O) in the next, then helium atoms (He), and free hydrogen atoms (H) in the highest level.

Embedded within the lower heterosphere is the ionosphere, containing ionic species such as O^+, NO^+, O_2^+, N_2^+, and free electrons (Figure B5.1). Ionospheric chemistry involves numerous light-induced bond-breaking *(photodissociation)* and light-induced electron-removing *(photoionization)* processes. One of the simpler ways that O atoms form, for instance, involves a four-step sequence that absorbs energy:

$$N_2 \longrightarrow N_2^+ + e^- \text{ [photoionization]}$$
$$N_2^+ + e^- \longrightarrow N + N$$
$$N + O_2 \longrightarrow NO + O$$
$$N + NO \longrightarrow N_2 + O$$
$$O_2 \longrightarrow O + O \text{ [overall photodissociation]}$$

When the resulting high-energy O atoms collide with other neutral or ionic components, the average kinetic energy of thermospheric particles increases.

Table B5.1 Composition of Clean, Dry Air at Sea Level

Component	Mole Fraction
Nitrogen (N_2)	0.78084
Oxygen (O_2)	0.20946
Argon (Ar)	0.00934
Carbon dioxide (CO_2)	0.00033
Neon (Ne)	1.818×10^{-5}
Helium (He)	5.24×10^{-6}
Methane (CH_4)	2×10^{-6}
Krypton (Kr)	1.14×10^{-6}
Hydrogen (H_2)	5×10^{-7}
Dinitrogen monoxide (N_2O)	5×10^{-7}
Carbon monoxide (CO)	1×10^{-7}
Xenon (Xe)	8×10^{-8}
Ozone (O_3)	2×10^{-8}
Ammonia (NH_3)	6×10^{-9}
Nitrogen dioxide (NO_2)	6×10^{-9}
Nitrogen monoxide (NO)	6×10^{-10}
Sulfur dioxide (SO_2)	2×10^{-10}
Hydrogen sulfide (H_2S)	2×10^{-10}

The Importance of Stratospheric Ozone Although most high-energy radiation is absorbed by the thermosphere, a small amount reaches the stratosphere and breaks O_2 into O atoms. The energetic O atoms collide with more O_2 to form ozone (O_3), another molecular form of oxygen:

$$O_2(g) \xrightarrow{\text{high-energy radiation}} 2O(g)$$
$$M + O(g) + O_2(g) \longrightarrow O_3(g) + M$$

where M is any particle that can carry away excess energy. This reaction releases heat, which is the reason stratospheric temperatures increase with altitude.

Stratospheric ozone is vital to life on the surface because it absorbs a great proportion of solar ultraviolet (UV) radiation, which results in decomposition of the ozone:

$$O_3(g) \xrightarrow{\text{UV light}} O_2(g) + O(g)$$

UV radiation is extremely harmful because it is strong enough to break chemical bonds and, thus, interrupt normal biological processes. Without the presence of stratospheric ozone, much more of this radiation would reach the surface, resulting in increased mutation and cancer rates. The depletion of the ozone layer as a result of industrial gases is discussed in Chapter 16.

Earth's Primitive Atmosphere

The composition of the present atmosphere bears little resemblance to that covering the young Earth, but scientists disagree about what that primitive composition actually was: Did the carbon and nitrogen have low oxidation numbers, as in CH_4 (O.N. of C = −4) and NH_3 (O.N. of N = −3)? Or did these atoms have higher oxidation numbers, as in CO_2 (O.N. of C = +4) and N_2 (O.N. of N = 0)? One point generally accepted is that the primitive mixture did not contain free O_2.

Origin-of-life models propose that about 1 billion years after the earliest organisms appeared, blue-green algae evolved. These one-celled plants used solar energy to produce glucose by photosynthesis:

$$6CO_2(g) + 6H_2O(l) \xrightarrow{\text{light}} C_6H_{12}O_6(\text{glucose}) + 6O_2(g)$$

As a result of this reaction, the O_2 content of the atmosphere increased and the CO_2 content decreased. More O_2 allowed more oxidation to occur, which changed the geological and biological makeup of the early Earth. Iron(II) minerals changed to iron(III) minerals, sulfites changed to sulfates, and eventually organisms evolved that could use O_2 to oxidize other organisms to obtain energy. For these organisms to have survived exposure to the more energetic forms of solar radiation (particularly UV radiation), enough O_2 must have formed to create a protective ozone layer. Estimates indicate that the level of O_2 increased to the current level of about 20 mol % approximately 1.5 billion years ago.

A Survey of Planetary Atmospheres

Earth's combination of pressure and temperature and its oxygen-rich atmosphere and watery surface are unique in the Solar System. (Indeed, if similar conditions and composition were discovered on a planet circling any other star, excitement about the possibility of life there would be enormous.) Atmospheres on the Sun's other planets are strikingly different from Earth's. Some, especially those on the outer planets, exist under conditions that cause extreme deviations from ideal gas behavior (Section 5.7). Based on current data from NASA spacecraft and Earth-based observations, Table B5.2 lists conditions and composition of the atmospheres on the planets within the Solar System and on some of their moons.

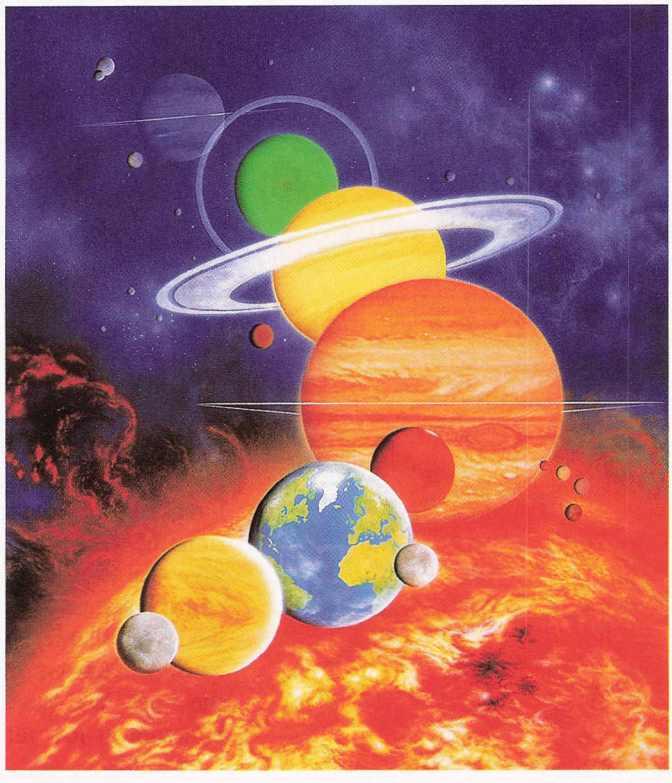

Table B5.2 Planetary Atmospheres

Planet (Satellite)	Pressure* (atm)	Temperature† (K)	Composition (mol %)
Mercury	$<10^{-12}$	~700 (day) ~100 (night)	He, H_2, O_2, Ar, Ne (Na and K from solar wind)
Venus	~90	~730	CO_2 (96), N_2 (3), He, SO_2, H_2O, Ar, Ne
Earth	1.0	avg. range 250–310	N_2 (78), O_2 (21), Ar (0.9), H_2O, CO_2, Ne, He, CH_4, Kr
(Moon)	$\sim 2\times10^{-14}$	370 (day) 120 (night)	Ne, Ar, He
Mars	7×10^{-3}	300 (summer day) 140 (pole in winter) 218 average	CO_2 (95), N_2(3), Ar (1.6), O_2, H_2O, Ne, CO, Kr
Jupiter	$(\sim 4\times10^{6})$	(~140)	H_2 (89), He (11), CH_4, NH_3, C_2H_6, C_2H_2, PH_3
(Io)	$\sim10^{-10}$	~110	SO_2, S vapor
Saturn	$(\sim 4\times10^{6})$	(~130)	H_2 (93), He (7), CH_4, NH_3, H_2O, C_2H_6, PH_3
(Titan)	1.6	~94	N_2 (90), Ar (<6), CH_4 (3?), C_2H_6, C_2H_2, C_2H_4, HCN, H_2
Uranus	$(>10^{6})$	(~60)	H_2 (83), He (15), CH_4 (2)
Neptune	$(>10^{6})$	(~60)	H_2 (<90), He (~10), CH_4
Pluto	$\sim10^{-6}$	~50	N_2, CO, CH_4

*Values in parentheses refer to interior pressures.
†Values in parentheses refer to cloud-top temperatures.

SECTION SUMMARY

The kinetic-molecular theory postulates that gas molecules take up a negligible portion of the gas volume, move in straight-line paths between elastic collisions, and have average kinetic energies proportional to the absolute temperature of the gas. This theory explains the gas laws in terms of changes in distances between molecules and the container walls and changes in molecular speed. Temperature is a measure of the average kinetic energy of molecules. Effusion and diffusion rates are inversely proportional to the square root of the molar mass (Graham's law) because they are directly proportional to molecular speed. Molecular motion is characterized by a temperature-dependent most probable speed within a range of speeds, a mean free path, and a collision frequency. The atmosphere is a complex mixture of gases that exhibits variations in pressure, temperature, and composition with altitude.

5.7 REAL GASES: DEVIATIONS FROM IDEAL BEHAVIOR

A fundamental principle of science is that simpler models are more useful than complex ones—as long as they explain the data. You can certainly appreciate the usefulness of the kinetic-molecular theory. With simple postulates, it explains ideal gas behavior in terms of particles acting like infinitesimal "billiard balls," moving at speeds governed by the absolute temperature, and experiencing only perfectly elastic collisions.

In reality, however, you know that *molecules are not points of mass*. They have volumes determined by the sizes of their atoms and the lengths and directions of their bonds. You also know that atoms contain charged particles, which give rise to *attractive and repulsive forces among molecules*. (In fact, such forces cause substances to undergo changes of states; we'll discuss these forces in great detail in Chapter 12.) Therefore, we expect these real properties of molecules to cause deviations from ideal behavior under some conditions, and this is indeed the case. We must alter the simple model and the ideal gas law to predict gas behavior at low temperatures and very high pressures.

Effects of Extreme Conditions on Gas Behavior

At ordinary conditions—relatively high temperatures and low pressures—most simple gases exhibit nearly ideal behavior. Even at STP (0°C and 1 atm), however, gases deviate *slightly* from ideal behavior. Table 5.4 shows the standard molar volumes of several gases to five significant figures. Note that they do not quite equal the ideal value. The phenomena that cause these slight deviations under standard conditions exert more influence as the temperature decreases toward the condensation point of the gas, the temperature at which it liquefies. As you can see, the largest deviations from ideal behavior in Table 5.4 are for Cl_2 and NH_3 because, at the standard temperature of 0°C, they are already close to their condensation points.

Table 5.4 Molar Volume of Some Common Gases at STP (0°C and 1 atm)

Gas	Molar Volume (L/mol)	Condensation Point (°C)
He	22.435	−268.9
H_2	22.432	−252.8
Ne	22.422	−246.1
Ideal gas	**22.414**	—
Ar	22.397	−185.9
N_2	22.396	−195.8
O_2	22.390	−183.0
CO	22.388	−191.5
Cl_2	22.184	−34.0
NH_3	22.079	−33.4

At pressures greater than 10 atm, we begin to see significant deviations from ideal behavior in many gases. Figure 5.21 shows a plot of PV/RT versus P_{ext} for *1 mol* of several real gases and an ideal gas. For 1 mol of an *ideal* gas, the ratio PV/RT is equal to 1 at any pressure. The values on the horizontal axis are the external pressures at which the PV/RT ratios are calculated. The pressures range from normal (at 1 atm, $PV/RT = 1$) to very high (at ~1000 atm, $PV/RT \approx 1.6$ to 2.3).

The PV/RT curve shown in Figure 5.21 for 1 mol of methane (CH_4) is typical of that for most real gases: it decreases below the ideal value at moderately high pressures and then rises above it as pressure increases further. This shape arises from two overlapping effects of the two characteristics of real molecules just mentioned:

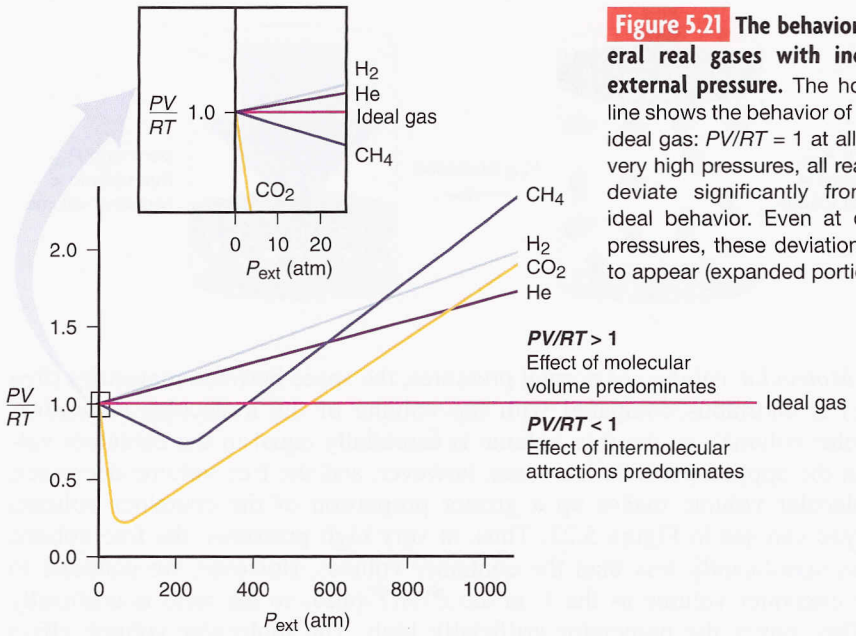

Figure 5.21 The behavior of several real gases with increasing external pressure. The horizontal line shows the behavior of 1 mol of ideal gas: $PV/RT = 1$ at all P_{ext}. At very high pressures, all real gases deviate significantly from such ideal behavior. Even at ordinary pressures, these deviations begin to appear (expanded portion).

1. At moderately high pressure, values of PV/RT lower than ideal (less than 1) are due predominantly to *intermolecular attractions*.
2. At very high pressure, values of PV/RT greater than ideal (more than 1) are due predominantly to *molecular volume*.

Let's examine these effects on the molecular level:

1. *Intermolecular attractions*. Attractive forces between molecules are *much* weaker than the covalent bonding forces that hold a molecule together. Most intermolecular attractions are caused by slight imbalances in electron distributions and are important only over relatively short distances. At normal pressures, the spaces between gas molecules are so large that attractions are negligible, and the gas behaves nearly ideally. As the pressure rises and the volume of the sample decreases, however, the average intermolecular distance becomes smaller and attractions have a greater effect.

Picture a molecule at these higher pressures (Figure 5.22). As it approaches the container wall, nearby molecules attract it, which lessens the force of its impact. *Repeated throughout the sample, this effect results in decreased gas pressure and, thus, a smaller numerator in the PV/RT ratio.* Lowering the temperature has the same effect because it slows the molecules, so attractive forces exert an influence for a longer time. At a low enough temperature, the attractions among molecules become overwhelming, and the gas condenses to a liquid.

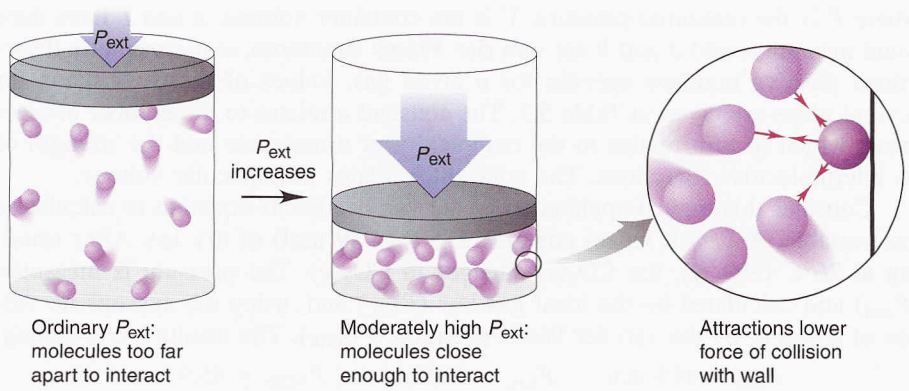

Figure 5.22 The effect of intermolecular attractions on measured gas pressure. At ordinary pressures, the volume is large and gas molecules are too far apart to experience significant attractions. At moderately high external pressures, the volume decreases enough for the molecules to influence each other. As the close-up shows, a gas molecule approaching the container wall experiences intermolecular attractions from neighboring molecules that reduce the force of its impact. As a result, gases exert *less* pressure than the ideal gas law predicts.

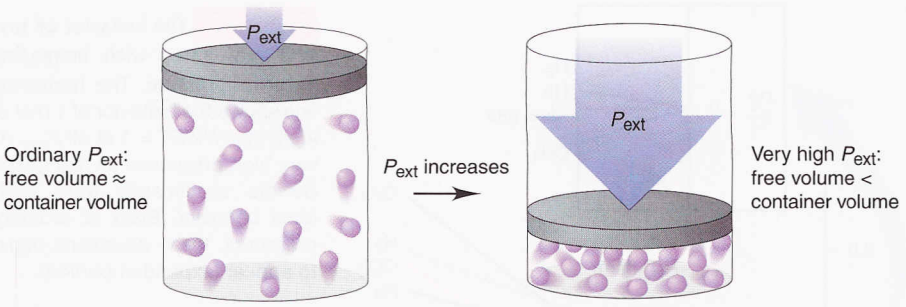

Figure 5.23 The effect of molecular volume on measured gas volume. At ordinary pressures, the volume *between* molecules (free volume) is essentially equal to the container volume because the molecules occupy only a tiny fraction of the available space. At very high external pressures, however, the free volume is significantly *less* than the container volume because of the volume of the molecules themselves.

2. *Molecular volume.* At normal pressures, the space between molecules (free volume) is enormous compared with the volume of the molecules *themselves* (molecular volume), so the free volume is essentially equal to the container volume. As the applied pressure increases, however, and the free volume decreases, the molecular volume makes up a greater proportion of the container volume, which you can see in Figure 5.23. Thus, at very high pressures, the free volume becomes significantly *less* than the container volume. However, we continue to use the container volume as the V in the PV/RT ratio, so the ratio is artificially high. This makes the numerator artificially high. The molecular volume effect becomes more important as the pressure increases, eventually outweighing the effect of the intermolecular attractions and causing PV/RT to rise above the ideal value.

In Figure 5.21, the H_2 and He curves do not show the typical dip at moderate pressures. These gases consist of particles with such weak intermolecular attractions that the molecular volume effect predominates at all pressures.

The van der Waals Equation: The Ideal Gas Law Redesigned

To describe real gas behavior more accurately, we need to "redesign" the ideal gas equation to do two things:

1. Adjust the measured pressure *up* by adding a factor that accounts for intermolecular attractions, and
2. Adjust the measured volume *down* by subtracting a factor from the entire container volume that accounts for the molecular volume.

In 1873, Johannes van der Waals realized the limitations of the ideal gas law and proposed an equation that accounts for the behavior of real gases. The **van der Waals equation** for n moles of a real gas is

$$\underbrace{\left(P + \frac{n^2a}{V^2}\right)}_{\substack{\text{adjusts}\\ P \text{ up}}}\underbrace{(V - nb)}_{\substack{\text{adjusts}\\ V \text{ down}}} = nRT$$

where P is the measured pressure, V is the container volume, n and T have their usual meanings, and a and b are **van der Waals constants,** experimentally determined positive numbers specific for a given gas. Values of these constants for several gases are given in Table 5.5. The constant a relates to the number of electrons, which in turn relates to the complexity of a molecule and the strength of its intermolecular attractions. The constant b relates to molecular volume.

Consider this typical application of the van der Waals equation to calculate a gas variable. A 1.98-L vessel contains 215 g (4.89 mol) of dry ice. After standing at 26°C (299 K), the $CO_2(s)$ changes to $CO_2(g)$. The pressure is measured (P_{real}) and calculated by the ideal gas law (P_{IGL}) and, using the appropriate values of a and b, by the van der Waals equation (P_{VDW}). The results are revealing:

$$P_{real} = 44.8 \text{ atm} \qquad P_{IGL} = 60.6 \text{ atm} \qquad P_{VDW} = 45.9 \text{ atm}$$

Table 5.5 Van der Waals Constants for Some Common Gases

Gas	$a\left(\frac{\text{atm}\cdot\text{L}^2}{\text{mol}^2}\right)$	$b\left(\frac{\text{L}}{\text{mol}}\right)$
He	0.034	0.0237
Ne	0.211	0.0171
Ar	1.35	0.0322
Kr	2.32	0.0398
Xe	4.19	0.0511
H_2	0.244	0.0266
N_2	1.39	0.0391
O_2	1.36	0.0318
Cl_2	6.49	0.0562
CH_4	2.25	0.0428
CO	1.45	0.0395
CO_2	3.59	0.0427
NH_3	4.17	0.0371
H_2O	5.46	0.0305

Comparing the real with each calculated value shows that P_{IGL} is 35.3% greater than P_{real}, but P_{VDW} is only 2.5% greater than P_{real}. At these conditions, CO_2 deviates so much from ideal behavior that the ideal gas law is not very useful.

Here is one final point to realize: According to kinetic-molecular theory, the constants a and b are zero for an ideal gas because the particles do not attract each other and have no volume. Yet, even for a real gas at ordinary pressures, the molecules are very far apart. Thus,

- Attractive forces are miniscule, so $P + \frac{n^2a}{V^2} \approx P$
- The molecular volume is a miniscule fraction of the container volume, so $V - nb \approx V$

Therefore, *at ordinary conditions, the van der Waals equation becomes the ideal gas equation.*

SECTION SUMMARY

At very high pressures or low temperatures, all gases deviate greatly from ideal behavior. As pressure increases, most real gases exhibit first a lower and then a higher *PV/RT* ratio than the value for the same amount (1 mol) of an ideal gas. These deviations are due to attractions between molecules, which lower the pressure (and the ratio), and to the larger fraction of the container volume occupied by the molecules, which increases the ratio. By including parameters characteristic of each gas, the van der Waals equation corrects for these deviations.

Chapter Perspective

As with the atomic model (Chapter 2), we have seen in this chapter how a simple molecular-scale model can explain macroscopic observations and how it often must be revised to predict a wider range of chemical behavior. Gas behavior is relatively easy to understand because gas structure is so randomized—very different from the structures of liquids and solids with their complex molecular interactions, as you'll see in Chapter 12. In Chapter 6, we return to chemical reactions, but from the standpoint of the heat involved in such changes. The meaning of kinetic energy, which we discussed in this chapter, bears directly on this central topic.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. How gases differ in their macroscopic properties from liquids and solids (5.1)
2. The meaning of pressure and the operation of a barometer and a manometer (5.2)
3. The relations among gas variables expressed by Boyle's, Charles's, and Avogadro's laws (5.3)
4. How the individual gas laws are incorporated into the ideal gas law (5.3)
5. How the ideal gas law can be used to study gas density and molar mass (5.4)
6. The relation between the density and the temperature of a gas (5.4)
7. The meaning of Dalton's law and the relation between partial pressure and mole fraction of a gas; how Dalton's law applies to collecting a gas over water (5.4)
8. How the postulates of the kinetic-molecular theory are applied to explain the origin of pressure and the gas laws (5.6)
9. The relations among molecular speed, average kinetic energy, and temperature (5.6)
10. The meanings of *effusion* and *diffusion* and how their rates are related to molar mass (5.6)
11. The relations among mean free path, molecular speed, and collision frequency (5.6)
12. Why intermolecular attractions and molecular volume cause gases to deviate from ideal behavior at low temperatures and high pressures (5.7)
13. How the van der Waals equation corrects the ideal gas law for extreme conditions (5.7)

Learning Objectives *(continued)*

Master These Skills

1. Interconverting among the units of pressure (atm, mmHg, torr, pascal, psi) (SP 5.1)
2. Reducing the ideal gas law to the individual gas laws (SPs 5.2–5.5)
3. Applying gas laws to balancing a chemical equation (SP 5.6)
4. Rearranging the ideal gas law to calculate gas density (SP 5.7) and molar mass of a volatile liquid (SP 5.8)
5. Calculating the mole fraction and partial pressure of a gas (SP 5.9)
6. Using the vapor pressure of water to find the amount of a gas collected over water (SP 5.10)
7. Applying stoichiometry and gas laws to calculate amounts of reactants and products (SPs 5.11 and 5.12)
8. Using Graham's law to solve problems of gaseous effusion (SP 5.13)

Key Equations and Relationships

5.1 Expressing the volume-pressure relationship (Boyle's law) (184):

$$V \propto \frac{1}{P} \quad \text{or} \quad PV = \text{constant} \quad [T \text{ and } n \text{ fixed}]$$

5.2 Expressing the volume-temperature relationship (Charles's law) (185):

$$V \propto T \quad \text{or} \quad \frac{V}{T} = \text{constant} \quad [P \text{ and } n \text{ fixed}]$$

5.3 Expressing the pressure-temperature relationship (Amontons's law) (186):

$$P \propto T \quad \text{or} \quad \frac{P}{T} = \text{constant} \quad [V \text{ and } n \text{ fixed}]$$

5.4 Expressing the volume-amount relationship (Avogadro's law) (187):

$$V \propto n \quad \text{or} \quad \frac{V}{n} = \text{constant} \quad [P \text{ and } T \text{ fixed}]$$

5.5 Defining standard temperature and pressure (187):

STP: 0°C (273.15 K) and 1 atm (760 torr)

5.6 Defining the volume of 1 mol of an ideal gas at STP (187):

Standard molar volume = 22.4141 L = 22.4 L [3 sf]

5.7 Relating volume to pressure, temperature, and amount (ideal gas law) (188):

$$PV = nRT \quad \text{and} \quad \frac{P_1V_1}{n_1T_1} = \frac{P_2V_2}{n_2T_2}$$

5.8 Calculating the value of R (188):

$$R = \frac{PV}{nT} = \frac{1 \text{ atm} \times 22.4141 \text{ L}}{1 \text{ mol} \times 273.15 \text{ K}}$$

$$= 0.082058 \frac{\text{atm·L}}{\text{mol·K}} = 0.0821 \frac{\text{atm·L}}{\text{mol·K}} \quad [3 \text{ sf}]$$

5.9 Rearranging the ideal gas law to find gas density (193):

$$PV = \frac{m}{\mathcal{M}}RT \quad \text{so} \quad \frac{m}{V} = d = \frac{\mathcal{M} \times P}{RT}$$

5.10 Rearranging the ideal gas law to find molar mass (194):

$$n = \frac{m}{\mathcal{M}} = \frac{PV}{RT} \quad \text{so} \quad \mathcal{M} = \frac{mRT}{PV} \quad \text{or} \quad \mathcal{M} = \frac{dRT}{P}$$

5.11 Relating the total pressure of a gas mixture to the partial pressures of the components (Dalton's law of partial pressures) (196):

$$P_{total} = P_1 + P_2 + P_3 + \cdots$$

5.12 Relating partial pressure to mole fraction (196):

$$P_A = X_A \times P_{total}$$

5.13 Defining rms speed as a function of molar mass and temperature (204):

$$u_{rms} = \sqrt{\frac{3RT}{\mathcal{M}}}$$

5.14 Applying Graham's law of effusion (205):

$$\frac{\text{Rate}_A}{\text{Rate}_B} = \frac{\sqrt{\mathcal{M}_B}}{\sqrt{\mathcal{M}_A}} = \sqrt{\frac{\mathcal{M}_B}{\mathcal{M}_A}}$$

Brief Solutions to Follow-up Problems

5.1 $P_{CO_2}\,(\text{torr}) = (753.6\ \text{mmHg} - 174.0\ \text{mmHg}) \times \dfrac{1\ \text{torr}}{1\ \text{mmHg}}$

$= 579.6\ \text{torr}$

$P_{CO_2}\,(\text{Pa}) = 579.6\ \text{torr} \times \dfrac{1\ \text{atm}}{760\ \text{torr}} \times \dfrac{1.01325\times10^5\ \text{Pa}}{1\ \text{atm}}$

$= 7.727\times10^4\ \text{Pa}$

$P_{CO_2}\,(\text{lb/in}^2) = 579.6\ \text{torr} \times \dfrac{1\ \text{atm}}{760\ \text{torr}} \times \dfrac{14.7\ \text{lb/in}^2}{1\ \text{atm}}$

$= 11.2\ \text{lb/in}^2$

5.2 $P_2\,(\text{atm}) = 26.3\ \text{kPa} \times \dfrac{1\ \text{atm}}{101.325\ \text{kPa}} = 0.260\ \text{atm}$

$V_2\,(\text{L}) = 105\ \text{mL} \times \dfrac{1\ \text{L}}{1000\ \text{mL}} \times \dfrac{0.871\ \text{atm}}{0.260\ \text{atm}} = 0.352\ \text{L}$

5.3 $T_2\,(\text{K}) = 273\ \text{K} \times \dfrac{9.75\ \text{cm}^3}{6.83\ \text{cm}^3} = 390.\ \text{K}$

5.4 $P_2\,(\text{torr}) = 793\ \text{torr} \times \dfrac{35.0\ \text{g} - 5.0\ \text{g}}{35.0\ \text{g}} = 680.\ \text{torr}$

(There is no need to convert mass to moles because the ratio of masses equals the ratio of moles.)

5.5 $n = \dfrac{PV}{RT} = \dfrac{1.37\ \text{atm} \times 438\ \text{L}}{0.0821\ \dfrac{\text{atm·L}}{\text{mol·K}} \times 294\ \text{K}} = 24.9\ \text{mol O}_2$

$\text{Mass (g) of O}_2 = 24.9\ \text{mol O}_2 \times \dfrac{32.00\ \text{g O}_2}{1\ \text{mol O}_2} = 7.97\times10^2\ \text{g O}_2$

5.6 The balanced equation is $2\text{CD} \longrightarrow \text{C}_2 + \text{D}_2$, so n does not change. Therefore, given constant P, the absolute temperature T must double: $T_1 = -73°\text{C} + 273.15 = 200\ \text{K}$; so $T_2 = 400\ \text{K}$, or $400\ \text{K} - 273.15 = 127°\text{C}$.

5.7 $d\ (\text{at } 0°\text{C and } 380\ \text{torr}) = \dfrac{44.01\ \text{g/mol} \times \dfrac{380\ \text{torr}}{760\ \text{torr/atm}}}{0.0821\ \dfrac{\text{atm·L}}{\text{mol·K}} \times 273\ \text{K}}$

$= 0.982\ \text{g/L}$

The density is lower at the smaller P because V is larger. In this case, d is lowered by one-half because P is one-half as much.

5.8 $\mathcal{M} = \dfrac{1.26\ \text{g} \times 0.0821\ \dfrac{\text{atm·L}}{\text{mol·K}} \times 283.2\ \text{K}}{\dfrac{102.5\ \text{kPa}}{101.325\ \text{kPa/1 atm}} \times 1.00\ \text{L}} = 29.0\ \text{g/mol}$

5.9 $n_{\text{total}} = \left(5.50\ \text{g He} \times \dfrac{1\ \text{mol He}}{4.003\ \text{g He}}\right) + \left(15.0\ \text{g Ne} \times \dfrac{1\ \text{mol Ne}}{20.18\ \text{g Ne}}\right) + \left(35.0\ \text{g Kr} \times \dfrac{1\ \text{mol Kr}}{83.80\ \text{g Kr}}\right)$

$= 2.53\ \text{mol}$

$P_{\text{He}} = \left(\dfrac{5.50\ \text{g He} \times \dfrac{1\ \text{mol He}}{4.003\ \text{g He}}}{2.53\ \text{mol}}\right) \times 1\ \text{atm} = 0.543\ \text{atm}$

$P_{\text{Ne}} = 0.294\ \text{atm} \qquad P_{\text{Kr}} = 0.165\ \text{atm}$

5.10 $P_{H_2} = 752\ \text{torr} - 13.6\ \text{torr} = 738\ \text{torr}$

$\text{Mass (g) of H}_2 = \left(\dfrac{\dfrac{738\ \text{torr}}{760\ \text{torr/atm}} \times 1.495\ \text{L}}{0.0821\ \dfrac{\text{atm·L}}{\text{mol·K}} \times 289\ \text{K}}\right) \times \dfrac{2.016\ \text{g H}_2}{1\ \text{mol H}_2}$

$= 0.123\ \text{g H}_2$

5.11 $\text{H}_2\text{SO}_4(aq) + 2\text{NaCl}(s) \longrightarrow \text{Na}_2\text{SO}_4(aq) + 2\text{HCl}(g)$

$n_{\text{HCl}} = 0.117\ \text{kg NaCl} \times \dfrac{10^3\ \text{g}}{1\ \text{kg}} \times \dfrac{1\ \text{mol NaCl}}{58.44\ \text{g NaCl}} \times \dfrac{2\ \text{mol HCl}}{2\ \text{mol NaCl}}$

$= 2.00\ \text{mol HCl}$

$\text{At STP, } V\,(\text{mL}) = 2.00\ \text{mol} \times \dfrac{22.4\ \text{L}}{1\ \text{mol}} \times \dfrac{10^3\ \text{mL}}{1\ \text{L}}$

$= 4.48\times10^4\ \text{mL}$

5.12 $\text{NH}_3(g) + \text{HCl}(g) \longrightarrow \text{NH}_4\text{Cl}(s)$

$n_{\text{NH}_3} = 0.187\ \text{mol} \qquad n_{\text{HCl}} = 0.0522\ \text{mol}$

n_{NH_3} after reaction

$= 0.187\ \text{mol NH}_3 - \left(0.0522\ \text{mol HCl} \times \dfrac{1\ \text{mol NH}_3}{1\ \text{mol HCl}}\right)$

$= 0.135\ \text{mol NH}_3$

$P = \dfrac{0.135\ \text{mol} \times 0.0821\ \dfrac{\text{atm·L}}{\text{mol·K}} \times 295\ \text{K}}{10.0\ \text{L}} = 0.327\ \text{atm}$

5.13 $\dfrac{\text{Rate of He}}{\text{Rate of C}_2\text{H}_6} = \sqrt{\dfrac{30.07\ \text{g/mol}}{4.003\ \text{g/mol}}} = 2.741$

Time for C_2H_6 to effuse $= 1.25\ \text{min} \times 2.741 = 3.43\ \text{min}$

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

An Overview of the Physical States of Matter

Concept Review Questions

5.1 How does a sample of gas differ in its behavior from a sample of liquid in each of the following situations?
(a) The sample is transferred from one container to a larger one.
(b) The sample is heated in an expandable container, but no change of state occurs.
(c) The sample is placed in a cylinder with a piston, and an external force is applied.

5.2 Are the particles in a gas farther apart or closer together than the particles in a liquid? Use your answer to this question in order to explain each of the following general observations:
(a) Gases are more compressible than liquids.
(b) Gases have lower viscosities than liquids.
(c) After thorough stirring, all gas mixtures are solutions.
(d) The density of a substance in the gas state is lower than in the liquid state.

Gas Pressure and Its Measurement

(Sample Problem 5.1)

Concept Review Questions

5.3 How does a barometer work? Is the column of mercury in a barometer shorter when it is on a mountaintop or at sea level? Explain.

5.4 How can a unit of length such as millimeter of mercury (mmHg) be used as a unit of pressure, which has the dimensions of force per unit area?

5.5 In a closed-end manometer, the mercury level in the arm attached to the flask can never be higher than the mercury level in the other arm, whereas in an open-end manometer, it *can* be higher. Explain.

Skill-Building Exercises *(grouped in similar pairs)*

5.6 On a cool, rainy day, the barometric pressure is 725 mmHg. Calculate the barometric pressure in centimeters of water (cmH_2O) (d of Hg = 13.5 g/mL; d of H_2O = 1.00 g/mL).

5.7 A long glass tube, sealed at one end, has an inner diameter of 10.0 mm. The tube is filled with water and inverted into a pail of water. If the atmospheric pressure is 755 mmHg, how high (in mmH_2O) is the column of water in the tube (d of Hg = 13.5 g/mL; d of H_2O = 1.00 g/mL)?

5.8 Convert the following:
(a) 0.745 atm to mmHg
(b) 992 torr to bar
(c) 365 kPa to atm
(d) 804 mmHg to kPa

5.9 Convert the following:
(a) 74.8 cmHg to atm
(b) 27.0 atm to kPa
(c) 8.50 atm to bar
(d) 0.907 kPa to torr

5.10 In Figure P5.10, what is the pressure of the gas in the flask (in atm) if the barometer reads 738.5 torr?

5.11 In Figure P5.11, what is the pressure of the gas in the flask (in kPa) if the barometer reads 765.2 mmHg?

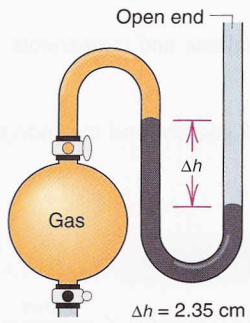

Figure P5.10

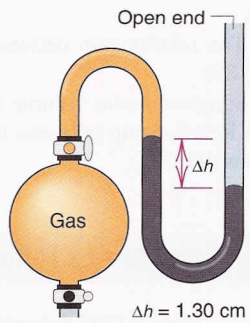

Figure P5.11

5.12 If the sample flask in Figure P5.12 is open to the air, what is the atmospheric pressure in atmospheres?

5.13 What is the pressure in pascals of the gas in the flask in Figure P5.13?

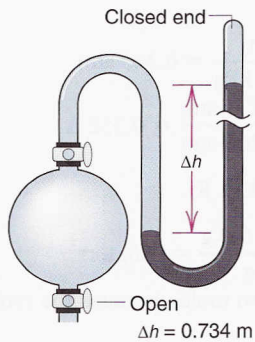

Figure P5.12

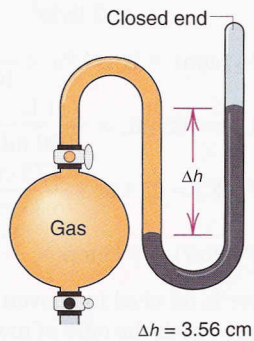

Figure P5.13

Problems in Context

5.14 Convert each of the pressures described below into atmospheres:
(a) At the peak of Mt. Everest, atmospheric pressure is only 2.75×10^2 mmHg.
(b) A cyclist fills her bike tires to 91 psi.
(c) The surface of Venus has an atmospheric pressure of 9.15×10^6 Pa.
(d) At 100 ft below sea level, a scuba diver experiences a pressure of 2.44×10^4 torr.

5.15 The gravitational force exerted by an object is given by $F = mg$, where F is the force in newtons, m is the mass in kilograms, and g is the acceleration due to gravity (9.81 m/s^2).
(a) Use the definition of the pascal to calculate the mass (in kg) of the atmosphere on 1 m^2 of ocean.
(b) Osmium (Z = 76) has the highest density of any element (22.6 g/mL). If an osmium column is 1 m^2 in area, how high must it be for its pressure to equal atmospheric pressure? [Use the answer from part (a) in your calculation.]

The Gas Laws and Their Experimental Foundations
(Sample Problems 5.2 to 5.6)

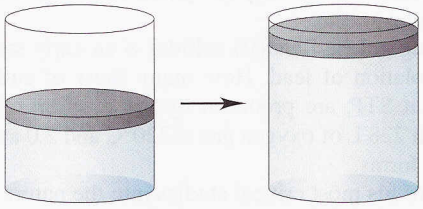
Concept Review Questions

5.16 When asked to state Boyle's law, a student replies, "The volume of a gas is inversely proportional to its pressure." How is this statement incomplete? Give a correct statement of Boyle's law.

5.17 Which quantities are variables and which are fixed in each of the following laws: (a) Charles's law; (b) Avogadro's law; (c) Amontons's law?

5.18 Boyle's law relates gas volume to pressure, and Avogadro's law relates gas volume to number of moles. State a relationship between gas pressure and number of moles.

5.19 Each of the following processes caused the gas volume to double, as shown. For each process, state how the remaining gas variable changed or that it remained fixed:
(a) T doubles at fixed P
(b) T and n are fixed
(c) At fixed T, the reaction is $CD_2 \longrightarrow C + D_2$
(d) At fixed P, the reaction is $A_2 + B_2 \longrightarrow 2AB$



Skill-Building Exercises *(grouped in similar pairs)*

5.20 What is the effect of the following on the volume of 1 mol of an ideal gas?
(a) The pressure is tripled (at constant T).
(b) The absolute temperature is increased by a factor of 2.5 (at constant P).
(c) Two more moles of the gas are added (at constant P and T).

5.21 What is the effect of the following on the volume of 1 mol of an ideal gas?
(a) The pressure is reduced by a factor of 4 (at constant T).
(b) The pressure changes from 760 torr to 202 kPa, and the temperature changes from 37°C to 155 K.
(c) The temperature changes from 305 K to 32°C, and the pressure changes from 2 atm to 101 kPa.

5.22 What is the effect of the following on the volume of 1 mol of an ideal gas?
(a) The temperature is decreased from 700 K to 350 K (at constant P).
(b) The temperature is increased from 350°C to 700°C (at constant P).
(c) The pressure is increased from 2 atm to 8 atm (at constant T).

5.23 What is the effect of the following on the volume of 1 mol of an ideal gas?
(a) Half the gas escapes through a stopcock (at constant P and T).
(b) The initial pressure is 722 torr, and the final pressure is 0.950 atm; the initial temperature is 32°F, and the final temperature is 273 K.
(c) Both the pressure and temperature are reduced by one-fourth of their initial values.

5.24 A sample of sulfur hexafluoride gas occupies a volume of 5.10 L at 198°C. Assuming that the pressure remains constant, what temperature (in °C) is needed to reduce the volume to 2.50 L?

5.25 A 93-L sample of dry air is cooled from 145°C to −22°C while the pressure is maintained at 2.85 atm. What is the final volume?

5.26 A sample of Freon-12 (CF_2Cl_2) occupies 25.5 L at 298 K and 153.3 kPa. Find its volume at STP.

5.27 Calculate the volume of a sample of carbon monoxide that is at −14°C and 367 torr if it occupies 3.65 L at 298 K and 745 torr.

5.28 A sample of chlorine gas is confined in a 5.0-L container at 228 torr and 27°C. How many moles of gas are in the sample?

5.29 If 1.47×10^{-3} mol of argon occupies a 75.0-mL container at 26°C, what is the pressure (in torr)?

5.30 You have 207 mL of chlorine trifluoride gas at 699 mmHg and 45°C. What is the mass (in g) of the sample?

5.31 A 75.0-g sample of dinitrogen monoxide is confined in a 3.1-L vessel. What is the pressure (in atm) at 115°C?

Problems in Context

5.32 In preparation for a demonstration, your professor brings a 1.5-L bottle of sulfur dioxide into the lecture hall before class to allow the gas to reach room temperature. If the pressure gauge reads 85 psi and the lecture hall is 23°C, how many moles of sulfur dioxide are in the bottle? (*Hint:* The gauge reads zero when 14.7 psi of gas remains.)

5.33 A gas-filled weather balloon with a volume of 55.0 L is released at sea-level conditions of 755 torr and 23°C. The balloon can expand to a maximum volume of 835 L. When the balloon rises to an altitude at which the temperature is −5°C and the pressure is 0.066 atm, will it reach its maximum volume?

Further Applications of the Ideal Gas Law
(Sample Problems 5.7 to 5.10)

Concept Review Questions

5.34 Why is moist air less dense than dry air?

5.35 To collect a beaker of H_2 gas by displacing the air already in the beaker, would you hold the beaker upright or inverted? Why? How would you hold the beaker to collect CO_2?

5.36 Why can we use a gas mixture, such as air, to study the general behavior of an ideal gas under ordinary conditions?

5.37 How does the partial pressure of gas A in a mixture compare to its mole fraction in the mixture? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

5.38 What is the density of Xe gas at STP?

5.39 What is the density of Freon-11 ($CFCl_3$) at 120°C and 1.5 atm?

5.40 How many moles of gaseous arsine (AsH_3) will occupy 0.0400 L at STP? What is the density of gaseous arsine?

5.41 The density of a noble gas is 2.71 g/L at 3.00 atm and 0°C. Identify the gas.

5.42 Calculate the molar mass of a gas at 388 torr and 45°C if 206 ng occupies 0.206 μL.

5.43 When an evacuated 63.8-mL glass bulb is filled with a gas at 22°C and 747 mmHg, the bulb gains 0.103 g in mass. Is the gas N_2, Ne, or Ar?

5.44 When 0.600 L of Ar at 1.20 atm and 227°C is mixed with 0.200 L of O_2 at 501 torr and 127°C in a 400-mL flask at 27°C, what is the pressure in the flask?

5.45 A 355-mL container holds 0.146 g of Ne and an unknown amount of Ar at 35°C and a total pressure of 626 mmHg. Calculate the moles of Ar present.

Problems in Context

5.46 The air in a hot-air balloon at 744 torr is heated from 17°C to 60.0°C. Assuming that the moles of air and the pressure remain constant, what is the density of the air at each temperature? (The average molar mass of air is 28.8 g/mol.)

5.47 On a certain winter day in Utah, the average atmospheric pressure is 650. torr. What is the molar density (in mol/L) of air if the temperature is −25°C?

5.48 A sample of a liquid hydrocarbon known to consist of molecules with five carbon atoms is vaporized in a 0.204-L flask by immersion in a water bath at 101°C. The barometric pressure is 767 torr, and the remaining gas condenses to 0.482 g of liquid. What is the molecular formula of the hydrocarbon?

5.49 A sample of air contains 78.08% nitrogen, 20.94% oxygen, 0.05% carbon dioxide, and 0.93% argon, by volume. How many molecules of each gas are present in 1.00 L of the sample at 25°C and 1.00 atm?

5.50 An environmental chemist is sampling industrial exhaust gases from a coal-burning plant. He collects a CO_2-SO_2-H_2O mixture in a 21-L steel tank until the pressure reaches 850. torr at 45°C.

(a) How many moles of gas are collected?

(b) If the SO_2 concentration in the mixture is 7.95×10^3 parts per million by volume (ppmv), what is its partial pressure? [*Hint:* ppmv = (volume of component/volume of mixture) × 10^6.]

The Ideal Gas Law and Reaction Stoichiometry

(Sample Problems 5.11 and 5.12)

Skill-Building Exercises *(grouped in similar pairs)*

5.51 How many grams of phosphorus react with 35.5 L of O_2 at STP to form tetraphosphorus decaoxide?

$$P_4(s) + 5O_2(g) \longrightarrow P_4O_{10}(s)$$

5.52 How many grams of potassium chlorate decompose to potassium chloride and 638 mL of O_2 at 128°C and 752 torr?

$$2KClO_3(s) \longrightarrow 2KCl(s) + 3O_2(g)$$

5.53 How many grams of phosphine (PH_3) can form when 37.5 g of phosphorus and 83.0 L of hydrogen gas react at STP?

$$P_4(s) + H_2(g) \longrightarrow PH_3(g) \quad \text{[unbalanced]}$$

5.54 When 35.6 L of ammonia and 40.5 L of oxygen gas at STP burn, nitrogen monoxide and water are produced. After the products return to STP, how many grams of nitrogen monoxide are present?

$$NH_3(g) + O_2(g) \longrightarrow NO(g) + H_2O(l) \quad \text{[unbalanced]}$$

5.55 Aluminum reacts with excess hydrochloric acid to form aqueous aluminum chloride and 35.8 mL of hydrogen gas over water at 27°C and 751 mmHg. How many grams of aluminum reacted?

5.56 How many liters of hydrogen gas are collected over water at 18°C and 725 mmHg when 0.84 g of lithium reacts with water? Aqueous lithium hydroxide also forms.

Problems in Context

5.57 "Strike anywhere" matches contain the compound tetraphosphorus trisulfide, which burns to form tetraphosphorus decaoxide and sulfur dioxide gas. How many milliliters of sulfur dioxide, measured at 725 torr and 32°C, can be produced from burning 0.800 g of tetraphosphorus trisulfide?

5.58 Freon-12 (CF_2Cl_2), which has been widely used as a refrigerant and aerosol propellant, is a dangerous air pollutant. In the troposphere, it traps heat 25 times as effectively as CO_2, and in the stratosphere, it participates in the breakdown of ozone. Freon-12 is prepared industrially by reaction of gaseous carbon tetrachloride with hydrogen fluoride. Hydrogen chloride gas also forms. How many grams of carbon tetrachloride are required for the production of 16.0 dm^3 of Freon-12 at 27°C and 1.20 atm?

5.59 Xenon hexafluoride was one of the first noble gas compounds synthesized. The solid reacts rapidly with the silicon dioxide in glass or quartz containers to form liquid $XeOF_4$ and gaseous silicon tetrafluoride. What is the pressure in a 1.00-L container at 25°C after 2.00 g of xenon hexafluoride reacts? (Assume that silicon tetrafluoride is the only gas present and that it occupies the entire volume.)

5.60 Roasting galena [lead(II) sulfide] is an early step in the industrial isolation of lead. How many liters of sulfur dioxide, measured at STP, are produced by the reaction of 3.75 kg of galena with 228 L of oxygen gas at 220°C and 2.0 atm? Lead(II) oxide also forms.

5.61 In one of his most critical studies into the nature of combustion, Lavoisier heated mercury(II) oxide and isolated elemental mercury and oxygen gas. If 40.0 g of mercury(II) oxide is heated in a 502-mL vessel and 20.0% (by mass) decomposes, what is the pressure (in atm) of the oxygen that forms at 25.0°C? (Assume that the gas occupies the entire volume.)

The Kinetic-Molecular Theory: A Model for Gas Behavior

(Sample Problem 5.13)

Concept Review Questions

5.62 Use the kinetic-molecular theory to explain the change in gas pressure that results from warming a sample of gas.

5.63 How does the kinetic-molecular theory explain why 1 mol of krypton and 1 mol of helium have the same volume at STP?

5.64 Is the rate of effusion of a gas higher than, lower than, or equal to its rate of diffusion? Explain. For two gases with molecules of approximately the same size, is the ratio of their effusion rates higher than, lower than, or equal to the ratio of their diffusion rates? Explain.

5.65 Consider two 1-L samples of gas: one is H_2 and the other is O_2. Both are at 1 atm and 25°C. How do the samples compare in terms of (a) mass, (b) density, (c) mean free path, (d) average molecular kinetic energy, (e) average molecular speed, and (f) time for a given fraction of molecules to effuse?

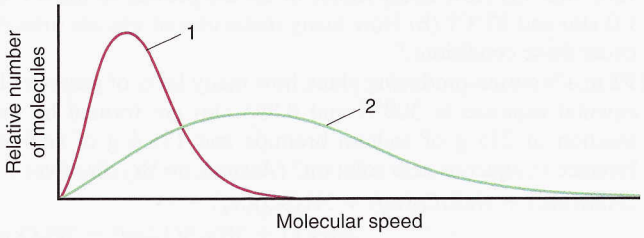
5.66 Three 5-L flasks, fixed with pressure gauges and small valves, each contain 4 g of gas at 273 K. Flask A contains H_2, flask B contains He, and flask C contains CH_4. Rank the flask contents in terms of (a) pressure, (b) average molecular kinetic energy, (c) diffusion rate after the valve is opened, (d) total kinetic energy of the molecules, (e) density, and (f) collision frequency.

Skill-Building Exercises *(grouped in similar pairs)*

5.67 What is the ratio of effusion rates for the lightest gas, H_2, and the heaviest known gas, UF_6?

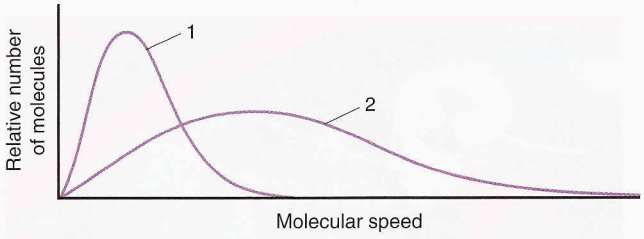
5.68 What is the ratio of effusion rates for O_2 and Kr?

5.69 The graph below shows the distribution of molecular speeds for argon and helium at the same temperature.



(a) Does curve 1 or 2 better represent the behavior of argon?
(b) Which curve represents the gas that effuses more slowly?
(c) Which curve more closely represents the behavior of fluorine gas? Explain.

5.70 The graph below shows the distribution of molecular speeds for a gas at two different temperatures.



(a) Does curve 1 or 2 better represent the behavior of the gas at the lower temperature?
(b) Which curve represents the sample with the higher $\overline{E_k}$?
(c) Which curve represents the sample that diffuses more quickly?

5.71 At a given pressure and temperature, it takes 4.55 min for a 1.5-L sample of He to effuse through a membrane. How long does it take for 1.5 L of F_2 to effuse under the same conditions?

5.72 A sample of an unknown gas effuses in 11.1 min. An equal volume of H_2 in the same apparatus at the same temperature and pressure effuses in 2.42 min. What is the molar mass of the unknown gas?

Problems in Context

5.73 Solid white phosphorus melts and then vaporizes at high temperature. Gaseous white phosphorus effuses at a rate that is 0.404 times that of neon in the same apparatus under the same conditions. How many atoms are in a molecule of gaseous white phosphorus?

5.74 Helium is the lightest noble gas component of air, and xenon is the heaviest. [For this problem, use $R = 8.314$ J/(mol·K) and $\mathcal{M}$ in kg/mol.]
(a) Calculate the rms speed of helium in winter (0.°C) and in summer (30.°C).
(b) Compare the rms speed of helium with that of xenon at 30.°C.
(c) Calculate the average kinetic energy per mole of helium and of xenon at 30.°C.
(d) Calculate the average kinetic energy per molecule of helium at 30.°C.

Real Gases: Deviations from Ideal Behavior

Skill-Building Exercises *(grouped in similar pairs)*

5.75 Do intermolecular attractions cause negative or positive deviations from the *PV/RT* ratio of an ideal gas? Use data from Table 5.5 to rank Kr, CO_2, and N_2 in order of increasing magnitude of these deviations.

5.76 Does molecular size cause negative or positive deviations from the *PV/RT* ratio of an ideal gas? Use data from Table 5.5 to rank Cl_2, H_2, and O_2 in order of increasing magnitude of these deviations.

5.77 Does N_2 behave more ideally at 1 atm or at 500 atm? Explain.

5.78 Does SF_6 (boiling point = 16°C at 1 atm) behave more ideally at 150°C or at 20°C? Explain.

Comprehensive Problems

5.79 An "empty" gasoline can with dimensions 15.0 cm by 40.0 cm by 12.5 cm is attached to a vacuum pump and evacuated. If the atmospheric pressure is 14.7 lb/in^2, what is the total force (in pounds) on the outside of the can?

5.80 Hemoglobin is the protein that transports O_2 through the blood from the lungs to the rest of the body. In doing so, each molecule of hemoglobin combines with four molecules of O_2. If 1.00 g of hemoglobin combines with 1.53 mL of O_2 at 37°C and 743 torr, what is the molar mass of hemoglobin?

5.81 A baker uses sodium hydrogen carbonate (baking soda) as the leavening agent in a banana-nut quickbread. The baking soda decomposes according to two possible reactions:

Reaction 1. $2NaHCO_3(s) \longrightarrow Na_2CO_3(s) + H_2O(l) + CO_2(g)$

Reaction 2. $NaHCO_3(s) + H^+(aq) \longrightarrow H_2O(l) + CO_2(g) + Na^+(aq)$

Calculate the volume (in mL) of CO_2 that forms at 200.°C and 0.975 atm per gram of $NaHCO_3$ by each of the reaction processes.

5.82 A weather balloon containing 600. L of He is released near the equator at 1.01 atm and 305 K. It rises to a point where conditions are 0.489 atm and 218 K and eventually lands in the northern hemisphere under conditions of 1.01 atm and 250 K. If one-fourth of the helium leaked out during this journey, what is the volume (in L) of the balloon at landing?

5.83 Chlorine is produced from concentrated seawater by the electrochemical chlor-alkali process. During the process, the chlorine is collected in a container that is isolated from the other products to prevent unwanted (and explosive) reactions. If a 15.00-L container holds 0.5850 kg of Cl_2 gas at 225°C, calculate

(a) P_{IGL} (b) P_{VDW} $\left(\text{use } R = 0.08206 \dfrac{\text{atm·L}}{\text{mol·K}}\right)$

5.84 In a certain experiment, magnesium boride (Mg_3B_2) reacted with acid to form a mixture of four boron hydrides (B_xH_y), three as liquids (labeled I, II, and III) and one as a gas (IV).
(a) When a 0.1000-g sample of each liquid was transferred to an evacuated 750.0-mL container and volatilized at 70.00°C, sample I had a pressure of 0.05951 atm, sample II 0.07045 atm, and sample III 0.05767 atm. What is the molar mass of each liquid?
(b) The mass of boron was found to be 85.63% in sample I, 81.10% in II, and 82.98% in III. What is the molecular formula of each sample?
(c) Sample IV was found to be 78.14% boron. Its rate of effusion was compared to that of sulfur dioxide and under identical

conditions, 350.0 mL of sample IV effused in 12.00 min and 250.0 mL of sulfur dioxide effused in 13.04 min. What is the molecular formula of sample IV?

5.85 Will the volume of a gas increase, decrease, or remain unchanged for each of the following sets of changes?
(a) The pressure is decreased from 2 atm to 1 atm, while the temperature is decreased from 200°C to 100°C.
(b) The pressure is increased from 1 atm to 3 atm, while the temperature is increased from 100°C to 300°C.
(c) The pressure is increased from 3 atm to 6 atm, while the temperature is increased from −73°C to 127°C.
(d) The pressure is increased from 0.2 atm to 0.4 atm, while the temperature is decreased from 300°C to 150°C.

5.86 When air is inhaled, it enters the alveoli of the lungs, and varying amounts of the component gases exchange with dissolved gases in the blood. The resulting alveolar gas mixture is quite different from the atmospheric mixture. The following table presents selected data on the composition and partial pressure of four gases in the atmosphere and in the alveoli:

	Atmosphere (sea level)		Alveoli	
Gas	Mol %	Partial Pressure (torr)	Mol %	Partial Pressure (torr)
N_2	78.6	—	—	569
O_2	20.9	—	—	104
CO_2	0.04	—	—	40
H_2O	0.46	—	—	47

If the total pressure of each gas mixture is 1.00 atm, calculate the following:
(a) The partial pressure (in torr) of each gas in the atmosphere
(b) The mol % of each gas in the alveoli
(c) The number of O_2 molecules in 0.50 L of alveolar air (volume of an average breath at rest) at 37°C

5.87 Radon (Rn) is the heaviest, and only radioactive, member of Group 8A(18) (noble gases). It is a product of the disintegration of heavier radioactive nuclei found in minute concentrations in many common rocks used for building and construction. In recent years, health concerns about the cancers caused from inhaled residential radon have grown. If 1.0×10^{15} atoms of radium (Ra) produce an average of 1.373×10^{4} atoms of Rn per second, how many liters of Rn, measured at STP, are produced per day by 1.0 g of Ra?

5.88 At 1400. mmHg and 286 K, a skin diver exhales a 208-mL bubble of air that is 77% N_2, 17% O_2, and 6.0% CO_2 by volume.
(a) How many milliliters would the volume of the bubble be if it were exhaled at the surface at 1 atm and 298 K?
(b) How many moles of N_2 are in the bubble?

5.89 The mass of Earth's atmosphere is estimated as 5.14×10^{15} t (1 t = 1000 kg).
(a) The average molar mass of air is 28.8 g/mol. How many moles of gas are in the atmosphere?
(b) How many liters would the atmosphere occupy at 25°C and 1 atm?
(c) If the surface area of Earth is 5.100×10^{8} km^2, how high should this volume of air extend? Why does the atmosphere actually extend much higher?

5.90 Nitrogen dioxide is used industrially to produce nitric acid, but it contributes to acid rain and photochemical smog. What volume of nitrogen dioxide is formed at 735 torr and 28.2°C by reacting 4.95 cm^3 of copper (d = 8.95 g/cm^3) with 230.0 mL of nitric acid (d = 1.42 g/cm^3, 68.0% HNO_3 by mass):

$$Cu(s) + 4HNO_3(aq) \longrightarrow Cu(NO_3)_2(aq) + 2NO_2(g) + 2H_2O(l)$$

5.91 In the average adult male, the residual volume (RV) of the lungs, the volume of air remaining after a forced exhalation, is 1200 mL. (a) How many moles of air are present in the RV at 1.0 atm and 37°C? (b) How many molecules of gas are present under these conditions?

5.92 In a bromine-producing plant, how many liters of gaseous elemental bromine at 300°C and 0.855 atm are formed by the reaction of 275 g of sodium bromide and 175.6 g of sodium bromate in aqueous acid solution? (Assume no Br_2 dissolves.)

$$5NaBr(aq) + NaBrO_3(aq) + 3H_2SO_4(aq) \longrightarrow 3Br_2(g) + 3Na_2SO_4(aq) + 3H_2O(g)$$

5.93 In a collision of sufficient force, automobile air bags respond by electrically triggering the explosive decomposition of sodium azide (NaN_3) to its elements. A 50.0-g sample of sodium azide was decomposed, and the nitrogen gas generated was collected over water at 26°C. The total pressure was 745.5 mmHg. How many liters of dry N_2 were generated?

5.94 An anesthetic gas contains 64.81% carbon, 13.60% hydrogen, and 21.59% oxygen, by mass. If 2.00 L of the gas at 25°C and 0.420 atm weighs 2.57 g, what is the molecular formula of the anesthetic?

5.95 Aluminum chloride is easily vaporized at temperatures above 180°C. The gas escapes through a pinhole 0.122 times as fast as helium at the same conditions of temperature and pressure in the same apparatus. What is the molecular formula of gaseous aluminum chloride?

5.96 (a) What is the total volume of gaseous *products*, measured at 350°C and 735 torr, when an automobile engine burns 100. g of C_8H_{18} (a typical component of gasoline)?
(b) For part (a), the source of O_2 is air, which is about 78% N_2, 21% O_2, and 1.0% Ar by volume. Assuming all the O_2 reacts, but none of the N_2 or Ar does, what is the total volume of gaseous *exhaust*?

5.97 An atmospheric chemist studying the reactions of the pollutant SO_2 places a mixture of SO_2 and O_2 in a 2.00-L container at 900. K and an initial pressure of 1.95 atm. When the reaction occurs, gaseous SO_3 forms, and the pressure eventually falls to 1.65 atm. How many moles of SO_3 form?

5.98 Liquid nitrogen trichloride is heated in a 2.50-L closed reaction vessel until it decomposes completely to gaseous elements. The resulting mixture exerts a pressure of 754 mmHg at 95°C.
(a) What is the partial pressure of each gas in the container?
(b) What is the mass of the original sample?

5.99 Ammonium nitrate, a common fertilizer, is used as an explosive in fireworks and by terrorists. It was the material used in the tragic explosion of the Oklahoma City federal building in 1995. How many liters of gas at 307°C and 1.00 atm are formed by the explosive decomposition of 15.0 kg of ammonium nitrate to nitrogen, oxygen, and water vapor?

5.100 An environmental engineer analyzes a sample of air contaminated with sulfur dioxide. To a 500.-mL sample at 700. torr and 38°C, she adds 20.00 mL of 0.01017 *M* aqueous iodine, which reacts as follows:

$$SO_2(g) + I_2(aq) + H_2O(l) \longrightarrow HSO_4^-(aq) + I^-(aq) + H^+(aq) \quad \text{[unbalanced]}$$

Excess I_2 reacts with 11.37 mL of 0.0105 *M* sodium thiosulfate:

$$I_2(aq) + S_2O_3^{2-}(aq) \longrightarrow I^-(aq) + S_4O_6^{2-}(aq) \quad \text{[unbalanced]}$$

What is the volume % of SO_2 in the air sample?

5.101 Canadian chemists have developed a modern variation of the 1899 Mond process for preparing extremely pure metallic nickel. A sample of impure nickel reacts with carbon monoxide at 50°C to form gaseous nickel carbonyl, $Ni(CO)_4$.

(a) How many grams of nickel can be converted to the carbonyl with 3.55 m^3 of CO at 100.7 kPa?

(b) The carbonyl is then decomposed at 21 atm and 155°C to pure (>99.95%) nickel. How many grams of nickel are obtained per cubic meter of the carbonyl?

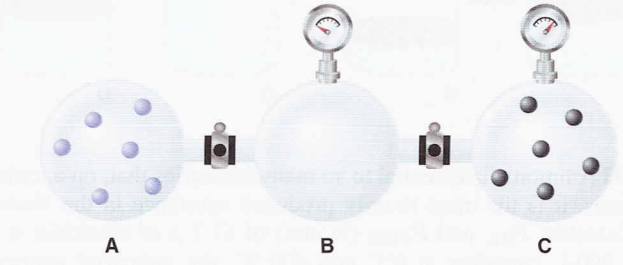
(c) The released carbon monoxide is cooled and collected for reuse by passing it through water at 35°C. If the barometric pressure is 769 torr, what volume (in m^3) of CO is formed per cubic meter of carbonyl?

5.102 Analysis of a newly discovered gaseous silicon-fluorine compound shows that it contains 33.01 mass % silicon. At 27°C, 2.60 g of the compound exerts a pressure of 1.50 atm in a 0.250-L vessel. What is the molecular formula of the compound?

5.103 A gaseous organic compound containing only carbon, hydrogen, and nitrogen is burned in oxygen gas, and the individual volume of each reactant and product is measured under the same conditions of temperature and pressure. Reaction of four volumes of the compound produces four volumes of CO_2, two volumes of N_2, and ten volumes of water vapor. (a) What volume of oxygen gas was required? (b) What is the empirical formula of the compound?

5.104 A piece of dry ice (solid CO_2, d = 0.900 g/mL) weighing 10.0 g is placed in a 0.800-L bottle filled with air at 0.980 atm and 550.0°C. The bottle is capped, and the dry ice changes to gas. What is the final pressure inside the bottle?

5.105 Containers A, B, and C are attached by closed stopcocks of negligible volume.



If each particle shown in the picture represents 10^6 particles, (a) How many blue particles and black particles are in B after the stopcocks are opened and the system reaches equilibrium? (b) How many blue particles and black particles are in A after the stopcocks are opened and the system reaches equilibrium? (c) If the pressure in C, P_C, is 750 torr before the stopcocks are opened, what is P_C afterward? (d) What is P_B afterward?

5.106 At the temperatures that exist in the thermosphere (see Figure B5.1), instruments would break down and astronauts would be killed. Yet satellites function in orbit there for many years and astronauts routinely repair equipment on space walks. Explain.

5.107 By what factor would a scuba diver's lungs expand if she ascended rapidly to the surface from a depth of 125 ft without inhaling or exhaling? If an expansion factor greater than 1.5 causes lung rupture, how far could she safely ascend from 125 ft without breathing? Assume constant temperature (d of seawater = 1.04 g/mL; d of Hg = 13.5 g/mL).

5.108 When 15.0 g of fluorite (CaF_2) reacts with excess sulfuric acid, hydrogen fluoride gas is collected at 744 torr and 25.5°C. Solid calcium sulfate is the other product. What gas temperature is required to store the gas in an 8.63-L container at 875 torr?

5.109 Dilute aqueous hydrogen peroxide is used as a bleaching agent and for disinfecting surfaces and small cuts. Its concentration is sometimes given as a certain number of "volumes hydrogen peroxide," which refers to the number of volumes of O_2 gas, measured at STP, that a given volume of hydrogen peroxide solution will release when it decomposes to O_2 and liquid H_2O. How many grams of hydrogen peroxide are in 0.100 L of "20 volumes hydrogen peroxide" solution?

5.110 At a height of 300 km above Earth's surface, an astronaut finds that the atmospheric pressure is about 10^{-8} mmHg and the temperature is 500 K. How many molecules of gas are there per milliliter at this altitude?

5.111 (a) What is the rms speed of O_2 molecules at STP? (b) If the mean free path of O_2 molecules at STP is 6.33×10^{-8} m, what is their collision frequency? [Use R = 8.314 J/(mol·K) and $\mathcal{M}$ in kg/mol.]

5.112 Standard conditions are based on relevant environmental conditions. If normal average surface temperature and pressure on Venus are 730. K and 90 atm, respectively, what is the standard molar volume of an ideal gas on Venus?

5.113 A barometer tube is 1.00×10^2 cm long and has a cross-sectional area of 1.20 cm^2. The height of the mercury column is 74.0 cm, and the temperature is 24°C. A small amount of N_2 is introduced into the evacuated space above the mercury, which causes the mercury level to drop to a height of 66.0 cm. How many grams of N_2 were introduced?

5.114 What is the molar concentration of the cleaning solution formed when 10.0 L of ammonia gas at 31°C and 735 torr dissolves in enough water to give a final volume of 0.750 L?

5.115 The Hawaiian volcano Kilauea emits an average of 1.5×10^3 m^3 of gas each day, when corrected to 298 K and 1.00 atm. The mixture contains gases that contribute to global warming and acid rain, and some are toxic. An atmospheric chemist analyzes a sample and finds the following mole fractions: 0.4896 CO_2, 0.0146 CO, 0.3710 H_2O, 0.1185 SO_2, 0.0003 S_2, 0.0047 H_2, 0.0008 HCl, and 0.0003 H_2S. How many metric tons (t) of each gas is emitted per year (1 t = 1000 kg)?

5.116 To study a key fuel-cell reaction, a chemical engineer has 20.0-L tanks of H_2 and of O_2 and wants to use up both tanks to form 28.0 mol of water at 23.8°C. (a) Use the ideal gas law to find the pressure needed in each tank. (b) Use the van der Waals

equation to find the pressure needed in each tank. (c) Compare the results from the two equations.

5.117 For each of the following, which shows the greater deviation from ideal behavior at the same set of conditions? Explain your choice.

(a) Argon or xenon (b) Water vapor or neon
(c) Mercury vapor or radon (d) Water vapor or methane

5.118 How many liters of gaseous hydrogen bromide at 27°C and 0.975 atm will a chemist need if she wishes to prepare 3.50 L of 1.20 *M* hydrobromic acid?

5.119 A mixture consisting of 7.0 g of CO and 10.0 g of SO_2, two atmospheric pollutants, has a pressure of 0.33 atm when placed in a sealed container. What is the partial pressure of CO?

5.120 Sulfur dioxide is used primarily to make sulfuric acid. One method of producing it is by roasting mineral sulfides, for example,

$$FeS_2(s) + O_2(g) \longrightarrow SO_2(g) + Fe_2O_3(s) \quad \text{[unbalanced]}$$

A production error leads to the sulfide being placed in a 950-L vessel with insufficient oxygen. The partial pressure of O_2 is 0.64 atm and the total pressure is initially 1.05 atm, with the balance N_2. The reaction is run until 85% of the O_2 is consumed, and the vessel is then cooled to its initial temperature. What is the total pressure and partial pressure of each gas in the vessel?

5.121 A mixture of CO_2 and Kr weighs 35.0 g and exerts a pressure of 0.708 atm in its container. Since Kr is expensive, you wish to recover it from the mixture. After the CO_2 is completely removed by absorption with NaOH(*s*), the pressure in the container is 0.250 atm. How many grams of CO_2 were originally present? How many grams of Kr can you recover?

5.122 When a car accelerates quickly, the passengers feel a force that presses them back into their seats, but a balloon filled with helium floats forward. Why?

5.123 Gases such as CO are gradually oxidized in the atmosphere, not by O_2 but by the hydroxyl radical, ·OH, a hydroxide ion with one fewer electron. At night, the radical's concentration is nearly zero, but during the day, it increases to 8.0×10^{12} molecules/m^3. At daytime conditions of 1.00 atm and 22°C, what is the partial pressure and mole percent of the hydroxyl radical?

5.124 Aqueous sulfurous acid (H_2SO_3) was made by dissolving 0.200 L of sulfur dioxide gas at 20.°C and 740. mmHg in water to yield 500.0 mL of solution. The acid solution required 10.0 mL of sodium hydroxide solution to reach the titration end point. What was the molarity of the sodium hydroxide solution?

5.125 During World War II, a portable source of hydrogen gas was needed for weather balloons, and solid metal hydrides were the most convenient form. Many metal hydrides react with water to generate the metal hydroxide and hydrogen. Two candidates were lithium hydride and magnesium hydride. What volume of gas is formed from 1.00 lb of each hydride at 750. torr and 27°C?

5.126 The lunar surface reaches 370 K at midday. The atmosphere consists of neon, argon, and traces of helium at a total pressure of only 2×10^{-14} atm. Calculate the rms speed of each component in the lunar atmosphere. [Use $R = 8.314$ J/(mol·K) and $\mathcal{M}$ in kg/mol.]

5.127 A person inhales air richer in O_2 and exhales air richer in CO_2 and water vapor. During each hour of sleep, a person exhales a total of about 300 L of this CO_2-enriched and H_2O-enriched air. (a) If the partial pressures of CO_2 and H_2O in exhaled air are each 30.0 torr at 37.0°C, calculate the masses of CO_2 and of H_2O exhaled in 1 h of sleep. (b) How many grams of body mass does the person lose in an 8-h sleep if all the CO_2 and H_2O exhaled come from the metabolism of glucose?

$$C_6H_{12}O_6(s) + 6O_2(g) \longrightarrow 6CO_2(g) + 6H_2O(g)$$

5.128 Popcorn pops because the horny endosperm, a tough, elastic material, resists gas pressure within the heated kernel until it reaches explosive force. A 0.25-mL kernel has a water content of 1.5% by mass, and the water vapor reaches 175°C and 9.0 atm before the kernel ruptures. Assume the water vapor can occupy 75% of the kernel's volume. (a) What is the mass of the kernel? (b) How many milliliters would this amount of water vapor occupy at 25°C and 1.00 atm?

5.129 Sulfur dioxide emissions from coal-based power plants are removed by *flue-gas desulfurization*. The flue gas passes through a scrubber, and a slurry of wet calcium carbonate reacts with it to form carbon dioxide and calcium sulfite. The calcium sulfite then reacts with oxygen to form calcium sulfate, which is sold as gypsum. (a) If the sulfur dioxide concentration is 1000 times higher than its mole fraction in clean dry air (2×10^{-10}), how much calcium sulfate (kg) can be made from scrubbing 4 GL of flue gas (1 GL $= 1\times10^9$ L)? A state-of-the-art scrubber removes at least 95% of the sulfur dioxide. (b) If the mole fraction of oxygen in air is 0.209, what volume (L) of air at 1.00 atm and 25°C is needed to react with all the calcium sulfite?

5.130 Given these relationships for average kinetic energy,

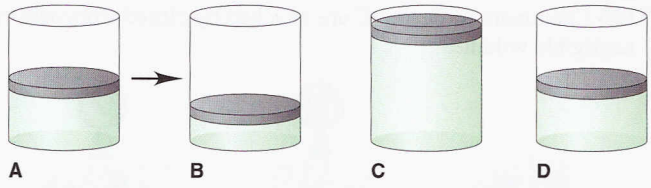
$$\overline{E_k} = \tfrac{1}{2}m\overline{u^2} \qquad \text{and} \qquad \overline{E_k} = \tfrac{3}{2}\left(\frac{R}{N_A}\right)T$$

where m is molecular mass, u is rms speed, R is the gas constant [in J/(mol·K)], N_A is Avogadro's number, and T is absolute temperature: (a) derive Equation 5.13; (b) derive Equation 5.14.

5.131 What would you observe if you tilted a barometer 30° from the vertical? Explain.

5.132 Cylinder A in the picture below contains 0.1 mol of a gas that behaves ideally. Choose the cylinder (B, C, or D) that correctly represents the volume of the gas after each of the following changes. If none of the cylinders is correct, specify "none":

(a) P is doubled at fixed n and T.
(b) T is reduced from 400 K to 200 K at fixed n and P.
(c) T is increased from 100°C to 200°C at fixed n and P.
(d) 0.1 mol of gas is added at fixed P and T.
(e) 0.1 mol of gas is added and P is doubled at fixed T.



5.133 Ammonia is essential to so many industries that, on a molar basis, it is the most heavily produced substance in the world. Calculate P_{IGL} and P_{VDW} (in atm) of 51.1 g of ammonia in a 3.000-L container at 0°C and 400.°C, the industrial temperature. (From Table 5.5, for NH_3, $a = 4.17$ atm·L^2/mol^2 and $b = 0.0371$ L/mol.)

5.134 A 6.0-L flask contains a mixture of methane (CH_4), argon, and helium at 45°C and 1.75 atm. If the mole fractions of helium and argon are 0.25 and 0.35, respectively, how many molecules of methane are present?

5.135 A large portion of metabolic energy arises from the biological combustion of glucose:

$$C_6H_{12}O_6(s) + 6O_2(g) \longrightarrow 6CO_2(g) + 6H_2O(g)$$

(a) If this reaction is carried out in an expandable container at 35°C and 780. torr, what volume of CO_2 is produced from 18.0 g of glucose and excess O_2? (b) If the reaction is carried out at the same conditions with the stoichiometric amount of O_2, what is the partial pressure of each gas when the reaction is 50% complete (9.0 g of glucose remains)?

5.136 What is the average kinetic energy and rms speed of N_2 molecules at STP? Compare these values with those of H_2 molecules at STP. [Use $R = 8.314$ J/(mol·K) and $\mathcal{M}$ in kg/mol.]

5.137 According to the American Conference of Governmental Industrial Hygienists, the *8-h threshold limit value* is 5000 ppmv for CO_2 and 0.1 ppmv for Br_2 (1 ppmv is 1 part by volume in 10^6 parts by volume). Exposure to either gas for 8 h above these limits is unsafe. At STP, which of the following would be unsafe for 8 h of exposure?

(a) Air with a partial pressure of 0.2 torr of Br_2
(b) Air with a partial pressure of 0.2 torr of CO_2
(c) 1000 L of air containing 0.0004 g of Br_2 gas
(d) 1000 L of air containing 2.8×10^{22} molecules of CO_2

5.138 One way to prevent emission of the pollutant NO from industrial plants is by reaction with NH_3:

$$4NH_3(g) + 4NO(g) + O_2(g) \longrightarrow 4N_2(g) + 6H_2O(g)$$

(a) If the NO has a partial pressure of 4.5×10^{-5} atm in the flue gas, how many liters of NH_3 are needed per liter of flue gas at 1.00 atm? (b) If the reaction takes place at 1.00 atm and 150°C, how many grams of NH_3 are needed per kL of flue gas?

5.139 An equimolar mixture of Ne and Xe is accidentally placed in a container that has a tiny leak. After a short while, a very small proportion of the mixture has escaped. What is the mole fraction of Ne in the effusing gas?

5.140 One way to utilize naturally occurring uranium (0.72% ^{235}U and 99.27% ^{238}U) as a nuclear fuel is to enrich it (increase its ^{235}U content) by allowing gaseous UF_6 to effuse through a porous membrane (see the margin note, p. 205). From the relative rates of effusion of $^{235}UF_6$ and $^{238}UF_6$, find the number of steps needed to produce uranium that is 3.0 mole % ^{235}U, the enriched fuel used in many nuclear reactors.

5.141 A slight deviation from ideal behavior exists even at normal conditions. If it behaved ideally, 1 mol of CO would occupy 22.414 L and exert 1 atm pressure at 273.15 K. Calculate P_{VDW} for 1.000 mol of CO at 273.15 K. $\left(\text{Use } R = 0.08206 \dfrac{\text{atm·L}}{\text{mol·K}}.\right)$

5.142 In preparation for a combustion demonstration, a professor's assistant fills a balloon with equal molar amounts of H_2 and O_2, but the demonstration has to be postponed until the next day. During the night, both gases leak through pores in the balloon. If 45% of the H_2 leaks, what is the O_2/H_2 ratio in the balloon the next day?

5.143 Phosphorus trichloride is important in the manufacture of insecticides, fuel additives, and flame retardants. Phosphorus has only one naturally occurring isotope, ^{31}P, whereas chlorine has two, 75% ^{35}Cl and 25% ^{37}Cl. (a) What different molecular masses (amu) can be found for PCl_3? (b) Which is the most abundant? (c) What is the ratio of the effusion rates for heaviest/lightest PCl_3 molecules?

5.144 A truck tire has a volume of 208 L and is filled with air to 35.0 psi at 295 K. After a drive, the air heats up to 319 K. (a) If the tire volume is constant, what is the pressure? (b) If the tire volume increases 2.0%, what is the pressure? (c) If the tire leaks 1.5 g of air per minute and the temperature is constant, how many minutes will it take for the tire to reach the original pressure of 35.0 psi ($\mathcal{M}$ of air = 28.8 g/mol)?

5.145 Allotropes are different molecular forms of an element. Dioxygen (O_2) and ozone (O_3) are the allotropes of oxygen. (a) What is the density of each allotrope at 0°C and 760 torr? (b) Calculate the ratio of densities of O_3/O_2, and explain the significance of this number.

5.146 When gaseous F_2 and solid I_2 are heated to high temperatures, the I_2 sublimes and gaseous iodine heptafluoride forms. If 350. torr of F_2 and 2.50 g of solid I_2 are put into a 2.50-L container at 250. K and the container is heated to 550. K, what is the final pressure? What is the partial pressure of I_2 gas?

5.147 Many water treatment plants use chlorine gas to kill microorganisms before the water is released for residential use. A plant engineer has to maintain the chlorine pressure in a tank below the 85.0-atm rating and, to be safe, decides to fill the tank to 80.0% of this maximum pressure. (a) How many moles of Cl_2 gas can be kept in the 850.-L tank at 298 K if she uses the ideal gas law in the calculation? (b) What is the tank pressure if she uses the van der Waals equation for this amount of gas? (c) Did the engineer fill the tank to the desired pressure?

Primeval Thermochemistry A campfire in a cave is surely one of the earliest forms of controlled combustion. We focus in this chapter on the release or absorption of heat during a process. Understanding and measuring changes in the energy content of matter is crucial to the fate of Earth's atmosphere and modern society.

Whenever matter changes, whether chemically or physically, the energy content of the matter changes also. In the inferno of a forest fire, the wood and oxygen reactants contain more energy than the ash and gas products, and this difference in energy is *released* as heat and light. In contrast, some of the energy in a flash of lightning is *absorbed* when lower energy N_2 and O_2 in the air react to form higher energy NO. Energy is *absorbed* when snow melts and is *released* when water vapor condenses.

The production and utilization of energy in its many forms have an enormous impact on society. Some of the largest industries manufacture products that release, absorb, or limit the flow of energy. Common fuels—oil, wood, coal, and natural gas—release energy for heating and for powering combustion engines and steam turbines. Fertilizers help crops absorb solar energy and convert it to the chemical energy of food, which our bodies convert into other forms. Numerous plastic, fiberglass, and ceramic materials serve as insulators that limit the flow of energy.

IN THIS CHAPTER . . . We investigate the heat, or *thermal energy,* associated with changes in matter. First, we examine some basic ideas of **thermodynamics,** the study of heat and its transformations. (The discussion begins here and is continued in Chapter 20.) Our focus is on **thermochemistry,** the branch of thermodynamics that deals with the heat involved in chemical and physical change and especially with the concept of *enthalpy.* We describe how heat is measured in a calorimeter and how the quantity of heat released or absorbed is related to the amounts of substances involved in a reaction. You'll learn how to combine equations to obtain the heat change for another equation and see the importance of standard conditions in studying the heat change. The chapter ends with an overview of current and future energy sources and the conflicts between energy demand and environmental quality.

Concepts & Skills to Review

before you study this chapter

- energy and its interconversion (Section 1.1)
- distinction between heat and temperature (Section 1.5)
- nature of chemical bonding (Section 2.7)
- calculations of reaction stoichiometry (Section 3.4)
- properties of the gaseous state (Section 5.1)
- relation between kinetic energy and temperature (Section 5.6)

6.1 FORMS OF ENERGY AND THEIR INTERCONVERSION

As we discussed in Chapter 1, all energy is either potential or kinetic, and these forms are convertible from one to the other. An object has potential energy by virtue of its position and kinetic energy by virtue of its motion. The potential energy of a weight raised above the ground is converted to kinetic energy as it falls (see Figure 1.3, p. 7). When the weight hits the ground, it transfers some of that kinetic energy to the soil and pebbles, causing them to move, and thereby doing *work*. In addition, some of the transferred kinetic energy appears as *heat*, as it slightly warms the soil and pebbles. Thus, the potential energy of the weight is converted to kinetic energy, which is transferred to the ground as work and as heat.

Modern atomic theory allows us to consider other forms of energy—solar, electrical, nuclear, and chemical—as examples of potential and kinetic energy on the atomic and molecular scales. No matter what the details of the situation, *when energy is transferred from one object to another, it appears as work and/or as heat*. In this section, we examine this idea in terms of the loss or gain of energy that takes place during a chemical or physical change.

The System and Its Surroundings

In order to observe and measure a change in energy, we must first define the **system**—the part of the universe that we are going to focus on. The moment that we define the system, everything else relevant to the change is defined as the **surroundings.**

Wherever You Look, There Is a System
In the example of the weight hitting the ground, if we define the falling weight as the system, the soil and pebbles that are moved and warmed are the surroundings. An astronomer may define a galaxy as the system and nearby galaxies as the surroundings. An ecologist studying African wildlife can define a zebra herd as the system and other animals, plants, and water supplies as the surroundings. A microbiologist may define a certain cell as the system and the extracellular solution as the surroundings. Thus, in general, it is the experiment and the experimenter that define the system and the surroundings.

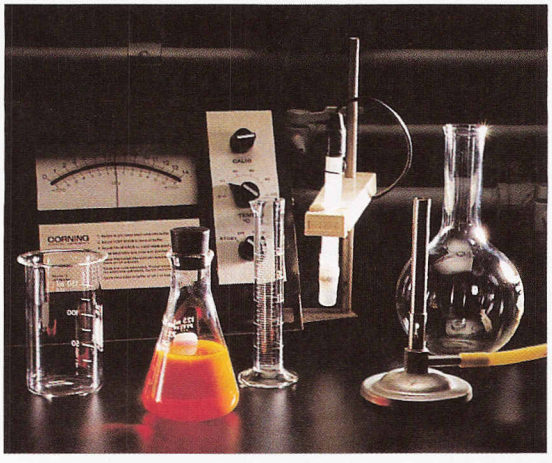

Figure 6.1 A chemical system and its surroundings. Once the contents of the flask (the orange solution) are defined as the system, the flask and the laboratory become defined as the surroundings.

Figure 6.1 shows a typical chemical system and its surroundings: the system is the contents of the flask; the flask itself, the other equipment, and perhaps the rest of the laboratory are the surroundings. In principle, the rest of the universe is the surroundings, but in practice, we need to consider only the portions of the universe relevant to the system. That is, it's not likely that a thunderstorm in central Asia or a methane blizzard on Neptune will affect the contents of the flask, but the temperature, pressure, and humidity of the lab might.

Energy Flow to and from a System

Each particle in a system has potential and kinetic energy, and the sum of these energies for all the particles in the system is the **internal energy, *E*** (some texts use the symbol U). When a chemical system, such as the contents of the flask in Figure 6.1, changes from reactants to products and the products return to the starting temperature, the internal energy has changed. To determine this change, ΔE, we measure the difference between the system's internal energy *after* the change (E_{final}) and *before* the change ($E_{initial}$):

$$\Delta E = E_{final} - E_{initial} = E_{products} - E_{reactants} \qquad (6.1)$$

where Δ (Greek *delta*) means "change (or difference) in." Note especially that Δ refers to the *final state of the system* ***minus*** *the initial state.*

Because energy must be conserved, *a change in the energy of the system is always accompanied by an* ***opposite*** *change in the energy of the surroundings.* We often represent this change with an *energy diagram* in which the final and initial states are horizontal lines on a vertical energy axis. The change in internal energy, ΔE, is the difference between the heights of the two lines. A system can change its internal energy in one of two ways:

1. By losing some energy *to* the surroundings, as shown in Figure 6.2A:

$$E_{final} < E_{initial} \qquad \Delta E < 0$$

2. By gaining some energy *from* the surroundings, as shown in Figure 6.2B:

$$E_{final} > E_{initial} \qquad \Delta E > 0$$

Note that the change in energy is always a *transfer* of energy from system to surroundings, or vice versa.

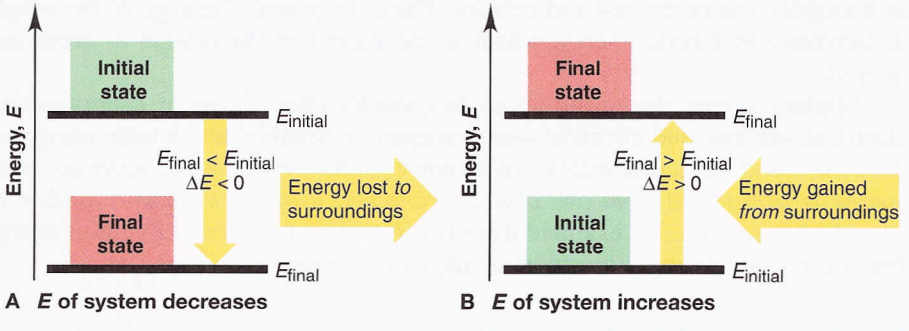

Figure 6.2 Energy diagrams for the transfer of internal energy (*E*) between a system and its surroundings. A, When the internal energy of a system *decreases,* the change in energy (ΔE) is lost *to* the surroundings; therefore, ΔE of the system ($E_{final} - E_{initial}$) is negative. **B,** When the system's internal energy *increases,* ΔE is gained *from* the surroundings and is positive. Note that the vertical yellow arrow, which signifies the direction of the change in energy, *always* has its tail at the initial state and its head at the final state.

Heat and Work: Two Forms of Energy Transfer

Just as we saw when a weight hits the ground, energy transfer outward from the system or inward from the surroundings can appear in two forms, heat and work. **Heat** (or *thermal energy,* symbol ***q***) is the energy transferred between a system and its surroundings as a result of a difference in their temperatures only. Energy in the form of heat is transferred from hot soup (system) to the bowl, air, and table (surroundings) because the surroundings have a lower temperature. All other forms of energy transfer (mechanical, electrical, and so on) involve some type of **work (*w*),** the energy transferred when an object is moved by a force. When you (system) kick a football (surroundings), energy is transferred as work to move the ball. When you inflate the ball, the inside air (system) exerts a force on the inner wall of the ball and nearby air (surroundings) and does work to move it outward.

The total change in a system's internal energy is the sum of the energy transferred as heat and/or work:

$$\Delta E = q + w \qquad (6.2)$$

The numerical values of q and w can be either positive or negative, depending on the change the *system* undergoes. In other words, *we define the sign of the energy transfer from the system's perspective.* Energy coming *into* the system is *positive.* Energy going *out from* the system is *negative.* Of the innumerable changes possible in the system's internal energy, we'll examine four simple cases—two that involve only heat and two that involve only work.

Energy Transfer as Heat Only For a system that does no work but transfers energy only as heat (q), we know that $w = 0$. Therefore, from Equation 6.2, we have $\Delta E = q + 0 = q$.

1. *Heat flowing* ***out from*** *a system.* Suppose a sample of hot water is the system; then, the beaker containing it and the rest of the lab are the surroundings. The water transfers energy as heat to the surroundings until the temperature of the water equals that of the surroundings. The system's energy decreases as heat flows *out from* the system, so the final energy of the system is less than its initial energy. Heat was lost by the system, so q *is negative,* and therefore ΔE *is negative.* Figure 6.3A shows this situation.

2. *Heat flowing* ***into*** *a system.* If the system consists of ice water, it gains energy as heat from the surroundings until the temperature of the water equals that of the surroundings. In this case, energy is transferred *into* the system, so the final energy of the system is higher than its initial energy. Heat was gained by the system, so q *is positive,* and therefore ΔE *is positive* (Figure 6.3B).

Thermodynamics in the Kitchen The air in a refrigerator (surroundings) has a lower temperature than a newly added piece of food (system), so the food loses energy as heat to the refrigerator air, $q < 0$. The air in a hot oven (surroundings) has a higher temperature than a newly added piece of food (system), so the food gains energy as heat from the oven air, $q > 0$.

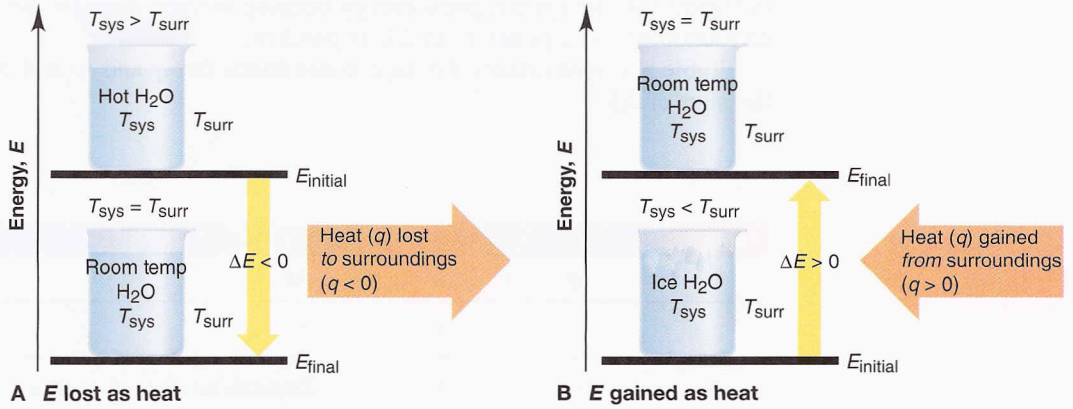

Figure 6.3 A system transferring energy as heat only. A, Hot water (the system, sys) transfers energy as heat (q) *to* the surroundings (surr) until $T_{sys} = T_{surr}$. Since $E_{initial} > E_{final}$ and $w = 0$, $\Delta E < 0$ and the sign of q is negative. **B,** Ice water gains energy as heat (q) *from* the surroundings until $T_{sys} = T_{surr}$. Since $E_{initial} < E_{final}$ and $w = 0$, $\Delta E > 0$ and the sign of q is positive.

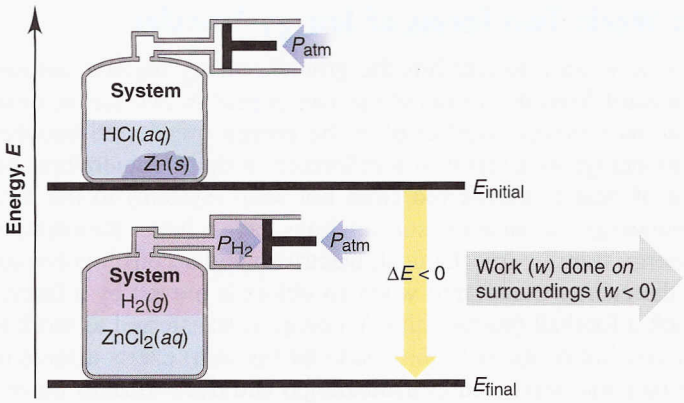

Figure 6.4 A system losing energy as work only. The internal energy of the system decreases as the reactants form products because the $H_2(g)$ does work (w) *on* the surroundings by pushing back the piston. The reaction vessel is insulated, so $q = 0$. Since $E_{initial} > E_{final}$, $\Delta E < 0$ and the sign of w is negative.

Animation: Energy Flow
Online Learning Center

Energy Transfer as Work Only For a system that transfers energy only as work (w) and not as heat, we know that $q = 0$; therefore, $\Delta E = 0 + w = w$.

1. *Work done* ***by*** *a system.* Consider the reaction between zinc and hydrochloric acid as it takes place in an insulated container attached to a piston-cylinder assembly. We define the system as the atoms that make up the substances. In the initial state, the system's internal energy is that of the atoms in the form of the reactants, metallic Zn and aqueous H^+ and Cl^- ions. In the final state, the system's internal energy is that of the same atoms in the form of the products, H_2 gas and aqueous Zn^{2+} and Cl^- ions:

$$Zn(s) + 2H^+(aq) + 2Cl^-(aq) \longrightarrow H_2(g) + Zn^{2+}(aq) + 2Cl^-(aq)$$

As the H_2 gas forms, some of the internal energy is used *by* the system to do work *on* the surroundings and push the piston outward. Energy is lost by the system as work, so w *is negative* and ΔE *is negative,* as you see in Figure 6.4. The H_2 gas is doing **pressure-volume work (*PV* work),** the type of work in which a volume changes against an external pressure. The work done here is not very useful because it simply pushes back the piston and outside air. But, if the system is a ton of burning coal and O_2, and the surroundings are a locomotive engine, much of the internal energy lost from the system does the work of moving a train.

2. *Work done* ***on*** *a system.* If we increase the external pressure on the piston in Figure 6.4, the system gains energy because work is done *on* the system *by* the surroundings: w *is positive,* so ΔE *is positive.*

Table 6.1 summarizes the sign conventions for q and w and their effect on the sign of ΔE.

Table 6.1 The Sign Conventions* for *q*, *w*, and ΔE

q	+	w	=	ΔE
+		+		+
+		−		Depends on *sizes* of q and w
−		+		Depends on *sizes* of q and w
−		−		−

*For *q:* + means system *gains* heat; − means system *loses* heat.
For *w:* + means work done *on* system; − means work done *by* system.

The Law of Energy Conservation

As you've seen, when a system gains energy, the surroundings lose it, and when a system loses energy, the surroundings gain it. Energy can be converted from one form to another as these transfers take place, but it cannot simply appear or disappear—it cannot be created or destroyed. The **law of conservation of energy** restates this basic observation as follows: *the total energy of the universe is constant*. This law is also known as the **first law of thermodynamics.**

Conservation of energy applies everywhere. As gasoline burns in a car engine, the released energy appears as an equivalent amount of heat and work. The heat warms the car parts, passenger compartment, and surrounding air. The work appears as mechanical energy to turn the car's wheels and belts. That energy is converted further into the electrical energy of the clock and radio, the radiant energy of the headlights, the chemical energy of the battery, the heat due to friction, and so forth. If you took the sum of all these energy forms, you would find that it equals the change in energy between the reactants and products as the gasoline is burned. Complex biological processes also obey energy conservation. Through photosynthesis, green plants convert radiant energy from the Sun into chemical energy, as low-energy CO_2 and H_2O are used to make high-energy carbohydrates (such as wood) and O_2. When the wood is burned in air, those low-energy compounds form again, and the energy difference is released to the surroundings.

Thus, energy transfers between system and surroundings can be in the forms of heat and/or various types of work—mechanical, electrical, radiant, chemical—but *the energy of the system plus the energy of the surroundings remains constant: energy is conserved*. A mathematical expression of the law of conservation of energy (first law of thermodynamics) is

$$\Delta E_{\text{universe}} = \Delta E_{\text{system}} + \Delta E_{\text{surroundings}} = 0 \qquad (6.3)$$

This profound idea pertains to all systems, from a burning match to the movement of continents, from the inner workings of your heart to the formation of the Solar System.

The Tragic Life of the First Law's Discoverer After studying the work habits, the food intake, and the blood of sailors in the tropics versus those in northern Europe, the young German doctor J. R. von Mayer concluded that the energy of food is used to heat the body *and* do work, and thus heat and work are different forms of energy. When colleagues ridiculed this idea, von Mayer became despondent. Soon thereafter, James Joule, an English brewer and amateur scientist, demonstrated this idea experimentally but gave von Mayer no credit for the concept. Around this time, von Mayer's children died unexpectedly, and he became severely depressed. He attempted suicide and was seriously injured and later sent to an insane asylum. Tainted by his conduct, his family declared him legally dead. Many years later, von Mayer was released and finally received recognition for his great insight.

Units of Energy

The SI unit of energy is the **joule (J),** a derived unit composed of three base units:

$$1\ \text{J} = 1\ \text{kg}\cdot\text{m}^2/\text{s}^2$$

Both heat and work are expressed in joules. Let's see how these units arise in the case of work. The work (w) done on a mass is the force (F) times the distance (d) that the mass moves: $w = F \times d$. A *force* changes the velocity of (accelerates) a mass. Velocity has units of meters per second (m/s), so acceleration (a) has units of m/s^2. Force, therefore, has units of mass (m, in kilograms) times acceleration:

$F = m \times a$ in units of $\text{kg}\cdot\text{m/s}^2$

Therefore, $w = F \times d$ has units of $(\text{kg}\cdot\text{m/s}^2) \times \text{m} = \text{kg}\cdot\text{m}^2/\text{s}^2 = \text{J}$

Potential energy, kinetic energy, and PV work are combinations of the same physical quantities and are also expressed in joules.

The **calorie (cal)** is an older unit that was defined originally as the quantity of energy needed to raise the temperature of 1 g of water by 1°C (from 14.5°C to 15.5°C). The calorie is now defined in terms of the joule:

$$1\ \text{cal} \equiv 4.184\ \text{J} \quad \text{or} \quad 1\ \text{J} = \frac{1}{4.184}\ \text{cal} = 0.2390\ \text{cal}$$

Since the quantities of energy involved in chemical reactions are usually quite large, chemists use the kilojoule (kJ), or sometimes the kilocalorie (kcal):

$$1\ \text{kJ} = 1000\ \text{J} = 0.2390\ \text{kcal} = 239.0\ \text{cal}$$

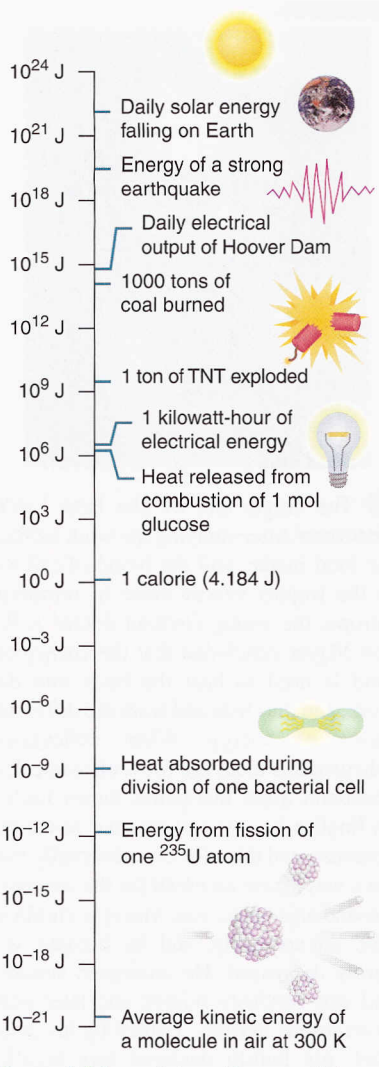

Figure 6.5 Some interesting quantities of energy. Note that the vertical scale is exponential.

The nutritional Calorie (note the capital C), the unit that diet tables use to show the energy available from food, is actually a kilocalorie. The *British thermal unit (Btu)*, a unit in engineering that you may have seen used to indicate energy output of appliances, is the quantity of energy required to raise the temperature of 1 lb of water by 1°F and is equivalent to 1055 J. In general, the SI unit (J or kJ) is used throughout this text. Some interesting quantities of energy appear in Figure 6.5.

SAMPLE PROBLEM 6.1 Determining the Change in Internal Energy of a System

Problem When gasoline burns in a car engine, the heat released causes the products CO_2 and H_2O to expand, which pushes the pistons outward. Excess heat is removed by the car's cooling system. If the expanding gases do 451 J of work on the pistons and the system loses 325 J to the surroundings as heat, calculate the change in energy (ΔE) in J, kJ, and kcal.

Plan We must define system and surroundings, assign signs to q and w, and then calculate ΔE with Equation 6.2. The system is the reactants and products, and the surroundings are the pistons, the cooling system, and the rest of the car. Heat is released by the system, so q is negative. Work is done by the system to push the pistons outward, so w is also negative. We obtain the answer in J and then convert it to kJ and kcal.

Solution Calculating ΔE (from Equation 6.2) in J:

$$q = -325 \text{ J}$$
$$w = -451 \text{ J}$$
$$\Delta E = q + w = -325 \text{ J} + (-451 \text{ J})$$
$$= -776 \text{ J}$$

Converting from J to kJ:

$$\Delta E = -776 \text{ J} \times \frac{1 \text{ kJ}}{1000 \text{ J}}$$
$$= -0.776 \text{ kJ}$$

Converting from kJ to kcal:

$$\Delta E = -0.776 \text{ kJ} \times \frac{1 \text{ kcal}}{4.184 \text{ kJ}}$$
$$= -0.185 \text{ kcal}$$

Check The answer is reasonable: combustion releases energy from the system, so $E_{final} < E_{initial}$ and ΔE should be negative. Rounding shows that, since 4 kJ $\approx$ 1 kcal, nearly 0.8 kJ should be nearly 0.2 kcal.

FOLLOW-UP PROBLEM 6.1 In a reaction, gaseous reactants form a liquid product. The heat absorbed by the surroundings is 26.0 kcal, and the work done on the system is 15.0 Btu. Calculate ΔE (in kJ).

State Functions and the Path Independence of the Energy Change

An important point to understand is that there is no particular sequence by which the internal energy (E) of a system must change. This is because E is a **state function,** a property dependent only on the *current* state of the system (its composition, volume, pressure, and temperature), *not* on the path the system took to reach that state.

In fact, the energy change of a system can occur by countless combinations of heat (q) and work (w). No matter what the combination, however, the same

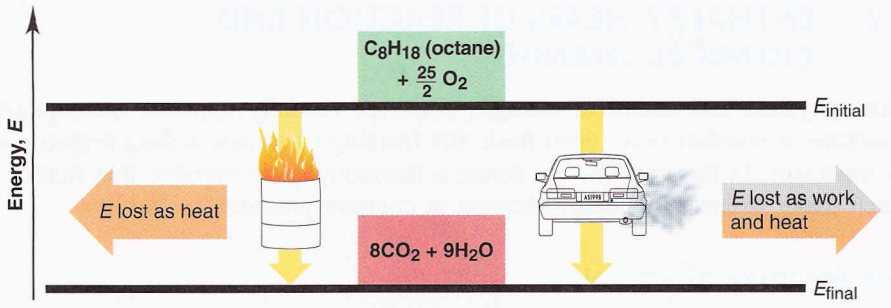

Figure 6.6 Two different paths for the energy change of a system. The change in internal energy when a given amount of octane burns in air is the same no matter how the energy is transferred. On the left, the fuel is burned in an open can, and the energy is lost almost entirely as heat. On the right, it is burned in a car engine; thus, a portion of the energy is lost as work to move the car, and less is lost as heat.

overall energy change occurs, because ΔE *does* ***not*** *depend on how the change takes place*. As an example, let's define a system in its initial state as 1 mol of octane (a component of gasoline) together with enough O_2 to burn it. In its final state, the system is the CO_2 and H_2O that form (a fractional coefficient is needed for O_2 because we specified 1 mol of octane):

$$C_8H_{18}(l) + \tfrac{25}{2}O_2(g) \longrightarrow 8CO_2(g) + 9H_2O(g)$$

initial state ($E_{initial}$) final state (E_{final})

Energy is released to warm the surroundings and/or do work on them, so ΔE is negative. Two of the ways the change can occur are shown in Figure 6.6. If we burn the octane in an open container, ΔE appears almost completely as heat (with a small amount of work done to push back the atmosphere). If we burn it in a car engine, a much larger portion (~30%) of ΔE appears as work that moves the car, with the rest used to heat the car, exhaust gases, and surrounding air. If we burn the octane in a lawn mower or a plane, ΔE appears as other combinations of work and heat.

Thus, even though the separate quantities of work and heat available from the change *do* depend on how the change occurs, the change in internal energy (the *sum* of the heat and work) *does not*. In other words, for a given change, ΔE *(sum of q and w) is constant, even though q and w can vary.* Thus, heat and work are *not* state functions because their values *do* depend on the path the system takes in undergoing the energy change.

The pressure (P) of an ideal gas or the volume (V) of water in a beaker are other examples of state functions. This path independence means that *changes in state functions*—ΔE, ΔP, and ΔV—*depend only on their initial and final states.* (Note that symbols for state functions, such as E, P, and V, are capitalized.)

Your Personal Financial State Function The *balance* in your checkbook is a state function of your personal financial system. You can open a new account with a birthday gift of $50, or you can open a new account with a deposit of a $100 paycheck and then write two $25 checks. The two paths to the balance are different, but the balance (current state) is the same.

SECTION SUMMARY

Energy is transferred as heat (q) when the system and surroundings are at different temperatures; energy is transferred as work (w) when an object is moved by a force. Heat or work gained by a system ($q > 0$; $w > 0$) increases its internal energy (E); heat or work lost by the system ($q < 0$; $w < 0$) decreases E. The total change in the system's internal energy is the sum of the heat and work: $\Delta E = q + w$. Heat and work are measured in joules (J). Energy is always conserved: it changes from one form into another, moving into or out of the system, but the total quantity of energy in the universe (system *plus* surroundings) is constant. Energy is a state function; therefore, the same ΔE can occur through any combination of q and w.

6.2 ENTHALPY: HEATS OF REACTION AND CHEMICAL CHANGE

Most physical and chemical changes occur at virtually constant atmospheric pressure—a reaction in an open flask, the freezing of a lake, a drug response in an organism. In this section, we define a thermodynamic variable that makes it much easier to measure energy changes at constant pressure.

The Meaning of Enthalpy

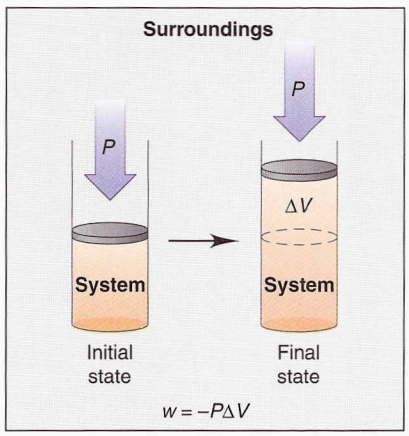

Figure 6.7 Pressure-volume work. When the volume (V) of a system increases by an amount ΔV against an external pressure (P), the system pushes back, and thus does PV work *on* the surroundings ($w = -P\Delta V$).

To determine ΔE, we must measure both heat and work. The two most important types of chemical work are electrical work, the work done by moving charged particles (Chapter 21), and PV work, the work done by an expanding gas. We find the quantity of PV work done by multiplying the external pressure (P) by the change in volume of the gas (ΔV, or $V_{final} - V_{initial}$). In an open flask (or a cylinder with a weightless, frictionless piston), a gas does work by pushing back the atmosphere. As Figure 6.7 shows, this work is done *on* the surroundings, so it has a negative sign because the system loses energy:

$$w = -P\Delta V \tag{6.4}$$

For reactions at constant pressure, a thermodynamic variable called **enthalpy** (***H***) eliminates the need to consider PV work separately. The enthalpy of a system is defined as the internal energy *plus* the product of the pressure and volume:

$$H = E + PV$$

The **change in enthalpy** (**ΔH**) is the change in internal energy *plus* the product of the constant pressure and the change in volume:

$$\Delta H = \Delta E + P\Delta V \tag{6.5}$$

Combining Equations 6.2 ($\Delta E = q + w$) and 6.4 leads to a key point about ΔH:

$$\Delta E = q + w = q + (-P\Delta V) = q - P\Delta V$$

At constant pressure, we denote q as q_P and solve for it:

$$q_P = \Delta E + P\Delta V$$

Notice the right side of this equation is identical to the right side of Equation 6.5:

$$q_P = \Delta E + P\Delta V = \Delta H \tag{6.6}$$

Thus, *the change in enthalpy equals the heat gained or lost at constant pressure.* With most changes occurring at constant pressure, ΔH is more relevant than ΔE *and* easier to find: *to find ΔH, measure q_P.*

We discuss the laboratory method for measuring the heat involved in a chemical or physical change in Section 6.3.

Comparing ΔE and ΔH

Knowing the *enthalpy* change of a system tells us a lot about its *energy* change as well. In fact, because many reactions involve little (if any) PV work, most (or all) of the energy change occurs as a transfer of heat. Here are three cases:

1. *Reactions that do not involve gases.* Gases do not appear in many reactions (precipitation, many acid-base, and many redox reactions). For example,

$$2KOH(aq) + H_2SO_4(aq) \longrightarrow K_2SO_4(aq) + 2H_2O(l)$$

Because liquids and solids undergo *very* small volume changes, $\Delta V \approx 0$; thus $P\Delta V \approx 0$ and $\Delta H \approx \Delta E$.

2. *Reactions in which the amount (mol) of gas does **not** change.* When the total amount of gaseous reactants equals the total amount of gaseous products, $\Delta V = 0$, so $P\Delta V = 0$ and $\Delta H = \Delta E$. For example,

$$N_2(g) + O_2(g) \longrightarrow 2NO(g)$$

3. *Reactions in which the amount (mol) of gas* ***does*** *change.* In these cases, $P\Delta V \neq 0$. However, q_P is usually so much larger than $P\Delta V$ that ΔH is very close to ΔE. For instance, in the combustion of H_2, 3 mol of gas yields 2 mol of gas:

$$2H_2(g) + O_2(g) \longrightarrow 2H_2O(g)$$

In this reaction, $\Delta H = -483.6$ kJ and $P\Delta V = -2.5$ kJ, so (from Equation 6.5), we get

$$\Delta E = \Delta H - P\Delta V = -483.6 \text{ kJ} - (-2.5 \text{ kJ}) = -481.1 \text{ kJ}$$

Obviously, most of ΔE occurs as heat transfer, so $\Delta H \approx \Delta E$.

The key point to realize from these three cases is that *for many reactions,* ΔH *equals, or is very close to,* ΔE.

Exothermic and Endothermic Processes

Because E, P, and V are state functions, H is also a state function, which means that ΔH depends only on the *difference* between H_{final} and H_{initial}. The enthalpy change of a reaction, also called the **heat of reaction,** $\boldsymbol{\Delta H_{\text{rxn}}}$, *always refers to* H_{final} ***minus*** $H_{initial}$:

$$\Delta H = H_{\text{final}} - H_{\text{initial}} = H_{\text{products}} - H_{\text{reactants}}$$

Therefore, because H_{products} can be either more or less than $H_{\text{reactants}}$, the sign of ΔH indicates whether heat is absorbed or released in the change. We determine the sign of ΔH *by imagining the heat as a "reactant" or "product."* When methane burns in air, for example, we know that heat is produced, so we show it as a product (on the right):

$$CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(g) + \textit{heat}$$

Because heat is released to the surroundings, the products (1 mol of CO_2 and 2 mol of H_2O) must have less enthalpy than the reactants (1 mol of CH_4 and 2 mol of O_2). Therefore, ΔH ($H_{\text{final}} - H_{\text{initial}}$) is negative, as the **enthalpy diagram** in Figure 6.8A shows. An **exothermic** ("heat out") **process** *releases* heat and results in a *decrease* in the enthalpy of the system:

$$\text{Exothermic:} \quad H_{\text{final}} < H_{\text{initial}} \quad \Delta H < 0$$

An **endothermic** ("heat in") **process** *absorbs* heat and results in an *increase* in the enthalpy of the system. When ice melts, for instance, heat flows *into* the ice from the surroundings, so we show the heat as a reactant (on the left):

$$\textit{heat} + H_2O(s) \longrightarrow H_2O(l)$$

Because heat is absorbed, the enthalpy of the liquid water is higher than that of the solid water, as Figure 6.8B shows. Therefore, ΔH ($H_{\text{water}} - H_{\text{ice}}$) is positive:

$$\text{Endothermic:} \quad H_{\text{final}} > H_{\text{initial}} \quad \Delta H > 0$$

In general, the value of an enthalpy change refers to reactants and products at the same temperature.

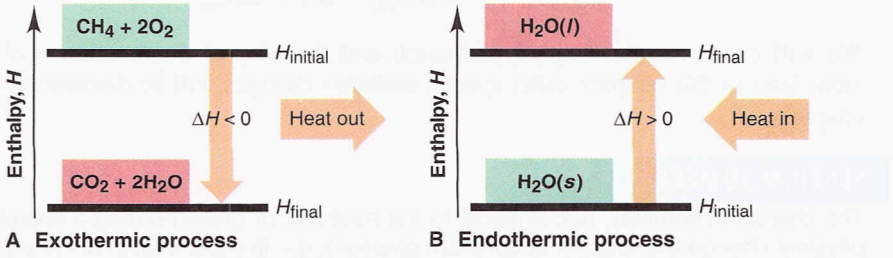

Figure 6.8 Enthalpy diagrams for exothermic and endothermic processes. A, Methane burns with a decrease in enthalpy because heat *leaves* the system. Therefore, $H_{\text{final}} < H_{\text{initial}}$, and the process is exothermic: $\Delta H < 0$. **B,** Ice melts with an increase in enthalpy because heat *enters* the system. Since $H_{\text{final}} > H_{\text{initial}}$, the process is endothermic: $\Delta H > 0$.

SAMPLE PROBLEM 6.2 Drawing Enthalpy Diagrams and Determining the Sign of ΔH

Problem In each of the following cases, determine the sign of ΔH, state whether the reaction is exothermic or endothermic, and draw an enthalpy diagram:

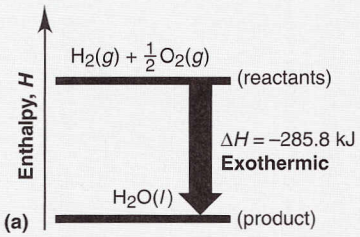
(a) $H_2(g) + \frac{1}{2}O_2(g) \longrightarrow H_2O(l) + 285.8\ kJ$

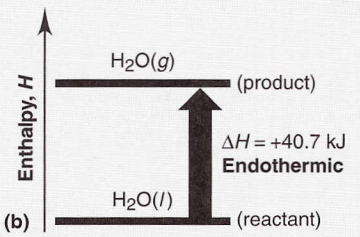
(b) $40.7\ kJ + H_2O(l) \longrightarrow H_2O(g)$

Plan From each equation, we see whether heat is a "product" (exothermic; $\Delta H < 0$) or a "reactant" (endothermic; $\Delta H > 0$). For exothermic reactions, reactants are above products on the enthalpy diagram; for endothermic reactions, reactants are below products. The ΔH arrow *always* points from reactants to products.

Solution **(a)** Heat is a product (on the right), so $\Delta H < 0$ and the reaction is exothermic. The enthalpy diagram appears in the margin (*top*).

(b) Heat is a reactant (on the left), so $\Delta H > 0$ and the reaction is endothermic. The enthalpy diagram appears in the margin (*bottom*).





Check Substances that are on the same side of the equation as the heat have less enthalpy than substances on the other side, so make sure they are placed on the lower line of the diagram.

Comment ΔH values depend on conditions. In (b), for instance, $\Delta H = 40.7$ kJ at 1 atm and 100°C; at 1 atm and 25°C, $\Delta H = 44.0$ kJ.

FOLLOW-UP PROBLEM 6.2 When 1 mol of nitroglycerine decomposes, it causes a violent explosion and releases 5.72×10^3 kJ of heat:

$$C_3H_5(NO_3)_3(l) \longrightarrow 3CO_2(g) + \tfrac{5}{2}H_2O(g) + \tfrac{1}{4}O_2(g) + \tfrac{3}{2}N_2(g)$$

Is the reaction exothermic or endothermic? Draw an enthalpy diagram for it.

Some Important Types of Enthalpy Change

Some enthalpy changes are frequently studied and, therefore, they have special names:

- When 1 mol of a substance combines with O_2 in a combustion reaction, the heat of reaction is called the **heat of combustion (ΔH_{comb}):**

$$C_4H_{10}(l) + \tfrac{13}{2}O_2(g) \longrightarrow 4CO_2(g) + 5H_2O(l) \quad \Delta H = \Delta H_{comb}$$

- When 1 mol of a compound is produced from its elements, the heat of reaction is called the **heat of formation (ΔH_f):**

$$K(s) + \tfrac{1}{2}Br_2(l) \longrightarrow KBr(s) \quad \Delta H = \Delta H_f$$

- When 1 mol of a substance melts, the enthalpy change is called the **heat of fusion (ΔH_{fus}):**

$$NaCl(s) \longrightarrow NaCl(l) \quad \Delta H = \Delta H_{fus}$$

- When 1 mol of a substance vaporizes, the enthalpy change is called the **heat of vaporization (ΔH_{vap}):**

$$C_6H_6(l) \longrightarrow C_6H_6(g) \quad \Delta H = \Delta H_{vap}$$

We will encounter the heat of formation and the heat of combustion in discussions later in this chapter; other special enthalpy changes will be discussed in later chapters.

SECTION SUMMARY

The change in enthalpy, ΔH, is equal to the heat lost or gained during a chemical or physical change that occurs at constant pressure, q_P. In most cases, ΔH is equal, or very close, to ΔE. A change that releases heat is exothermic ($\Delta H < 0$); a change that absorbs heat is endothermic ($\Delta H > 0$). Some special enthalpy changes involve combustion, formation of a compound from its elements, and physical changes from solid to liquid and liquid to gas.

6.3 CALORIMETRY: LABORATORY MEASUREMENT OF HEATS OF REACTION

Data about energy content and use is everywhere—the calories per serving of a slice of bread, the energy efficiency rating of a washing machine, or the city/highway mileage of a new car. How do we measure the heat released (or absorbed) by a product? To determine the energy content of a teaspoon of sugar, for example, you might think we can simply measure the enthalpies of the reactants (sucrose and O_2) and subtract them from the enthalpies of the products (CO_2 and H_2O). The problem is that the enthalpy (H) of a system in a given state cannot be measured because we have no starting point with which to compare it, no zero enthalpy. However, we *can* measure the *change* in enthalpy (ΔH) of a system. In this section, we'll see how ΔH values are determined.

To measure q_P, which is equal to ΔH, we construct "surroundings" that retain the heat, and we observe the temperature change. Then, we relate the quantity of heat released (or absorbed) to that temperature change through a physical property called the *specific heat capacity.*

Specific Heat Capacity

You know from everyday experience that the more you heat an object, the higher its temperature; that is, the quantity of heat (q) absorbed by an object is proportional to its temperature change:

$$q \propto \Delta T \quad \text{or} \quad q = \text{constant} \times \Delta T \quad \text{or} \quad \frac{q}{\Delta T} = \text{constant}$$

Every object has its own **heat capacity,** the quantity of heat required to change its temperature by 1 K. Heat capacity is the proportionality constant in the preceding equation:

$$\text{Heat capacity} = \frac{q}{\Delta T} \quad [\text{in units of J/K}]$$

A related property is **specific heat capacity (*c*),** the quantity of heat required to change the temperature of 1 *gram* of a substance by 1 K:*

$$\text{Specific heat capacity } (c) = \frac{q}{\text{mass} \times \Delta T} \quad [\text{in units of J/g·K}]$$

If we know c of the substance being heated (or cooled), we can measure its mass and temperature change and calculate the heat absorbed or released:

$$q = c \times \text{mass} \times \Delta T \tag{6.7}$$

Notice that when an object gets hotter, ΔT (that is, $T_{\text{final}} - T_{\text{initial}}$) is positive. The object gains heat, so $q > 0$, as we expect. Similarly, when an object gets cooler, ΔT is negative; so $q < 0$ because heat is lost. Table 6.2 lists the specific heat capacities of some representative substances and materials.

Closely related to the specific heat capacity is the **molar heat capacity (*C;*** note capital letter), the quantity of heat required to change the temperature of 1 *mole* of a substance by 1 K:

$$\text{Molar heat capacity } (C) = \frac{q}{\text{moles} \times \Delta T} \quad [\text{in units of J/mol·K}]$$

The specific heat capacity of liquid water is 4.184 J/g·K, so

$$C \text{ of } H_2O(l) = 4.184 \frac{\text{J}}{\text{g·K}} \times \frac{18.02 \text{ g}}{1 \text{ mol}} = 75.40 \frac{\text{J}}{\text{mol·K}}$$

Table 6.2 Specific Heat Capacities of Some Elements, Compounds, and Materials

Substance	Specific Heat Capacity (J/g·K)*
Elements	
Aluminum, Al	0.900
Graphite, C	0.711
Iron, Fe	0.450
Copper, Cu	0.387
Gold, Au	0.129
Compounds	
Water, $H_2O(l)$	4.184
Ethyl alcohol, $C_2H_5OH(l)$	2.46
Ethylene glycol, $(CH_2OH)_2(l)$	2.42
Carbon tetrachloride, $CCl_4(l)$	0.862
Solid materials	
Wood	1.76
Cement	0.88
Glass	0.84
Granite	0.79
Steel	0.45

*At 298 K (25°C).

*Some texts use the term *specific heat* in place of *specific heat capacity.* This usage is very common but somewhat incorrect. *Specific heat* is the ratio of the heat capacity of 1 g of a substance to the heat capacity of 1 g of H_2O and therefore has no units.

SAMPLE PROBLEM 6.3 Finding Quantity of Heat from Specific Heat Capacity

Problem A layer of copper welded to the bottom of a skillet weighs 125 g. How much heat is needed to raise the temperature of the copper layer from 25°C to 300.°C? The specific heat capacity (c) of Cu is 0.387 J/g·K.

Plan We know the mass and c of Cu and can find ΔT in °C, which equals ΔT in K. We use this ΔT and Equation 6.7 to solve for the heat.

Solution Calculating ΔT and q:

$$\Delta T = T_{final} - T_{initial} = 300.°C - 25°C = 275°C = 275\ K$$

$$q = c \times \text{mass (g)} \times \Delta T = 0.387\ J/g{\cdot}K \times 125\ g \times 275\ K = 1.33{\times}10^4\ J$$

Check Heat is absorbed by the copper bottom (system), so q is positive. Rounding shows that the arithmetic seems reasonable: $q \approx 0.4\ J/g{\cdot}K \times 100\ g \times 300\ K = 1.2{\times}10^4\ J$.

FOLLOW-UP PROBLEM 6.3 Find the heat transferred (in kJ) when 5.50 L of ethylene glycol (d = 1.11 g/mL; see Table 6.2 for c) in a car radiator cools from 37.0°C to 25.0°C.

The Practice of Calorimetry

The **calorimeter** is used to measure the heat released (or absorbed) by a physical or chemical process. This apparatus is the "surroundings" that change temperature when heat is transferred to or from the system. Two common types are the constant-pressure and constant-volume calorimeters.

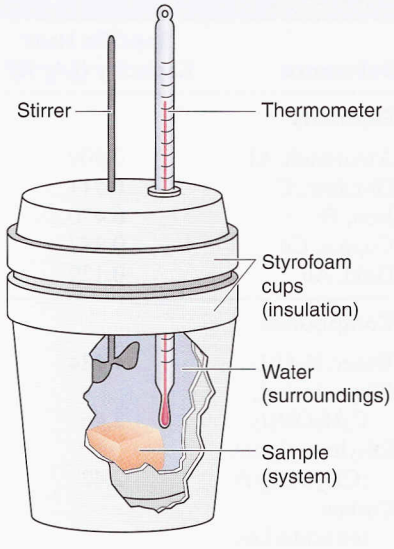


Figure 6.9 Coffee-cup calorimeter. This apparatus is used to measure the heat at constant pressure (q_P).

Constant-Pressure Calorimetry A "coffee-cup" calorimeter (Figure 6.9) is often used to measure the heat transferred (q_P) in processes open to the atmosphere. One common use is to find the specific heat capacity of a solid that does not react with or dissolve in water. The solid (system) is weighed, heated to some known temperature, and added to a sample of water (surroundings) of known temperature and mass in the calorimeter. With stirring, the final water temperature, which is also the final temperature of the solid, is measured.

The heat lost by the system ($-q_{sys}$, or $-q_{solid}$) is equal in magnitude but opposite in sign to the heat gained by the surroundings ($+q_{surr}$, or $+q_{H_2O}$):

$$-q_{solid} = q_{H_2O}$$

Substituting Equation 6.7 for each side of this equality gives

$$-(c_{solid} \times mass_{solid} \times \Delta T_{solid}) = c_{H_2O} \times mass_{H_2O} \times \Delta T_{H_2O}$$

All the quantities are known or measured except c_{solid}:

$$c_{solid} = -\frac{c_{H_2O} \times mass_{H_2O} \times \Delta T_{H_2O}}{mass_{solid} \times \Delta T_{solid}}$$

For example, suppose you heat a 25.64-g solid in a test tube to 100.00°C and carefully add it to 50.00 g of water in a coffee-cup calorimeter. The water temperature changes from 25.10°C to 28.49°C, and you want to find the specific heat capacity of the solid. Converting ΔT directly from °C to K, we know ΔT_{H_2O} = 3.39 K (28.49°C − 25.10°C) and ΔT_{solid} = −71.51 K (28.49°C − 100.00°C). Then, assuming all the heat lost by the solid is gained by the water, we have

$$c_{solid} = -\frac{c_{H_2O} \times mass_{H_2O} \times \Delta T_{H_2O}}{mass_{solid} \times \Delta T_{solid}} = -\frac{4.184\ J/g{\cdot}K \times 50.00\ g \times 3.39\ K}{25.64\ g \times (-71.51\ K)} = 0.387\ J/g{\cdot}K$$

The next follow-up problem applies this calculation, but the sample problem first shows how to find the heat of a reaction that takes place in the calorimeter.

SAMPLE PROBLEM 6.4 Determining the Heat of a Reaction

Problem You place 50.0 mL of 0.500 M NaOH in a coffee-cup calorimeter at 25.00°C and carefully add 25.0 mL of 0.500 M HCl, also at 25.00°C. After stirring, the final temperature is 27.21°C. Calculate q_{soln} (in J) and ΔH_{rxn} (in kJ/mol). (Assume the total vol-

ume is the sum of the individual volumes and that the final solution has the same density and specific heat capacity as water: $d = 1.00$ g/mL and $c = 4.184$ J/g·K.)

Plan We first find the heat given off to the solution (q_{soln}) for the amounts given and then use the equation to find the heat per mole of reaction. We know the solution volumes (25.0 mL and 50.0 mL), so we can find their masses from the given density (1.00 g/mL). Multiplying their total mass by the change in T and the given c, we can find q_{soln}. Then, writing the balanced net ionic equation for the acid-base reaction, we use the volumes and the concentrations (0.500 M) to find moles of reactants (H^+ and OH^-) and, thus, product (H_2O). Dividing q_{soln} by the moles of water formed gives ΔH_{rxn} per mole.

Solution Finding $mass_{soln}$ and ΔT_{soln}:

$$\text{Total mass (g) of solution} = (25.0 \text{ mL} + 50.0 \text{ mL}) \times 1.00 \text{ g/mL} = 75.0 \text{ g}$$

$$\Delta T = 27.21°\text{C} - 25.00°\text{C} = 2.21°\text{C} = 2.21 \text{ K}$$

Finding q_{soln}:

$$q_{soln} = c_{soln} \times mass_{soln} \times \Delta T_{soln} = (4.184 \text{ J/g·K})\,(75.0 \text{ g})\,(2.21 \text{ K}) = 693 \text{ J}$$

Writing the net ionic equation:

$$HCl(aq) + NaOH(aq) \longrightarrow H_2O(l) + NaCl(aq)$$
$$H^+(aq) + OH^-(aq) \longrightarrow H_2O(l)$$

Finding moles of reactants and products:

$$\text{Moles of } H^+ = 0.500 \text{ mol/L} \times 0.0250 \text{ L} = 0.0125 \text{ mol } H^+$$
$$\text{Moles of } OH^- = 0.500 \text{ mol/L} \times 0.0500 \text{ L} = 0.0250 \text{ mol } OH^-$$

Therefore, H^+ is limiting, so 0.0125 mol of H_2O is formed.

Finding ΔH_{rxn}: Heat gained by the water was lost by the reaction; that is,

$$q_{soln} = -q_{rxn} = 693 \text{ J} \quad \text{so} \quad q_{rxn} = -693 \text{ J}$$

$$\Delta H_{rxn}\,(\text{kJ/mol}) = \frac{q_{rxn}}{\text{mol } H_2O} \times \frac{1 \text{ kJ}}{1000 \text{ J}} = \frac{-693 \text{ J}}{0.0125 \text{ mol}} \times \frac{1 \text{ kJ}}{1000 \text{ J}} = -55.4 \text{ kJ/mol}$$

Check Rounding to check q_{soln} gives 4 J/g·K × 75 g × 2 K = 600 J. The volume of H^+ is half the volume of OH^-, so moles of H^+ determines moles of product. Taking the negative of q_{soln} to find ΔH_{rxn} gives -600 J/0.012 mol = -5×10^4 J/mol, or -50 kJ/mol.

FOLLOW-UP PROBLEM 6.4 In a purity check for industrial diamonds, a 10.25-carat (1 carat = 0.2000 g) diamond is heated to 74.21°C and immersed in 26.05 g of water in a constant-pressure calorimeter. The initial temperature of the water is 27.20°C. Calculate ΔT of the water and of the diamond ($c_{diamond} = 0.519$ J/g·K).

Constant-Volume Calorimetry In the coffee-cup calorimeter, we assume all the heat is gained by the water, but some must be gained by the stirrer, thermometer, and so forth. For more precise work, as in constant-volume calorimetry, the *heat capacity of the entire calorimeter* must be known. One type of constant-volume apparatus is the *bomb calorimeter,* designed to measure very precisely the heat released in a combustion reaction. As Sample Problem 6.5 (on the next page) will show, this need for greater precision requires that we know (or determine) the heat capacity of the calorimeter.

Figure 6.10 depicts the preweighed combustible sample in a metal-walled chamber (the bomb), which is filled with oxygen gas and immersed in an insulated water bath fitted with motorized stirrer and thermometer. A heating coil connected to an electrical source ignites the sample, and the heat evolved raises the temperature of the bomb, water, and other calorimeter parts. Because we know the mass of the sample and the heat capacity of the entire calorimeter, we can use the measured ΔT to calculate the heat released.

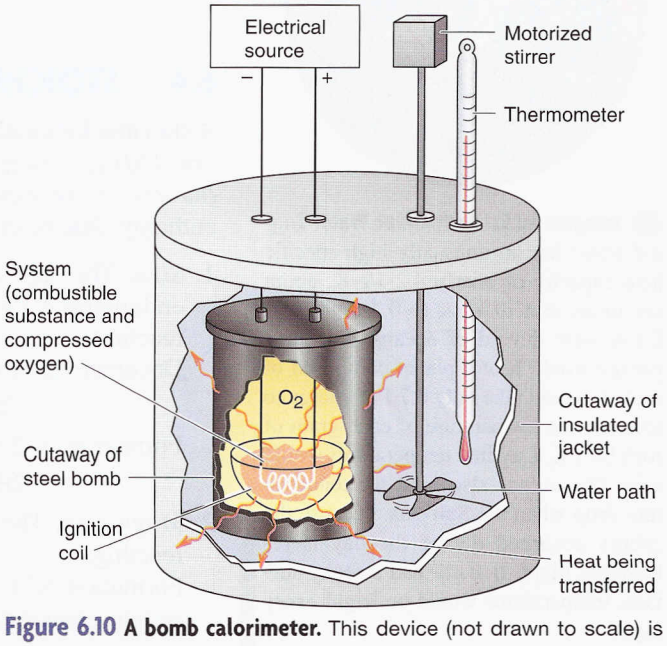

Figure 6.10 A bomb calorimeter. This device (not drawn to scale) is used to measure heat of combustion at constant volume (q_V).

SAMPLE PROBLEM 6.5 Calculating the Heat of Combustion

Problem A manufacturer claims that its new dietetic dessert has "fewer than 10 Calories per serving." To test the claim, a chemist at the Department of Consumer Affairs places one serving in a bomb calorimeter and burns it in O_2 (heat capacity of the calorimeter = 8.151 kJ/K). The temperature increases 4.937°C. Is the manufacturer's claim correct?

Plan When the dessert burns, the heat released is gained by the calorimeter:

$$-q_{\text{sample}} = q_{\text{calorimeter}}$$

To find the heat, we multiply the given heat capacity of the calorimeter (8.151 kJ/K) by ΔT (4.937°C).

Solution Calculating the heat gained by the calorimeter:

$$q_{\text{calorimeter}} = \text{heat capacity} \times \Delta T = 8.151 \text{ kJ/K} \times 4.937 \text{ K} = 40.24 \text{ kJ}$$

Recall that 1 Calorie = 1 kcal = 4.184 kJ. Therefore, 10 Calories = 41.84 kJ, so the claim is correct.

Check A quick math check shows that the answer is reasonable: 8 kJ/K × 5 K = 40 kJ.

Comment Since the volume of the steel bomb is fixed, $\Delta V = 0$, and thus $P\Delta V = 0$. Thus, the energy change measured is the *heat at constant volume* (q_V), which equals ΔE, not ΔH:

$$\Delta E = q + w = q_V + 0 = q_V$$

Recall from Section 6.2, however, that even though the number of moles of gas may change, ΔH is usually very close to ΔE. For example, ΔH is only 0.5% larger than ΔE for the combustion of H_2 and only 0.2% smaller for the combustion of octane.

FOLLOW-UP PROBLEM 6.5 A chemist burns 0.8650 g of graphite (a form of carbon) in a new bomb calorimeter, and CO_2 forms. If 393.5 kJ of heat is released per mole of graphite and T increases 2.613 K, what is the heat capacity of the bomb calorimeter?

SECTION SUMMARY

We calculate ΔH of a process by measuring the heat at constant pressure (q_P). To do this, we determine ΔT of the surroundings and relate it to q_P through the mass of the substance and its specific heat capacity (c), the quantity of energy needed to raise the temperature of 1 g of the substance by 1 K. Calorimeters measure the heat released from a system either at constant pressure ($q_P = \Delta H$) or at constant volume ($q_V = \Delta E$).

Imagine an Earth Without Water Liquid water has an unusually high specific heat capacity of nearly 4.2 J/g·K, about six times that of rock (~0.7 J/g·K). If Earth were devoid of oceans, the Sun's energy would heat a planet composed of rock. It would take only 0.7 J of energy to increase the temperature of each gram of rock by 1 K. Daytime temperatures would soar. The oceans also limit the temperature drop when the Sun sets, because the energy absorbed during the day is released at night. If Earth had a rocky surface, temperatures would be frigid every night.

6.4 STOICHIOMETRY OF THERMOCHEMICAL EQUATIONS

A **thermochemical equation** is a balanced equation that includes the heat of reaction (ΔH_{rxn}). Keep in mind that the ΔH_{rxn} value shown refers to the *amounts (moles) of substances* ***and*** *their states of matter in that specific equation.* The enthalpy change of any process has two aspects:

1. *Sign.* The sign of ΔH depends on whether the reaction is exothermic (−) or endothermic (+). A forward reaction has the *opposite* sign of the reverse reaction.

   Decomposition of 2 mol of water to its elements (endothermic):

   $$2H_2O(l) \longrightarrow 2H_2(g) + O_2(g) \quad \Delta H_{\text{rxn}} = 572 \text{ kJ}$$

   Formation of 2 mol of water from its elements (exothermic):

   $$2H_2(g) + O_2(g) \longrightarrow 2H_2O(l) \quad \Delta H_{\text{rxn}} = -572 \text{ kJ}$$

2. *Magnitude.* The magnitude of ΔH is *proportional to the amount of substance* reacting.

   Formation of 1 mol of water from its elements (half the amount in the preceding equation):

   $$H_2(g) + \tfrac{1}{2}O_2(g) \longrightarrow H_2O(l) \quad \Delta H_{\text{rxn}} = -286 \text{ kJ}$$

Note that, in thermochemical equations, we often use fractional coefficients to specify the magnitude of ΔH_{rxn} for a *particular amount of substance*. Moreover, *in a particular reaction,* a certain amount of substance is thermochemically equivalent to a certain quantity of energy. In the reaction just shown,

286 kJ is thermochemically equivalent to 1 mol of $H_2(g)$
286 kJ is thermochemically equivalent to $\frac{1}{2}$ mol of $O_2(g)$
286 kJ is thermochemically equivalent to 1 mol of $H_2O(l)$

Just as we use stoichiometrically equivalent molar ratios to find amounts of substances, we use thermochemically equivalent quantities to find the heat of reaction for a given amount of substance. Also, just as we use molar mass (in g/mol of substance) to convert moles of a substance to grams, we use the heat of reaction (in kJ/mol of substance) to convert moles of a substance to an equivalent quantity of heat (in kJ). Figure 6.11 shows this new relationship, and the next sample problem applies it.

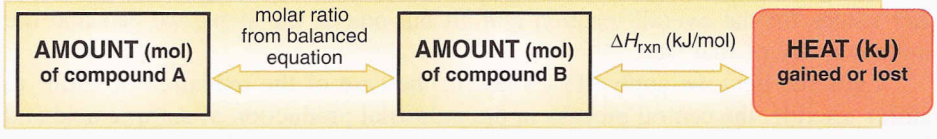

Figure 6.11 Summary of the relationship between amount (mol) of substance and the heat (kJ) transferred during a reaction.

SAMPLE PROBLEM 6.6 Using the Heat of Reaction (ΔH_{rxn}) to Find Amounts

Problem The major source of aluminum in the world is bauxite (mostly aluminum oxide). Its thermal decomposition can be represented by

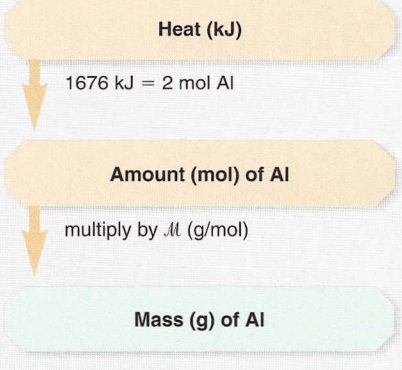
$$Al_2O_3(s) \xrightarrow{\Delta} 2Al(s) + \tfrac{3}{2}O_2(g) \quad \Delta H_{rxn} = 1676 \text{ kJ}$$

If aluminum is produced this way (see Comment), how many grams of aluminum can form when 1.000×10^3 kJ of heat is transferred?

Plan From the balanced equation and the enthalpy change, we see that 2 mol of Al forms when 1676 kJ of heat is absorbed. With this equivalent quantity, we convert the given kJ transferred to moles formed and then convert moles to grams.

Solution Combining steps to convert from heat transferred to mass of Al:

$$\text{Mass (g) of Al} = (1.000\times10^3 \text{ kJ}) \times \frac{2 \text{ mol Al}}{1676 \text{ kJ}} \times \frac{26.98 \text{ g Al}}{1 \text{ mol Al}} = 32.20 \text{ g Al}$$



Check The mass of aluminum seems correct: ~1700 kJ forms about 2 mol of Al (54 g), so 1000 kJ should form a bit more than half that amount (27 g).

Comment In practice, aluminum is not obtained by heating but by supplying electrical energy. Because ΔH is a state function, however, the total energy required for this chemical change is the same no matter how it occurs. (We examine the industrial method in Chapter 22.)

FOLLOW-UP PROBLEM 6.6 Organic hydrogenation reactions, in which H_2 and an "unsaturated" organic compound combine, are used in the food, fuel, and polymer industries. In the simplest case, ethene (C_2H_4) and H_2 form ethane (C_2H_6). If 137 kJ is given off per mole of C_2H_4 reacting, how much heat is released when 15.0 kg of C_2H_6 forms?

SECTION SUMMARY

A thermochemical equation shows the balanced equation *and* its ΔH_{rxn}. The sign of ΔH for a forward reaction is opposite that for the reverse reaction. The magnitude of ΔH depends on the amount and physical state of the substance reacting and the ΔH per mole of substance. We use the thermochemically equivalent amounts of substance and heat from the balanced equation as conversion factors to find the quantity of heat when a given amount of substance reacts.

6.5 HESS'S LAW OF HEAT SUMMATION

Many reactions are difficult, even impossible, to carry out separately. A reaction may be part of a complex biochemical process; or it may take place only under extreme environmental conditions; or it may even require a change in conditions while it is occurring. If we can't run a reaction in the lab, it is still possible to find its enthalpy change. One of the most powerful applications of the state-function property of enthalpy (H) allows us to find the ΔH of *any* reaction for which we can write an equation, even if it is impossible to carry out.

This application is based on **Hess's law of heat summation:** *the enthalpy change of an overall process is the sum of the enthalpy changes of its individual steps*. To use Hess's law, we imagine an overall reaction as the sum of a series of reaction steps, whether or not it really occurs that way. Each step is chosen because its ΔH is known. Because the overall ΔH depends only on the initial and final states, Hess's law says that we add together the known ΔH values for the steps to get the unknown ΔH of the overall reaction. Similarly, if we know the ΔH values for the overall reaction and all but one of the steps, we can find the unknown ΔH of that step.

Let's see how we apply Hess's law in the case of the oxidation of sulfur to sulfur trioxide, the central process in the industrial production of sulfuric acid and in the formation of acid rain. (To introduce the approach, we'll simplify the equations by using S as the formula for sulfur, rather than the more correct S_8.) When we burn S in an excess of O_2, sulfur dioxide (SO_2) forms, *not* sulfur trioxide (SO_3). Equation 1 shows this step and its ΔH. If we change conditions and then add more O_2, we can oxidize SO_2 to SO_3 (Equation 2). In other words, we cannot put S and O_2 in a calorimeter and find ΔH for the overall reaction of S to SO_3 (Equation 3). But, we can find it with Hess's law. The three equations are

$$\text{Equation 1:} \quad S(s) + O_2(g) \longrightarrow SO_2(g) \qquad \Delta H_1 = -296.8 \text{ kJ}$$

$$\text{Equation 2:} \quad 2SO_2(g) + O_2(g) \longrightarrow 2SO_3(g) \qquad \Delta H_2 = -198.4 \text{ kJ}$$

$$\text{Equation 3:} \quad S(s) + \tfrac{3}{2}O_2(g) \longrightarrow SO_3(g) \qquad \Delta H_3 = ?$$

Hess's law tells us that if we manipulate Equations 1 and/or 2 so that they add up to Equation 3, then ΔH_3 is the sum of the manipulated ΔH values of Equations 1 and 2.

First, we identify Equation 3 as our "target" equation, the one whose ΔH we want to find, and we carefully note the number of moles of reactants and products in it. We also note that ΔH_1 and ΔH_2 are the values for Equations 1 and 2 *as written*. Now we manipulate Equations 1 and/or 2 as follows to make them add up to Equation 3:

- Equations 1 and 3 contain the same amount of S, so we leave Equation 1 unchanged.
- Equation 2 has twice as much SO_3 as Equation 3, so we multiply it by $\frac{1}{2}$, being sure to halve ΔH_2 as well.
- With the targeted amounts of reactants and products present, we add Equation 1 to the halved Equation 2 and cancel terms that appear on both sides:

$$\text{Equation 1:} \quad S(s) + O_2(g) \longrightarrow SO_2(g) \qquad \Delta H_1 = -296.8 \text{ kJ}$$

$$\tfrac{1}{2}\text{(Equation 2):} \quad SO_2(g) + \tfrac{1}{2}O_2(g) \longrightarrow SO_3(g) \qquad \tfrac{1}{2}(\Delta H_2) = -99.2 \text{ kJ}$$

$$\text{Equation 3:} \quad S(s) + O_2(g) + \cancel{SO_2(g)} + \tfrac{1}{2}O_2(g) \longrightarrow \cancel{SO_2(g)} + SO_3(g) \qquad \Delta H_3 = ?$$

$$\text{or,} \quad S(s) + \tfrac{3}{2}O_2(g) \longrightarrow SO_3(g)$$

Adding the ΔH values gives

$$\Delta H_3 = \Delta H_1 + \tfrac{1}{2}(\Delta H_2) = -296.8 \text{ kJ} + (-99.2 \text{ kJ}) = -396.0 \text{ kJ}$$

Once again, the key point is that H is a state function, so the overall ΔH depends on the difference between the initial and final enthalpies only. Hess's law

tells us that the difference between the enthalpies of the reactants (1 mol of S and $\frac{3}{2}$ mol of O_2) and that of the product (1 mol of SO_3) is the same, whether S is oxidized directly to SO_3 (impossible) or through the formation of SO_2 (actual).

To summarize, calculating an unknown ΔH involves three steps:

1. Identify the target equation, the step whose ΔH is unknown, and note the number of moles of reactants and products.
2. Manipulate the equations with known ΔH values so that the target numbers of moles of reactants and products are on the correct sides. Remember to:
   - Change the sign of ΔH when you reverse an equation.
   - Multiply numbers of moles and ΔH by the same factor.
3. Add the manipulated equations to obtain the target equation. All substances except those in the target equation must cancel. Add their ΔH values to obtain the unknown ΔH.

SAMPLE PROBLEM 6.7 Using Hess's Law to Calculate an Unknown ΔH

Problem Two gaseous pollutants that form in auto exhaust are CO and NO. An environmental chemist is studying ways to convert them to less harmful gases through the following equation:

$$CO(g) + NO(g) \longrightarrow CO_2(g) + \tfrac{1}{2}N_2(g) \quad \Delta H = ?$$

Given the following information, calculate the unknown ΔH:

$$\text{Equation A:} \quad CO(g) + \tfrac{1}{2}O_2(g) \longrightarrow CO_2(g) \quad \Delta H_A = -283.0 \text{ kJ}$$
$$\text{Equation B:} \quad N_2(g) + O_2(g) \longrightarrow 2NO(g) \quad \Delta H_B = 180.6 \text{ kJ}$$

Plan We note the numbers of moles of substances in the target equation, manipulate Equations A and/or B *and* their ΔH values, and then add them together to obtain the target equation and the unknown ΔH.

Solution Noting moles of substances in the target equation: There is 1 mol each of reactants CO and NO, 1 mol of product CO_2, and $\frac{1}{2}$ mol of product N_2.

Manipulating the given equations: Equation A has the same number of moles of CO and CO_2 as the target, so we leave it as written. Equation B has twice the needed amounts of N_2 and NO, and they are on the opposite sides from the target; therefore, we reverse Equation B, change the sign of ΔH_B, and multiply both by $\frac{1}{2}$:

$$\tfrac{1}{2}[2NO(g) \longrightarrow N_2(g) + O_2(g)] \quad \Delta H = -\tfrac{1}{2}(\Delta H_B) = -\tfrac{1}{2}(180.6 \text{ kJ})$$
$$NO(g) \longrightarrow \tfrac{1}{2}N_2(g) + \tfrac{1}{2}O_2(g) \quad \Delta H = -90.3 \text{ kJ}$$

Adding the manipulated equations to obtain the target equation:

$$\text{Equation A:} \quad CO(g) + \cancel{\tfrac{1}{2}O_2(g)} \longrightarrow CO_2(g) \quad \Delta H = -283.0 \text{ kJ}$$
$$\tfrac{1}{2}\text{(Equation B reversed):} \quad NO(g) \longrightarrow \tfrac{1}{2}N_2(g) + \cancel{\tfrac{1}{2}O_2(g)} \quad \Delta H = -90.3 \text{ kJ}$$
$$\text{Target:} \quad CO(g) + NO(g) \longrightarrow CO_2(g) + \tfrac{1}{2}N_2(g) \quad \Delta H = -373.3 \text{ kJ}$$

Check Obtaining the desired target equation is its own check. Be sure to remember to change the sign of ΔH for any equation you reverse.

FOLLOW-UP PROBLEM 6.7 Nitrogen oxides undergo many interesting reactions in the environment and in industry. Given the following information, calculate ΔH for the overall equation $2NO_2(g) + \frac{1}{2}O_2(g) \longrightarrow N_2O_5(s)$:

$$N_2O_5(s) \longrightarrow 2NO(g) + \tfrac{3}{2}O_2(g) \quad \Delta H = 223.7 \text{ kJ}$$
$$NO(g) + \tfrac{1}{2}O_2(g) \longrightarrow NO_2(g) \quad \Delta H = -57.1 \text{ kJ}$$

SECTION SUMMARY

Because H is a state function, $\Delta H = H_{final} - H_{initial}$ and does not depend on how the reaction takes place. Using Hess's law ($\Delta H_{total} = \Delta H_1 + \Delta H_2 + \cdots + \Delta H_n$), we can determine ΔH of any equation by manipulating the coefficients of other appropriate equations and their known ΔH values.

Table 6.3 Selected Standard Heats of Formation at 25°C (298 K)

Formula	ΔH_f^0 (kJ/mol)

6.6 STANDARD HEATS OF REACTION (ΔH^0_{rxn})

In this section, we see how Hess's law is used to determine the ΔH values of an enormous number of reactions. To begin we must take into account that thermodynamic variables, such as ΔH, vary somewhat with conditions. Therefore, to use heats of reaction, as well as other thermodynamic data that we will encounter in later chapters, chemists have established **standard states,** a set of specified conditions and concentrations:

- For a *gas,* the standard state is 1 atm* with the gas behaving ideally.
- For a substance in *aqueous solution,* the standard state is 1 *M* concentration.
- For a *pure substance* (element or compound), the standard state is usually the most stable form of the substance at 1 atm and the temperature of interest. In this text, that temperature is usually 25°C (298 K).†

We use a right superscript zero to indicate these standard states. In other words, when the heat of reaction, ΔH_{rxn}, has been measured with all the reactants and products in their standard states, it is referred to as the **standard heat of reaction, ΔH^0_{rxn}.**

Formation Equations and Their Standard Enthalpy Changes

In a **formation equation,** 1 mole of a compound forms from its elements. The **standard heat of formation (ΔH^0_f)** is the enthalpy change for the formation equation when all the substances are in their standard states. For instance, the formation equation for methane (CH_4) is

$$\text{C(graphite)} + 2H_2(g) \longrightarrow CH_4(g) \qquad \Delta H^0_f = -74.9 \text{ kJ}$$

Thus, the standard heat of formation of methane is −74.9 kJ/mol. Some other examples are

$$\text{Na}(s) + \tfrac{1}{2}\text{Cl}_2(g) \longrightarrow \text{NaCl}(s) \qquad \Delta H^0_f = -411.1 \text{ kJ}$$

$$2\text{C(graphite)} + 3H_2(g) + \tfrac{1}{2}O_2(g) \longrightarrow C_2H_5OH(l) \qquad \Delta H^0_f = -277.6 \text{ kJ}$$

Standard heats of formation have been tabulated for many compounds. Table 6.3 shows ΔH^0_f values for several substances, and a much more extensive table appears in Appendix B.

The values in Table 6.3 were selected to make two points:

1. *An element in its standard state is assigned a ΔH^0_f of zero.* For example, note that $\Delta H^0_f = 0$ for Na(*s*), but $\Delta H^0_f = 107.8$ kJ/mol for Na(*g*). These values mean that the gaseous state is *not* the most stable state of sodium at 1 atm and 298.15 K, and that heat is required to form Na(*g*). Note also that the standard state of chlorine is Cl_2 molecules, not Cl atoms. Several elements exist in different forms, only one of which is the standard state. Thus, the standard state of carbon is graphite, not diamond, so ΔH^0_f of C(graphite) = 0. Similarly, the standard state of oxygen is dioxygen (O_2), not ozone (O_3), and the standard state of sulfur is S_8 in its rhombic crystal form, rather than its monoclinic form.
2. *Most compounds have a negative ΔH^0_f.* That is, most compounds have exothermic formation reactions under standard conditions: *heat is given off when the compound forms.*

*The definition of the standard state for gases has been changed to 1 bar, a slightly lower pressure than the 1 atm standard on which the data in this book are based (1 atm = 101.3 kPa = 1.013 bar). For most purposes, this makes *very* little difference in the standard enthalpy values.

†In the case of phosphorus, the most *common* form, white phosphorus (P_4), is chosen as the standard state, even though red phosphorus is more stable at 1 atm and 298 K.

SAMPLE PROBLEM 6.8 Writing Formation Equations

Problem Write balanced equations for the formation of 1 mol of each of the following compounds from their elements in their standard states, and include ΔH^0_f.

(a) Silver chloride, AgCl, a solid at standard conditions
(b) Calcium carbonate, $CaCO_3$, a solid at standard conditions
(c) Hydrogen cyanide, HCN, a gas at standard conditions

Plan We write the elements as the reactants and 1 mol of the compound as the product, being sure all substances are in their standard states. Then, we balance the atoms and obtain the ΔH^0_f values from Table 6.3 or Appendix B.

Solution **(a)** $Ag(s) + \frac{1}{2}Cl_2(g) \longrightarrow AgCl(s) \quad \Delta H^0_f = -127.0\ kJ$

(b) $Ca(s) + C(graphite) + \frac{3}{2}O_2(g) \longrightarrow CaCO_3(s) \quad \Delta H^0_f = -1206.9\ kJ$

(c) $\frac{1}{2}H_2(g) + C(graphite) + \frac{1}{2}N_2(g) \longrightarrow HCN(g) \quad \Delta H^0_f = 135\ kJ$

FOLLOW-UP PROBLEM 6.8 Write balanced equations for the formation of 1 mol of **(a)** $CH_3OH(l)$, **(b)** $CaO(s)$, and **(c)** $CS_2(l)$ from their elements in their standard states. Include ΔH^0_f for each reaction.

Determining ΔH^0_{rxn} from ΔH^0_f Values of Reactants and Products

By applying Hess's law, we can use ΔH^0_f values to determine ΔH^0_{rxn} for any reaction. All we have to do is view the reaction as an imaginary two-step process.

Step 1. Each reactant decomposes to its elements. This is the *reverse* of the formation reaction for each reactant, so each standard enthalpy change is $-\Delta H^0_f$.

Step 2. Each product forms from its elements. This step *is* the formation reaction for each product, so each standard enthalpy change is ΔH^0_f.

According to Hess's law, we add the enthalpy changes for these steps to obtain the overall enthalpy change for the reaction (ΔH^0_{rxn}). Figure 6.12 depicts the conceptual process. Suppose we want ΔH^0_{rxn} for

$$TiCl_4(l) + 2H_2O(g) \longrightarrow TiO_2(s) + 4HCl(g)$$

We write this equation as though it were the sum of four individual equations, one for each compound. The first two of these equations show the decomposition of the reactants to their elements (*reverse* of their formation), and the second two show the formation of the products from their elements:

$$\begin{aligned}
TiCl_4(l) &\longrightarrow Ti(s) + 2Cl_2(g) && -\Delta H^0_f[TiCl_4(l)] \\
2H_2O(g) &\longrightarrow 2H_2(g) + O_2(g) && -2\Delta H^0_f[H_2O(g)] \\
Ti(s) + O_2(g) &\longrightarrow TiO_2(s) && \Delta H^0_f[TiO_2(s)] \\
2H_2(g) + 2Cl_2(g) &\longrightarrow 4HCl(g) && 4\Delta H^0_f[HCl(g)]
\end{aligned}$$

$$TiCl_4(l) + 2H_2O(g) + \cancel{Ti(s)} + \cancel{O_2(g)} + \cancel{2H_2(g)} + \cancel{2Cl_2(g)} \longrightarrow \cancel{Ti(s)} + \cancel{2Cl_2(g)} + \cancel{2H_2(g)} + \cancel{O_2(g)} + TiO_2(s) + 4HCl(g)$$

Or,
$$TiCl_4(l) + 2H_2O(g) \longrightarrow TiO_2(s) + 4HCl(g)$$

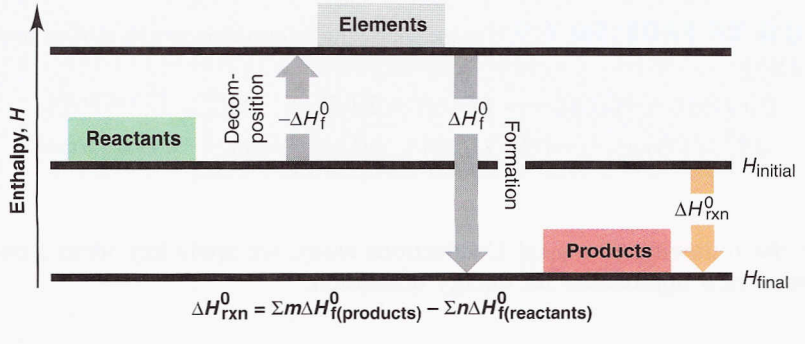

Figure 6.12 The general process for determining ΔH^0_{rxn} from ΔH^0_f values. For any reaction, ΔH^0_{rxn} can be considered as the sum of the enthalpy changes for the decomposition of reactants to their elements [$-\Sigma n\Delta H^0_{f(reactants)}$] and the formation of products from their elements [$+\Sigma m\Delta H^0_{f(products)}$]. [The factors m and n are the amounts (mol) of the products and reactants and equal the coefficients in the balanced equation, and Σ is the symbol for "sum of."]

It's important to realize that when titanium(IV) chloride and water react, the reactants don't *actually* decompose to their elements, which then recombine to form the products. But that is the great usefulness of Hess's law and the state-function concept. Because ΔH^0_{rxn} is the difference between two state functions, $H^0_{products}$ minus $H^0_{reactants}$, it doesn't matter *how* the change actually occurs. We simply add the individual enthalpy changes to find ΔH^0_{rxn}:

$$\begin{aligned}\Delta H^0_{rxn} &= \Delta H^0_f[TiO_2(s)] + 4\Delta H^0_f[HCl(g)] + \{-\Delta H^0_f[TiCl_4(l)]\} + \{-2\Delta H^0_f[H_2O(g)]\} \\ &= \underbrace{\{\Delta H^0_f[TiO_2(s)] + 4\Delta H^0_f[HCl(g)]\}}_{\text{Products}} - \underbrace{\{\Delta H^0_f[TiCl_4(l)] + 2\Delta H^0_f[H_2O(g)]\}}_{\text{Reactants}}\end{aligned}$$

Notice the pattern here. By generalizing it, we see that *the standard heat of reaction is the sum of the standard heats of formation of the* ***products*** *minus the sum of the standard heats of formation of the* ***reactants*** (see Figure 6.12):

$$\Delta H^0_{rxn} = \Sigma m\Delta H^0_{f\,(products)} - \Sigma n\Delta H^0_{f\,(reactants)} \qquad (6.8)$$

where the symbol Σ means "sum of," and m and n are the amounts (mol) of the products and reactants indicated by the coefficients from the balanced equation.

SAMPLE PROBLEM 6.9 Calculating the Heat of Reaction from Heats of Formation

Problem Nitric acid, whose worldwide annual production is nearly 10 billion kilograms, is used to make many products, including fertilizers, dyes, and explosives. The first step in the production process is the oxidation of ammonia:

$$4NH_3(g) + 5O_2(g) \longrightarrow 4NO(g) + 6H_2O(g)$$

Calculate ΔH^0_{rxn} from ΔH^0_f values.

Plan We use values from Table 6.3 (or Appendix B) and apply Equation 6.8 to find ΔH^0_{rxn}.

Solution Calculating ΔH^0_{rxn}:

$$\begin{aligned}\Delta H^0_{rxn} &= \Sigma m\Delta H^0_{f\,(products)} - \Sigma n\Delta H^0_{f\,(reactants)} \\ &= \{4\Delta H^0_f[NO(g)] + 6\Delta H^0_f[H_2O(g)]\} - \{4\Delta H^0_f[NH_3(g)] + 5\Delta H^0_f[O_2(g)]\} \\ &= (4\text{ mol})(90.3\text{ kJ/mol}) + (6\text{ mol})(-241.8\text{ kJ/mol}) \\ &\quad -[(4\text{ mol})(-45.9\text{ kJ/mol}) + (5\text{ mol})(0\text{ kJ/mol})] \\ &= 361\text{ kJ} - 1451\text{ kJ} + 184\text{ kJ} - 0\text{ kJ} \\ &= -906\text{ kJ}\end{aligned}$$

Check One way to check is to write formation equations for the amounts of individual compounds in the correct direction and take their sum:

$$\begin{array}{rcll} 4NH_3(g) & \longrightarrow & \cancel{2N_2(g)} + 6H_2(g) & -4(-45.9\text{ kJ}) = 184\text{ kJ} \\ \cancel{2N_2(g)} + 2O_2(g) & \longrightarrow & 4NO(g) & 4(90.3\text{ kJ}) = 361\text{ kJ} \\ \cancel{6H_2(g)} + 3O_2(g) & \longrightarrow & 6H_2O(g) & 6(-241.8\text{ kJ}) = -1451\text{ kJ} \\ \hline 4NH_3(g) + 5O_2(g) & \longrightarrow & 4NO(g) + 6H_2O(g) & -906\text{ kJ} \end{array}$$

Comment In this problem, we know the individual ΔH^0_f values and find the sum, ΔH^0_{rxn}. In the follow-up problem, we know the sum and want to find an individual value.

FOLLOW-UP PROBLEM 6.9 Use the following information to find ΔH^0_f of methanol [$CH_3OH(l)$]:

$$CH_3OH(l) + \tfrac{3}{2}O_2(g) \longrightarrow CO_2(g) + 2H_2O(g) \quad \Delta H^0_{comb} = -638.5\text{ kJ}$$

$$\Delta H^0_f \text{ of } CO_2(g) = -393.5\text{ kJ/mol} \quad \Delta H^0_f \text{ of } H_2O(g) = -241.8\text{ kJ/mol}$$

In the following Chemical Connections essay, we apply key ideas from this chapter to new approaches for energy utilization.

The Future of Energy Use

Out of necessity, we are seeing a global rethinking of the issue of energy use. The dwindling supply of the world's fuel and the environmental impact of its combustion threaten our standard of living and the well-being, even survival, of hundreds of millions of people in less developed countries. Chemical aspects of energy production and utilization provide scientists and engineers with some of the greatest challenges of our time.

Energy consumption increased enormously during the Industrial Revolution and again after World War II, and it continues to increase today. A century-long changeover from the use of wood to the use of coal and then petroleum took place. The **fossil fuels**—coal, petroleum, and natural gas—remain our major sources of energy, but their polluting combustion products and eventual depletion are major drawbacks to their use.

Natural processes form fossil fuels *much* more slowly than we consume them, so these resources are *nonrenewable:* once we use them up, they are gone. Estimates indicate that known oil reserves could be 90% depleted by the year 2040. Coal reserves are much more plentiful, so chemical research seeks new uses for coal. The most important *renewable* combustible fuels are wood, other fuels derived from *biomass* (plant and animal matter), and hydrogen gas. The following discussion highlights some approaches to more rational energy use and incorporates some aspects of *green chemistry,* the effort by government, industry, and academia to devise processes that avoid the release of harmful products into the environment: converting coal to cleaner fuels, producing fuels from biomass, understanding the effect of carbon-based fuels on climate, developing a hydrogen-fueled economy, utilizing energy sources that do not involve combustion, and conserving the fuels we have.

Chemical Approaches to Cleaner Carbon-Based Fuels

Coal Current U.S. reserves of coal are enormous, but coal is a highly polluting fuel because it produces SO_2 when it burns. Two processes—desulfurization and gasification—are designed to reduce emissions of this noxious pollutant.

Flue-gas *desulfurization* devices (*scrubbers*) heat powdered limestone ($CaCO_3$) or spray lime-water slurries [$Ca(OH)_2$] to remove SO_2 from the gaseous product mixture of coal combustion:

$$CaCO_3(s) + SO_2(g) \xrightarrow{\Delta} CaSO_3(s) + CO_2(g)$$

$$2CaSO_3(s) + O_2(g) + 4H_2O(l) \longrightarrow 2CaSO_4{\cdot}2H_2O(s;\ \text{gypsum})$$

$$2Ca(OH)_2(aq) + 2SO_2(g) + O_2(g) + 2H_2O(l) \longrightarrow 2CaSO_4{\cdot}2H_2O(s)$$

An innovative approach for disposing of the gypsum (nearly 1 ton per power-plant customer each year) has been to build a gypsum wallboard (drywall) plant adjacent to a coal-fired power plant. In 2002, 20% of drywall was made with synthetic gypsum.

In **coal gasification,** solid coal is converted to sulfur-free gaseous fuels and valuable chemical feedstocks. Reaction of coal with a limited amount of oxygen and water at 800–1500°C produces a gas stream consisting mainly of a 2:1 mixture of CO and H_2. Under these reducing conditions, the sulfur in the coal is converted to H_2S, which is removed from the mixture by an acid-base reaction with an amine such as ethanolamine ($HOCH_2CH_2NH_2$). The product is heated to release H_2S, which is converted to elemental sulfur, a valuable by-product, by the Claus process (Chapter 22).

The principal reactions are exothermic oxidation of carbon to CO and reaction of carbon with steam in the endothermic *water-gas reaction* (also known as the steam-carbon reaction) to form a mixture of CO and H_2 called *water gas*:

$$C(s) + \tfrac{1}{2}O_2(g) \longrightarrow CO(g) \qquad \Delta H^0 = -110\ \text{kJ}$$

$$C(s) + H_2O(g) \longrightarrow CO(g) + H_2(g) \qquad \Delta H^0 = 131\ \text{kJ}$$

To produce synthesis gas (**syngas**), which is used in the production of chemicals, the H_2 content of water gas is enhanced by the *CO-shift reaction* (also known as the water-gas shift reaction):

$$CO(g) + H_2O(g) \longrightarrow CO_2(g) + H_2(g) \qquad \Delta H^0 = -41\ \text{kJ}$$

Water gas has a much lower fuel value than methane. For example, a mixture containing 0.5 mol of CO and 0.5 mol of H_2 (that is, 1.0 mol of water gas) releases about one-third as much energy as combustion of 1.0 mol of methane ($\Delta H^0 = -802$ kJ/mol):

$$\tfrac{1}{2}H_2(g) + \tfrac{1}{4}O_2(g) \longrightarrow \tfrac{1}{2}H_2O(g) \quad \Delta H^0_{\text{comb}} = -121\ \text{kJ}$$

$$\tfrac{1}{2}CO(g) + \tfrac{1}{4}O_2(g) \longrightarrow \tfrac{1}{2}CO_2(g) \quad \Delta H^0_{\text{comb}} = -142\ \text{kJ}$$

$$\tfrac{1}{2}H_2(g) + \tfrac{1}{2}CO(g) + \tfrac{1}{2}O_2(g) \longrightarrow \tfrac{1}{2}H_2O(g) + \tfrac{1}{2}CO_2(g) \qquad \Delta H^0 = -263\ \text{kJ}$$

To produce methane, syngas having a 3:1 H_2:CO ratio and containing no CO_2 is employed:

$$CO(g) + 3H_2(g) \longrightarrow CH_4(g) + H_2O(g) \qquad \Delta H^0 = -206\ \text{kJ}$$

Drying the product mixture gives **synthetic natural gas (SNG).** Thus, in three reaction steps, coal is converted to methane.

Synthesis gas is also used to produce liquid hydrocarbon fuels in the *Fischer-Tropsch process*, which may be called upon in the future as petroleum supplies dwindle:

$$nCO(g) + (2n + 1)H_2(g) \longrightarrow C_nH_{2n+2}(l) + nH_2O(g)$$

Wood and Other Types of Biomass Nearly half the world's people rely on wood for energy. In principle, wood is renewable, but worldwide deforestation for fuel, and for lumber and paper in richer countries, has resulted in wood being depleted much faster than it can grow back. On the other hand, vegetable and animal waste *is* renewable, and several new processes focus on it.

One beneficial use of vegetable (sugarcane, corn, beets, soy) and tree waste is **biomass conversion,** which employs chemical and/or microbial methods to convert plant matter into combustible fuels. One such fuel is ethanol (C_2H_5OH), which is mixed with gasoline to form *gasohol*. Another is methane, which is produced in biogas generators through the microbial breakdown of plant and animal waste. China has active facilities applying these techniques. The United States is funding programs using similar technologies to produce gaseous fuels from garbage and sewage and liquid fuels by the chemical breakdown (thermal depolymerization) of plant and animal waste.

A useful approach is the chemical conversion of vegetable oils (soybean, cottonseed, sunflower, canola, and even used

(continued)

cooking oil) to a mixture of methylated fatty acids called *biodiesel*, which substitutes for diesel fuel in combustion engines. Compared to fossil-based diesel, biodiesel reduces visible smoke and sulfur and other toxic emissions, as well as the risk of lung cancer by 90%. As with any organic mixture, the combustion of biodiesel produces CO_2, a greenhouse gas, but this CO_2 has minimal impact on the net atmospheric load because it is taken up by plants grown as future biodiesel feedstocks, thereby creating a short-term loop that recycles the carbon.

The Greenhouse Effect and Global Warming

Carbon dioxide plays a key temperature-regulating role in the atmosphere. Much of the sunlight that shines on Earth is absorbed by the land and oceans and is converted to heat (Figure B6.1). Atmospheric CO_2 does not absorb visible light from the Sun, but it does absorb heat. Therefore, some of the heat radiating from the surface is trapped by the CO_2 and transferred to the atmosphere.

Over several billion years, due largely to the spread of plant life that uses CO_2 in photosynthesis, the amount of CO_2 originally present in Earth's atmosphere decreased to a relatively constant 0.028% by volume. However, for the past 150 years, this amount has been increasing as a result of the human use of fossil fuels, and it slightly exceeds 0.036% today. Thus, although the same amount of solar energy passes through the atmosphere, more is being trapped as heat in a process called the *greenhouse effect*, which has begun to cause *global warming* (Figure B6.2).

Based on current fossil fuel use, CO_2 concentrations are predicted to reach 0.070% to 0.075% by 2100. But, even if these projected increases in CO_2 occur, two closely related questions remain: (1) How much will the temperature of the atmosphere rise? (2) How will this temperature rise affect life on Earth?

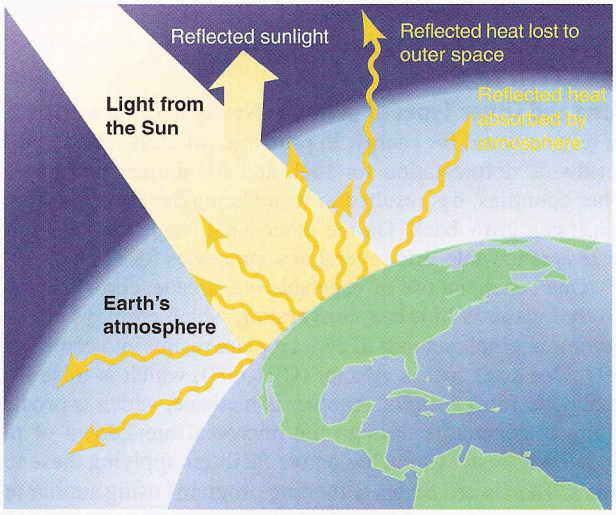

Figure B6.1 The trapping of heat by the atmosphere. About 25% of sunlight is reflected by the atmosphere. Much of the remaining sunlight is converted into heat by the air and Earth's surface. Some of the heat emanating from the surface is trapped by atmospheric gases, mostly CO_2, and some is lost to outer space.

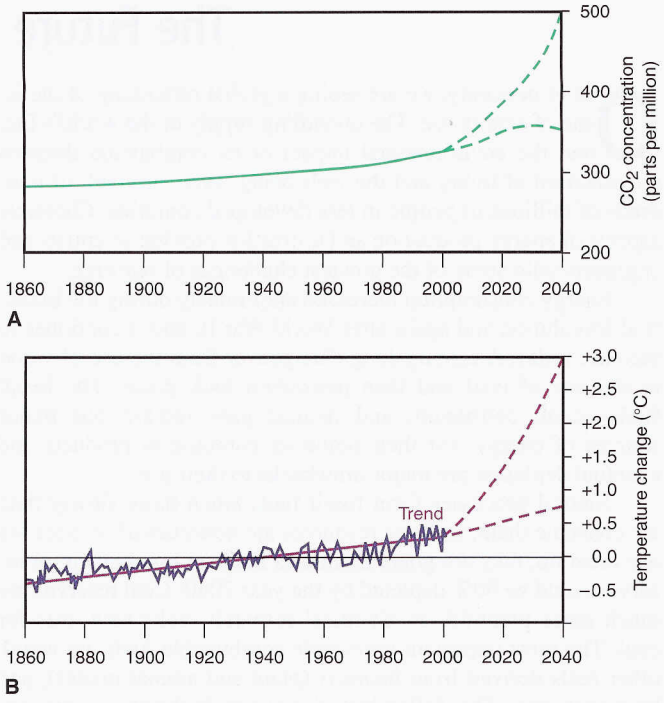

Figure B6.2 The accumulating evidence for the greenhouse effect. **A,** Since the mid-19th century, atmospheric CO_2 concentrations have increased. **B,** Coincident with this CO_2 increase, the average global temperature has risen about 0.6°C. (Zero equals the average global temperature from 1957 to 1970.) The projections in both graphs *(dashed lines)* are based on current fossil fuel consumption and deforestation either continuing *(upper line)* or being curtailed *(lower line)*.

For over a decade now, many academic, government, and private laboratories have been devising computer models to simulate the effects of increasing amounts of CO_2 and other greenhouse gases (most importantly, CH_4) on the temperature of the atmosphere. However, the atmospheric system is so complex that a definitive answer is difficult to obtain. Natural fluctuations in temperature must be taken into account, as well as cyclic changes in solar activity, which are expected to provide some additional warming for the first decade or so of the 21st century. Moreover, as the amount of CO_2 increases from fossil-fuel burning, so does the amount of soot, which may block sunlight and have a cooling effect. Water vapor also traps heat, and as temperatures rise, more water vapor forms. The increased amounts of water vapor may thicken the cloud cover and lead to cooling. Recent data indicate that decreased volcanic activity coupled with power plant innovations may reduce the SO_2-based particulates that also cool the atmosphere.

Nevertheless, despite these opposing factors, most models predict a net warming of the atmosphere, and scientists are now observing the trend and documenting the predicted climate disruptions. The average temperature has increased by 0.6°C over the past 50 years. When extra heat is trapped by elevated levels of greenhouse gases, 20% of the heat warms the air and 80% evaporates water. Globally, the 10 warmest years on record have occurred since 1980, with 1997–1999 among the hottest. The decade

from 1987 to 1997 included 10 times as many catastrophic floods from storms as did the previous decade, a trend that continued in 1998 and 1999. Other recently documented evidence includes a 10% decrease in global snow cover, a 40% thinning of Arctic Ocean ice, a 20% decrease in glacier extent, and a nearly 10% increase in rainfall in the northern hemisphere.

Five years ago, the most accepted models predicted a temperature rise of 1.0–3.5°C. Today, the best predictions are 1.4–5.8°C (2.5–10.4°F), about 40% greater. An average increase of 1°C in the U.S. Midwest could lower the grain yield by 20%; an increase of 3°C could alter rainfall patterns and crop yields throughout the world; a 5°C increase could melt large parts of the polar ice caps, increasing sea level by 3.5–34 inches, thus flooding low-lying regions such as the Netherlands, half of Florida, and much of India, and inundating some Pacific island nations. To make matters worse, as we burn fossil fuels and wood that *release* CO_2, we cut down the forests that naturally *absorb* CO_2.

Another solution to the problem of CO_2 emissions is *sequestration*. In its most common form, sequestration is performed by plants, and large-scale tree planting has been proposed. Another approach is to bury liquefied carbon dioxide underground or inject it into the deep oceans. The formations most suitable for underground storage may be those from which natural gas and petroleum are now extracted.

International conferences, such as the 1997 Conference on Climate Change in Kyoto, Japan, provided a forum for politicians, business interests, and scientists to agree on ways to cut emissions of greenhouse gases. But the largest producer of CO_2, the United States, refused to ratify the Kyoto Protocol and, as a result, many expect increased global warming and its associated effects on Earth's climate.

Hydrogen

Although combustion of H_2 ($\Delta H^0_{comb} = -242$ kJ/mol) produces only about one-third as much energy per mole as combustion of CH_4 ($\Delta H^0_{comb} = -802$ kJ/mol), it yields nonpolluting water vapor. Formation of H_2 from the decomposition of water, however, is endothermic (ΔH^0_{rxn} with liquid $H_2O = 286$ kJ/mol), and *direct* methods for this formation, such as by electrolysis, are still very costly. If future methods for generating electricity prove economical, the oceans provide an inexhaustible source of starting material.

Transporting and storing the hydrogen fuel could be accomplished with technologies used currently by utility companies. However, the actual method by which the H_2 will fuel, say, the family car is an open question. Earlier research showed that many metals, such as palladium and niobium, absorb large amounts of H_2 into the spaces between their atoms, and it was hoped that they might be used as fuel cartridges. But more recent studies show that the metals release the H_2 too slowly to be practical. The use of H_2 in fuel cells, however, is an active area of electrochemical research (which we discuss in Chapter 21). Tests are underway to commercialize this technology using the hydrogen that is a by-product of the petrochemical industry.

Production of hydrogen is feasible with nuclear power (by thermo- or electrochemical processes), but production from coal would require carbon sequestration. Ultimately, the hydrogen needed for a sustainable economy would have to be derived from renewable sources, such as decomposing water electrolytically using wind or solar power or photocatalytically using sunlight.

Solar Energy and Nuclear Energy

Solar Energy The quantity of solar energy striking the United States annually is *600 times greater than the country's total energy needs*. Despite this abundance, it is difficult to collect and store. The Sun's output is enormous but not concentrated, so vast surface areas must be devoted to collecting it.

Storing the energy is necessary because intense sunlight is available over most regions for only 6 to 8 hours a day and is greatly reduced in rainy or cloudy weather. One storage approach uses ionic hydrates, such as $Na_2SO_4 \cdot 10H_2O$. When warmed by sunlight to over 32°C, the 3 mol of ions dissolve in the 10 mol of water in an endothermic process:

$$Na_2SO_4 \cdot 10H_2O(s) \xrightarrow{>32°C} Na_2SO_4(aq) \quad \Delta H^0 = 354 \text{ kJ}$$

When cooled below 32°C after sunset, the solution recrystallizes, releasing the absorbed energy for heating:

$$Na_2SO_4(aq) \xrightarrow{<32°C} Na_2SO_4 \cdot 10H_2O(s) \quad \Delta H^0 = -354 \text{ kJ}$$

Photovoltaic cells convert light directly into electricity, but the electrical energy produced is only about 10% of the radiant energy supplied. However, novel combinations of elements from Groups 3A(13) and 5A(15), as in gallium arsenide (GaAs), result in higher yields and are approaching economic parity with certain types of fossil-fuel use.

Nuclear Energy Electricity from nuclear *fission* is used extensively, despite problems with the disposal of radioactive by-products, including fissile plutonium that can be used in weapons and heightens the risk of nuclear proliferation. Nuclear *fusion* avoids the problems of fission, but so far researchers have achieved fusion only with a net consumption of power. Practical application of fusion is still decades away. (We'll discuss these processes thoroughly in Chapter 24.)

Energy Conservation: More from Less

All systems on Earth, whether living organisms or industrial power plants, waste some energy, which in effect is a waste of fuel. In terms of the energy used to produce it, for example, every discarded aluminum can is equivalent to 0.25 L of gasoline. Energy conservation lowers production costs, extends our supply of fossil fuels, and reduces pollution.

One example of an energy-conserving device is a high-efficiency gas-burning furnace for domestic heating. Its design channels hot waste gases through the furnace to transfer more heat to the room and to an attached domestic hot water system. Moreover, the channeling path cools the gases to <100°C, so the water vapor condenses, thus releasing about 10% more heat:

$$\begin{aligned} CH_4(g) + 2O_2(g) &\longrightarrow CO_2(g) + 2H_2O(g) \quad \Delta H^0 = -802 \text{ kJ} \\ 2H_2O(g) &\longrightarrow 2H_2O(l) \quad \Delta H^0 = -88 \text{ kJ} \\ \hline CH_4(g) + 2O_2(g) &\longrightarrow CO_2(g) + 2H_2O(l) \quad \Delta H^0 = -890 \text{ kJ} \end{aligned}$$

Engineers and chemists will continue to explore alternatives for energy production and use, but a more hopeful energy future ultimately depends on our wisdom in obtaining and conserving planetary resources.

SECTION SUMMARY

Standard states are chosen conditions for substances. When 1 mol of a compound forms from its elements with all substances in their standard states, the enthalpy change is ΔH_f^0. Hess's law allows us to picture a reaction as the decomposition of reactants to their elements, followed by the formation of products from their elements. We use tabulated ΔH_f^0 values to find ΔH^0_{rxn} or use known ΔH^0_{rxn} and ΔH_f^0 values to find an unknown ΔH_f^0. Because of dwindling resources and environmental concerns, such as global warming, chemists are developing new energy alternatives, including coal and biomass conversion, hydrogen fuel, and noncombustible energy sources.

Chapter Perspective

Our investigation of energy in this chapter helps explain many chemical and physical phenomena: how gases do work, how reactions release or absorb heat, how the chemical energy in fuels and foods changes to other forms, and how we can use energy more wisely. We reexamine some of these ideas later in considering why physical and chemical changes occur. In Chapter 7, you'll see how the energy released or absorbed by the atom created a revolutionary view of matter and energy that led to our current model of atomic energy states.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The distinction between a system and its surroundings (6.1)
2. How energy is transferred to or from a system as heat and/or work (6.1)
3. The relation among internal energy change, heat, and work (6.1)
4. The meaning of energy conservation (6.1)
5. The meaning of a state function and why ΔE is constant even though q and w vary (6.1)
6. The meaning of enthalpy and the relation between ΔE and ΔH (6.2)
7. The meaning of ΔH and the distinction between exothermic and endothermic reactions (6.2)
8. The relation between specific heat capacity and heat transferred (6.3)
9. How constant-pressure (coffee-cup) and constant-volume (bomb) calorimeters work (6.3)
10. The relation between ΔH^0_{rxn} and amount of substance (6.4)
11. The importance of Hess's law and the manipulation of ΔH values (6.5)
12. The meaning of a formation equation and the standard heat of formation (6.6)
13. How a reaction can be viewed as the decomposition of reactants followed by the formation of products (6.6)

Master These Skills

1. Determining the change in energy in different units (SP 6.1)
2. Drawing enthalpy diagrams for chemical and physical changes (SP 6.2)
3. Solving problems involving specific heat capacity, heat of reaction, and heat of combustion (SPs 6.3 to 6.5)
4. Relating the heat of reaction and the amounts of substances changing (SP 6.6)
5. Using Hess's law to find an unknown ΔH (SP 6.7)
6. Writing formation equations and using ΔH_f^0 values to find ΔH^0_{rxn} (SPs 6.8 and 6.9)

Key Equations and Relationships

6.1 Defining the change in internal energy (226):

$$\Delta E = E_{final} - E_{initial} = E_{products} - E_{reactants}$$

6.2 Expressing the change in internal energy in terms of heat and work (227):

$$\Delta E = q + w$$

6.3 Stating the first law of thermodynamics (law of conservation of energy) (229):

$$\Delta E_{universe} = \Delta E_{system} + \Delta E_{surroundings} = 0$$

6.4 Determining the work due to a change in volume at constant pressure (PV work) (232):

$$w = -P\Delta V$$

6.5 Relating the enthalpy change to the internal energy change at constant pressure (232):

$$\Delta H = \Delta E + P\Delta V$$

6.6 Identifying the enthalpy change with the heat gained or lost at constant pressure (232):

$$q_P = \Delta E + P\Delta V = \Delta H$$

6.7 Calculating the heat absorbed or released when a substance undergoes a temperature change (235):

$$q = c \times \text{mass} \times \Delta T$$

6.8 Calculating the standard heat of reaction (244):

$$\Delta H^0_{rxn} = \Sigma m\Delta H^0_{f\,(products)} - \Sigma n\Delta H^0_{f\,(reactants)}$$

Highlighted Figures and Tables

These figures (F) and tables (T) provide a review of key ideas.

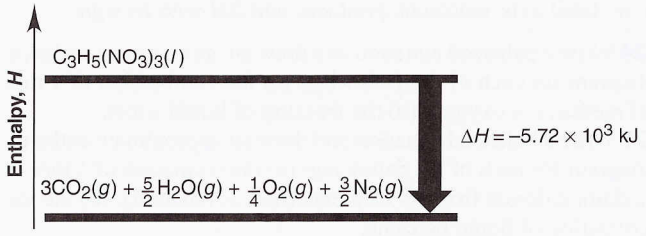
F6.2 Energy diagrams for the transfer of internal energy (E) between a system and its surroundings (226)
T6.1 Sign conventions for q, w, and ΔE (228)
F6.8 Enthalpy diagrams for exothermic and endothermic processes (233)
T6.2 Specific heat capacities of some elements, compounds, and materials (235)
F6.11 Summary of the relationship between amount (mol) of substance and heat (kJ) transferred during a reaction (239)
F6.12 The general process for determining ΔH^0_{rxn} from ΔH^0_f values (243)

Brief Solutions to Follow-up Problems

6.1

$$\Delta E = q + w$$
$$= \left(-26.0\text{ kcal} \times \frac{4.184\text{ kJ}}{1\text{ kcal}}\right) + \left(+15.0\text{ Btu} \times \frac{1.055\text{ kJ}}{1\text{ Btu}}\right)$$
$$= -93\text{ kJ}$$

6.2 The reaction is exothermic.



6.3

$$\Delta T = 25.0°\text{C} - 37.0°\text{C} = -12.0°\text{C} = -12.0\text{ K}$$

$$\text{Mass (g)} = 1.11\text{ g/mL} \times \frac{1000\text{ mL}}{1\text{ L}} \times 5.50\text{ L} = 6.10\times10^3\text{ g}$$

$$q = c \times \text{mass} \times \Delta T$$
$$= (2.42\text{ J/g·K})\left(\frac{1\text{ kJ}}{1000\text{ J}}\right)(6.10\times10^3\text{ g})(-12.0\text{ K})$$
$$= -177\text{ kJ}$$

6.4

$$-q_{solid} = q_{water}$$
$$-[(0.519\text{ J/g·K})(2.050\text{ g})(x - 74.21)]$$
$$= [(4.184\text{ J/g·K})(26.05\text{ g})(x - 27.20)]$$
$$x = 27.65\text{ K}$$

$$\Delta T_{diamond} = -46.56\text{ K} \text{ and } \Delta T_{water} = 0.45\text{ K}$$

6.5

$$-q_{sample} = q_{calorimeter}$$
$$-(0.8650\text{ g C})\left(\frac{1\text{ mol C}}{12.01\text{ g C}}\right)(-393.5\text{ kJ/mol C}) = (2.613\text{ K})x$$
$$x = 10.85\text{ kJ/K}$$

6.6

$$C_2H_4(g) + H_2(g) \longrightarrow C_2H_6(g) + 137\text{ kJ}$$

$$\text{Heat (kJ)} = 15.0\text{ kg} \times \frac{1000\text{ g}}{1\text{ kg}} \times \frac{1\text{ mol } C_2H_6}{30.07\text{ g } C_2H_6} \times \frac{137\text{ kJ}}{1\text{ mol}}$$
$$= 6.83\times10^4\text{ kJ}$$

6.7

$$2NO(g) + \tfrac{3}{2}O_2(g) \longrightarrow N_2O_5(s) \qquad \Delta H = -223.7\text{ kJ}$$
$$2NO_2(g) \longrightarrow 2NO(g) + O_2(g) \qquad \Delta H = 114.2\text{ kJ}$$

$$\cancel{2NO(g)} + \tfrac{1}{2}\tfrac{\cancel{3}}{\cancel{2}}O_2(g) + 2NO_2(g) \longrightarrow N_2O_5(s) + \cancel{2NO(g)} + \cancel{O_2(g)}$$

$$2NO_2(g) + \tfrac{1}{2}O_2(g) \longrightarrow N_2O_5(s) \qquad \Delta H = -109.5\text{ kJ}$$

6.8 (a) $C(\text{graphite}) + 2H_2(g) + \frac{1}{2}O_2(g) \longrightarrow CH_3OH(l)$ $\quad \Delta H^0_f = -238.6\text{ kJ}$

(b) $Ca(s) + \frac{1}{2}O_2(g) \longrightarrow CaO(s)$ $\quad \Delta H^0_f = -635.1\text{ kJ}$

(c) $C(\text{graphite}) + \frac{1}{4}S_8(\text{rhombic}) \longrightarrow CS_2(l)$ $\quad \Delta H^0_f = 87.9\text{ kJ}$

6.9 ΔH^0_f of $CH_3OH(l)$

$$= -\Delta H^0_{comb} + 2\Delta H^0_f[H_2O(g)] + \Delta H^0_f[CO_2(g)]$$
$$= 638.5\text{ kJ} + (2\text{ mol})(-241.8\text{ kJ/mol}) + (1\text{ mol})(-393.5\text{ kJ/mol})$$
$$= -238.6\text{ kJ}$$

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Forms of Energy and Their Interconversion

(Sample Problem 6.1)

Concept Review Questions

6.1 Why do heat (q) and work (w) have positive values when entering a system and negative values when leaving?

6.2 If you feel warm after exercising, have you increased the internal energy of your body? Explain.

6.3 An *adiabatic* process is one that involves no heat transfer. What is the relationship between work and the change in internal energy in an adiabatic process?

6.4 State two ways that you increase the internal energy of your body and two ways that you decrease it.

6.5 Name a common device that is used to accomplish each energy change:
(a) Electrical energy to thermal energy
(b) Electrical energy to sound energy
(c) Electrical energy to light energy
(d) Mechanical energy to electrical energy
(e) Chemical energy to electrical energy

6.6 In winter, an electric heater uses a certain amount of electrical energy to heat a room to 20°C. In summer, an air conditioner uses the same amount of electrical energy to cool the room to 20°C. Is the change in internal energy of the heater larger, smaller, or the same as that of the air conditioner? Explain.

6.7 Imagine lifting your textbook into the air and dropping it onto a desktop. Describe all the energy transformations (from one form to another) that occur, moving backward in time from a moment after impact.

Skill-Building Exercises *(grouped in similar pairs)*

6.8 A system receives 425 J of heat and delivers 425 J of work to its surroundings. What is the change in internal energy of the system (in J)?

6.9 A system conducts 255 cal of heat to the surroundings while delivering 428 cal of work. What is the change in internal energy of the system (in cal)?

6.10 What is the change in internal energy (in J) of a system that releases 675 J of thermal energy to its surroundings and has 525 cal of work done on it?

6.11 What is the change in internal energy (in J) of a system that absorbs 0.615 kJ of heat from its surroundings and has 0.247 kcal of work done on it?

6.12 Complete combustion of 1.0 metric ton of coal (assuming pure carbon) to gaseous carbon dioxide releases 3.3×10^{10} J of heat. Convert this energy to (a) kilojoules; (b) kilocalories; (c) British thermal units.

6.13 Thermal decomposition of 5.0 metric tons of limestone to lime and carbon dioxide requires 9.0×10^{6} kJ of heat. Convert this energy to (a) joules; (b) calories; (c) British thermal units.

Problems in Context

6.14 The nutritional calorie (Calorie) is equivalent to 1 kcal. One pound of body fat is equivalent to about 4.1×10^{3} Calories. Express this quantity of energy in joules and kilojoules.

6.15 If an athlete expends 1850 kJ/h, how long does she have to play to work off 1.0 lb of body fat? (See Problem 6.14.)

Enthalpy: Heats of Reaction and Chemical Change

(Sample Problem 6.2)

Concept Review Questions

6.16 Why is the work done when a system expands against a constant external pressure assigned a negative sign?

6.17 Why is it usually more convenient to measure ΔH than ΔE?

6.18 "Hot packs" used by skiers, climbers, and others for warmth are based on the crystallization of sodium acetate from a highly concentrated solution. What is the sign of ΔH for this crystallization? Is the reaction exothermic or endothermic?

6.19 Classify the following processes as exothermic or endothermic: (a) freezing of water; (b) boiling of water; (c) digestion of food; (d) a person running; (e) a person growing; (f) wood being chopped; (g) heating with a furnace.

6.20 What are the two main components of the internal energy of a substance? On what are they based?

6.21 For each process, state whether ΔH is less than (more negative), equal to, or greater than ΔE of the system. Explain.
(a) An ideal gas is cooled at constant pressure.
(b) A mixture of gases undergoes an exothermic reaction in a container of fixed volume.
(c) A solid yields a mixture of gases in an exothermic reaction that takes place in a container of variable volume.

Skill-Building Exercises *(grouped in similar pairs)*

6.22 Draw an enthalpy diagram for a general exothermic reaction; label axis, reactants, products, and ΔH with its sign.

6.23 Draw an enthalpy diagram for a general endothermic reaction; label axis, reactants, products, and ΔH with its sign.

6.24 Write a balanced equation and draw an approximate enthalpy diagram for each of the following: (a) the combustion of 1 mol of methane in oxygen; (b) the freezing of liquid water.

6.25 Write a balanced equation and draw an approximate enthalpy diagram for each of the following: (a) the formation of 1 mol of sodium chloride from its elements (heat is released); (b) the vaporization of liquid benzene.

6.26 Write a balanced equation and draw an approximate enthalpy diagram for each of the following changes: (a) the combustion of 1 mol of liquid ethanol (C_2H_5OH); (b) the formation of 1 mol of nitrogen dioxide from its elements (heat is absorbed).

6.27 Write a balanced equation and draw an approximate enthalpy diagram for each of the following changes: (a) the sublimation of dry ice [conversion of $CO_2(s)$ directly to $CO_2(g)$]; (b) the reaction of 1 mol of sulfur dioxide with oxygen.

Calorimetry: Laboratory Measurement of Heats of Reaction

(Sample Problems 6.3 to 6.5)

Concept Review Questions

6.28 Why can we measure only *changes* in enthalpy, not absolute enthalpy values?

6.29 What data do you need to determine the specific heat capacity of a substance?

6.30 Is the specific heat capacity of a substance an intensive or extensive property? Explain.

6.31 Distinguish between "specific heat capacity" and "heat capacity." Which parameter would you more likely use if you were calculating heat changes in (a) a chrome-plated, brass bathroom fixture; (b) a sample of high-purity copper wire; (c) a sample of pure water? Explain.

6.32 Both a coffee-cup calorimeter and a bomb calorimeter can be used to measure the heat involved in a reaction. Which measures ΔE and which measures ΔH? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

6.33 Calculate q when 12.0 g of water is heated from 20.°C to 100.°C.

6.34 Calculate q when 0.10 g of ice is cooled from 10.°C to −75°C (c_{ice} = 2.087 J/g·K).

6.35 A 295-g aluminum engine part at an initial temperature of 3.00°C absorbs 85.0 kJ of heat. What is the final temperature of the part (c of Al = 0.900 J/g·K)?

6.36 A 27.7-g sample of ethylene glycol, a car radiator coolant, loses 688 J of heat. What was the initial temperature of the ethylene glycol if the final temperature is 32.5°C (c of ethylene glycol = 2.42 J/g·K)?

6.37 Two iron bolts of equal mass—one at 100.°C, the other at 55°C—are placed in an insulated container. Assuming the heat capacity of the container is negligible, what is the final temperature inside the container (c of iron = 0.450 J/g·K)?

6.38 One piece of copper jewelry at 105°C has exactly twice the mass of another piece, which is at 45°C. Both pieces are placed inside a calorimeter whose heat capacity is negligible. What is the final temperature inside the calorimeter (c of copper = 0.387 J/g·K)?

6.39 When 165 mL of water at 22°C is mixed with 85 mL of water at 82°C, what is the final temperature? (Assume that no heat is lost to the surroundings; d of water is 1.00 g/mL.)

6.40 An unknown volume of water at 18.2°C is added to 24.4 mL of water at 35.0°C. If the final temperature is 23.5°C, what was the unknown volume? (Assume that no heat is lost to the surroundings; d of water is 1.00 g/mL.)

6.41 A 505-g piece of copper tubing is heated to 99.9°C and placed in an insulated vessel containing 59.8 g of water at 24.8°C. Assuming no loss of water and a heat capacity for the vessel of 10.0 J/K, what is the final temperature of the system (c of copper = 0.387 J/g·K)?

6.42 A 30.5-g sample of an alloy at 93.0°C is placed into 50.0 g of water at 22.0°C in an insulated coffee cup with a heat capacity of 9.2 J/K. If the final temperature of the system is 31.1°C, what is the specific heat capacity of the alloy?

Problems in Context

6.43 High-purity benzoic acid (C_6H_5COOH; ΔH_{comb} = −3227 kJ/mol) is a combustion standard for calibrating bomb calorimeters. A 1.221-g sample burns in a calorimeter (heat capacity = 1365 J/°C) that contains exactly 1.200 kg of water. What temperature change is observed?

6.44 Two aircraft rivets, one of iron and the other of copper, are placed in a calorimeter that has an initial temperature of 20.°C. The data for the metals are as follows:

	Iron	Copper
Mass (g)	30.0	20.0
Initial T (°C)	0.0	100.0
c (J/g·K)	0.450	0.387

(a) Will heat flow from Fe to Cu or from Cu to Fe?
(b) What other information is needed to correct any measurements that would be made in an actual experiment?
(c) What is the maximum final temperature of the system (assuming the heat capacity of the calorimeter is negligible)?

6.45 A chemical engineer studying the properties of fuels placed 1.500 g of a hydrocarbon in the bomb of a calorimeter and filled it with O_2 gas (see Figure 6.10, p. 237). The bomb was immersed in 2.500 L of water and the reaction initiated. The water temperature rose from 20.00°C to 23.55°C. If the calorimeter (excluding the water) had a heat capacity of 403 J/K, what was the heat of combustion (q_V) per gram of the fuel?

6.46 When 25.0 mL of 0.500 M H_2SO_4 is added to 25.0 mL of 1.00 M KOH in a coffee-cup calorimeter at 23.50°C, the temperature rises to 30.17°C. Calculate ΔH of this reaction. (Assume that the total volume is the sum of the individual volumes and that the density and specific heat capacity of the solution are the same as for pure water.)

Stoichiometry of Thermochemical Equations

(Sample Problem 6.6)

Concept Review Questions

6.47 Does a negative ΔH_{rxn} mean that the heat of reaction can be thought of as a reactant or as a product?

6.48 Would you expect $O_2(g) \longrightarrow 2O(g)$ to have a positive or a negative ΔH_{rxn}? Explain.

6.49 Is ΔH positive or negative when 1 mol of water vapor condenses to liquid water? Why? How does this value compare with that for the vaporization of 2 mol of liquid water to water vapor?

Skill-Building Exercises *(grouped in similar pairs)*

6.50 Consider the following balanced thermochemical equation for a reaction sometimes used for H_2S production:

$$\tfrac{1}{8}S_8(s) + H_2(g) \longrightarrow H_2S(g) \quad \Delta H_{rxn} = -20.2 \text{ kJ}$$

(a) Is this an exothermic or endothermic reaction?
(b) What is ΔH_{rxn} for the reverse reaction?
(c) What is ΔH when 3.2 mol of S_8 reacts?
(d) What is ΔH when 20.0 g of S_8 reacts?

6.51 Consider the following balanced thermochemical equation for the decomposition of the mineral magnesite:

$$MgCO_3(s) \longrightarrow MgO(s) + CO_2(g) \quad \Delta H_{rxn} = 117.3 \text{ kJ}$$

(a) Is heat absorbed or released in the reaction?
(b) What is ΔH_{rxn} for the reverse reaction?
(c) What is ΔH when 5.35 mol of CO_2 reacts with excess MgO?
(d) What is ΔH when 35.5 g of CO_2 reacts with excess MgO?

6.52 When 1 mol of NO(g) forms from its elements, 90.29 kJ of heat is absorbed. (a) Write a balanced thermochemical equation for this reaction. (b) How much heat is involved when 1.50 g of NO decomposes to its elements?

6.53 When 1 mol of KBr(s) decomposes to its elements, 394 kJ of heat is absorbed. (a) Write a balanced thermochemical equation for this reaction. (b) How much heat is released when 10.0 kg of KBr forms from its elements?

Problems in Context

6.54 Liquid hydrogen peroxide, an oxidizing agent in many rocket fuel mixtures, releases oxygen gas on decomposition:

$$2H_2O_2(l) \longrightarrow 2H_2O(l) + O_2(g) \quad \Delta H_{rxn} = -196.1 \text{ kJ}$$

How much heat is released when 732 kg of H_2O_2 decomposes?

6.55 Compounds of boron and hydrogen are remarkable for their unusual bonding (described in Section 14.5) and also for their reactivity. With the more reactive halogens, for example, diborane (B_2H_6) forms trihalides even at low temperatures:

$$B_2H_6(g) + 6Cl_2(g) \longrightarrow 2BCl_3(g) + 6HCl(g) \quad \Delta H_{rxn} = -755.4 \text{ kJ}$$

How much heat is released per kilogram of diborane that reacts?

6.56 Deterioration of buildings, bridges, and other structures through the rusting of iron costs millions of dollars every day. Although the actual process also requires water, a simplified equation (with rust shown as Fe_2O_3) is

$$4Fe(s) + 3O_2(g) \longrightarrow 2Fe_2O_3(s) \quad \Delta H_{rxn} = -1.65\times10^3 \text{ kJ}$$

(a) How much heat is evolved when 0.100 kg of iron rusts?
(b) How much rust forms when 4.93×10^3 kJ of heat is released?

6.57 A mercury mirror forms inside a test tube by the thermal decomposition of mercury(II) oxide:

$$2HgO(s) \longrightarrow 2Hg(l) + O_2(g) \quad \Delta H_{rxn} = 181.6 \text{ kJ}$$

(a) How much heat is needed to decompose 555 g of the oxide?
(b) If 275 kJ of heat is absorbed, how many grams of Hg form?

6.58 Ethylene (C_2H_4) is the starting material for the preparation of polyethylene. Although typically made during the processing of petroleum, ethylene occurs naturally as a fruit-ripening hormone and as a component of natural gas.
(a) If the heat of combustion of C_2H_4 is -1411 kJ/mol, write a balanced thermochemical equation for the combustion of C_2H_4.
(b) How many grams of C_2H_4 must burn to give 70.0 kJ of heat?

6.59 Sucrose ($C_{12}H_{22}O_{11}$, table sugar) is oxidized in the body by O_2 via a complex set of reactions that ultimately produces $CO_2(g)$ and $H_2O(g)$ and releases 5.64×10^3 kJ/mol sucrose.
(a) Write a balanced thermochemical equation for this reaction.
(b) How much heat is released per gram of sucrose oxidized?

Hess's Law of Heat Summation

(Sample Problem 6.7)

Concept Review Questions

6.60 Express Hess's law in your own words.

6.61 What is the main use of Hess's law?

6.62 It is very difficult to burn carbon in a deficiency of O_2 and produce only CO; some CO_2 forms as well. However, carbon burns in excess O_2 to form only CO_2, and CO burns in excess O_2 to form only CO_2. Use the heats of the latter two reactions (from Appendix B) to calculate ΔH_{rxn} for the following reaction:

$$C(\text{graphite}) + \tfrac{1}{2}O_2(g) \longrightarrow CO(g)$$

Skill-Building Exercises *(grouped in similar pairs)*

6.63 Calculate ΔH_{rxn} for

$$Ca(s) + \tfrac{1}{2}O_2(g) + CO_2(g) \longrightarrow CaCO_3(s)$$

given the following set of reactions:

$$Ca(s) + \tfrac{1}{2}O_2(g) \longrightarrow CaO(s) \quad \Delta H = -635.1 \text{ kJ}$$
$$CaCO_3(s) \longrightarrow CaO(s) + CO_2(g) \quad \Delta H = 178.3 \text{ kJ}$$

6.64 Calculate ΔH_{rxn} for

$$2NOCl(g) \longrightarrow N_2(g) + O_2(g) + Cl_2(g)$$

given the following set of reactions:

$$\tfrac{1}{2}N_2(g) + \tfrac{1}{2}O_2(g) \longrightarrow NO(g) \quad \Delta H = 90.3 \text{ kJ}$$
$$NO(g) + \tfrac{1}{2}Cl_2(g) \longrightarrow NOCl(g) \quad \Delta H = -38.6 \text{ kJ}$$

6.65 At a specific set of conditions, 241.8 kJ is given off when 1 mol of $H_2O(g)$ forms from its elements. Under the same conditions, 285.8 kJ is given off when 1 mol of $H_2O(l)$ forms from its elements. Calculate the heat of vaporization of water at these conditions.

6.66 When 1 mol of $CS_2(l)$ forms from its elements at 1 atm and 25°C, 89.7 kJ is absorbed, and it takes 27.7 kJ to vaporize 1 mol of the liquid. How much heat is absorbed when 1 mol of $CS_2(g)$ forms from its elements at these conditions?

6.67 Write the balanced overall equation for the following process (equation 3), calculate $\Delta H_{overall}$, and match the number of each equation with the letter of the appropriate arrow in Figure P6.67:

(1) $N_2(g) + O_2(g) \longrightarrow 2NO(g)$ $\quad \Delta H = 180.6$ kJ
(2) $2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$ $\quad \Delta H = -114.2$ kJ
(3) $\quad \Delta H_{overall} = ?$

6.68 Write the balanced overall equation for the following process (equation 3), calculate $\Delta H_{overall}$, and match the number of each equation with the letter of the appropriate arrow in Figure P6.68:

(1) $P_4(s) + 6Cl_2(g) \longrightarrow 4PCl_3(g)$ $\quad \Delta H = -1148$ kJ
(2) $4PCl_3(g) + 4Cl_2(g) \longrightarrow 4PCl_5(g)$ $\quad \Delta H = -460$ kJ
(3) $\quad \Delta H_{overall} = ?$

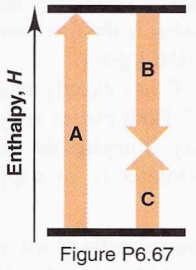


Figure P6.67

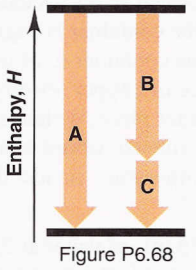

Figure P6.68

Problems in Context

6.69 Diamond and graphite are two crystalline forms of carbon. At 1 atm and 25°C, diamond changes to graphite so slowly that the enthalpy change of the process must be obtained indirectly. Determine ΔH_{rxn} for

$$C(\text{diamond}) \longrightarrow C(\text{graphite})$$

with equations from the following list:

(1) $C(\text{diamond}) + O_2(g) \longrightarrow CO_2(g)$ $\quad \Delta H = -395.4$ kJ
(2) $2CO_2(g) \longrightarrow 2CO(g) + O_2(g)$ $\quad \Delta H = 566.0$ kJ
(3) $C(\text{graphite}) + O_2(g) \longrightarrow CO_2(g)$ $\quad \Delta H = -393.5$ kJ
(4) $2CO(g) \longrightarrow C(\text{graphite}) + CO_2(g)$ $\quad \Delta H = -172.5$ kJ

Standard Heats of Reaction (ΔH^0_{rxn})

(Sample Problems 6.8 and 6.9)

Concept Review Questions

6.70 What is the difference between the standard heat of formation and the standard heat of reaction?

6.71 How are ΔH^0_f values used to calculate ΔH^0_{rxn}?

6.72 Make any changes needed in each of the following equations to make ΔH^0_{rxn} equal to ΔH^0_f for the compound present:
(a) $Cl(g) + Na(s) \longrightarrow NaCl(s)$
(b) $H_2O(g) \longrightarrow 2H(g) + \tfrac{1}{2}O_2(g)$
(c) $\tfrac{1}{2}N_2(g) + \tfrac{3}{2}H_2(g) \longrightarrow NH_3(g)$

Skill-Building Exercises *(grouped in similar pairs)*

6.73 Use Table 6.3 or Appendix B to write balanced formation equations at standard conditions for each of the following compounds: (a) $CaCl_2$; (b) $NaHCO_3$; (c) CCl_4; (d) HNO_3.

6.74 Use Table 6.3 or Appendix B to write balanced formation equations at standard conditions for each of the following compounds: (a) HI; (b) SiF_4; (c) O_3; (d) $Ca_3(PO_4)_2$.

6.75 Calculate ΔH^0_{rxn} for each of the following:

(a) $2H_2S(g) + 3O_2(g) \longrightarrow 2SO_2(g) + 2H_2O(g)$

(b) $CH_4(g) + Cl_2(g) \longrightarrow CCl_4(l) + HCl(g)$ [unbalanced]

6.76 Calculate ΔH^0_{rxn} for each of the following:

(a) $SiO_2(s) + 4HF(g) \longrightarrow SiF_4(g) + 2H_2O(l)$

(b) $C_2H_6(g) + O_2(g) \longrightarrow CO_2(g) + H_2O(g)$ [unbalanced]

6.77 Copper(I) oxide can be oxidized to copper(II) oxide:

$$Cu_2O(s) + \tfrac{1}{2}O_2(g) \longrightarrow 2CuO(s) \quad \Delta H^0_{rxn} = -146.0 \text{ kJ}$$

Given that ΔH^0_f of $Cu_2O(s) = -168.6$ kJ/mol, what is ΔH^0_f of $CuO(s)$?

6.78 Acetylene burns in air according to the following equation:

$$C_2H_2(g) + \tfrac{5}{2}O_2(g) \longrightarrow 2CO_2(g) + H_2O(g) \qquad \Delta H^0_{rxn} = -1255.8 \text{ kJ}$$

Given that ΔH^0_f of $CO_2(g) = -393.5$ kJ/mol and that ΔH^0_f of $H_2O(g) = -241.8$ kJ/mol, what is ΔH^0_f of $C_2H_2(g)$?

Problems in Context

6.79 Nitroglycerine, $C_3H_5(NO_3)_3(l)$, a powerful explosive used in mining, detonates to produce a hot gaseous mixture of nitrogen, water, carbon dioxide, and oxygen.

(a) Write a balanced equation for this reaction using the smallest whole-number coefficients.

(b) If $\Delta H^0_{rxn} = -2.29\times10^4$ kJ for the equation as written in part (a), calculate ΔH^0_f of nitroglycerine.

6.80 The common lead-acid car battery produces a large burst of current, even at low temperatures, and is rechargeable. The reaction that occurs while recharging a "dead" battery is

$$2PbSO_4(s) + 2H_2O(l) \longrightarrow Pb(s) + PbO_2(s) + 2H_2SO_4(l)$$

(a) Use ΔH^0_f values from Appendix B to calculate ΔH^0_{rxn}.

(b) Use the following equations to check your answer in part (a):

(1) $Pb(s) + PbO_2(s) + 2SO_3(g) \longrightarrow 2PbSO_4(s) \qquad \Delta H^0 = -768$ kJ

(2) $SO_3(g) + H_2O(l) \longrightarrow H_2SO_4(l) \qquad \Delta H^0 = -132$ kJ

Comprehensive Problems

6.81 Stearic acid ($C_{18}H_{36}O_2$) is a typical fatty acid, a molecule with a long hydrocarbon chain and an organic acid group (COOH) at the end. It is used to make cosmetics, ointments, soaps, and candles and is found in animal tissue as part of many saturated fats. In fact, when you eat meat, chances are that you are ingesting some fats that contain stearic acid.

(a) Write a balanced equation for the complete combustion of stearic acid to gaseous products.

(b) Calculate its heat of combustion ($\Delta H^0_f = -948$ kJ/mol).

(c) Calculate the heat (q) in kJ and kcal when 1.00 g of stearic acid is burned completely.

(d) The nutritional information for a candy bar states that one serving contains 11.0 g of fat and 100. Cal from fat (1 Cal = 1 kcal). Is this information consistent with your answer for part (c)?

6.82 When you dilute sulfuric acid with water, you must be very careful because the dilution process is highly exothermic:

$$H_2SO_4(l) \xrightarrow{H_2O} H_2SO_4(aq) + heat$$

(a) Use Appendix B to calculate ΔH^0 for diluting 1.00 mol of $H_2SO_4(l)$ to 1 L of 1.00 M $H_2SO_4(aq)$.

(b) Suppose you carry out the dilution in a calorimeter. The initial T is 25.0°C, the density of the final solution is 1.060 g/mL, and its specific heat capacity is 3.50 J/g·K. What is the final T?

(c) Use the idea of heat capacity to explain why you should carry out the dilution by adding acid to water rather than water to acid.

6.83 A balloonist is preparing to make a trip in a helium-filled balloon. The trip begins in early morning at a temperature of 15°C. By midafternoon, the temperature has increased to 30.°C. Assuming the pressure remains constant at 1.00 atm, for each mole of helium, calculate:

(a) The initial and final volumes

(b) The change in internal energy, ΔE [*Hint:* Helium behaves like an ideal gas, so $E = \frac{3}{2}nRT$. Be sure the units of R are consistent with those of E.]

(c) The work (w) done by the helium (in J)

(d) The heat (q) transferred (in J)

(e) ΔH for the process (in J)

(f) Explain the relationship between the answers to (d) and (e).

6.84 In winemaking, the sugars in grapes undergo *fermentation* by yeast to yield CH_3CH_2OH and CO_2. During cellular *respiration*, sugar and ethanol are "burned" to water vapor and CO_2.

(a) Using $C_6H_{12}O_6$ for sugar, calculate ΔH^0_{rxn} of fermentation and of respiration (combustion).

(b) Write a combustion reaction for ethanol. Which has a higher ΔH^0_{comb} per mol of C, sugar or ethanol?

6.85 Three of the reactions that occur when the paraffin of a candle (typical formula $C_{21}H_{44}$) burns are

(1) Complete combustion forms CO_2 and water vapor.

(2) Incomplete combustion forms CO and water vapor.

(3) Some wax also forms elemental C (soot) and water vapor.

(a) Find ΔH^0_{rxn} of each reaction (ΔH^0_f of $C_{21}H_{44} = -476$ kJ/mol; use graphite for elemental carbon).

(b) Find q (in kJ) when an 854-g candle burns completely.

(c) Find q (in kJ) when 5.00% by mass of the candle burns incompletely and another 5.00% of it undergoes soot formation.

6.86 Silicon carbide (SiC) is used as an abrasive. After the blue-black crystals are produced, they are crushed and glued on paper to make sandpaper or set in clay to make grinding wheels. Silicon carbide is formed by heating sand (SiO_2) with coke, a form of carbon. Carbon monoxide gas is also formed in this endothermic process, which absorbs 624.7 kJ per mole of SiC formed.

(a) What is ΔH^0_f of SiC? (Assume coke is the same as graphite.)

(b) How many kJ are needed per kg of SiC produced?

6.87 Iron metal is produced in a blast furnace through a complex series of reactions that involve reduction of iron(III) oxide with carbon monoxide.

(a) Write a balanced overall equation for the process, including the other product.

(b) Use the equations below to calculate ΔH^0_{rxn} for the overall equation:

(1) $3Fe_2O_3(s) + CO(g) \longrightarrow 2Fe_3O_4(s) + CO_2(g) \qquad \Delta H^0 = -48.5$ kJ

(2) $Fe(s) + CO_2(g) \longrightarrow FeO(s) + CO(g) \qquad \Delta H^0 = -11.0$ kJ

(3) $Fe_3O_4(s) + CO(g) \longrightarrow 3FeO(s) + CO_2(g) \qquad \Delta H^0 = 22$ kJ

6.88 Pure liquid octane (C_8H_{18}; d = 0.702 g/mL) is used as the fuel in a test of a new automobile drive train.
(a) How much energy (in kJ) is released by complete combustion of the octane in a 20.4-gal fuel tank to gases ($\Delta H^0_{comb} = -5.45\times10^3$ kJ/mol)?
(b) The energy delivered to the wheels at 65 mph is 5.5×10^4 kJ/h. Assuming all the energy is transferred to the wheels, what is the cruising range (in km) of the car on a full tank?
(c) If the actual cruising range is 455 miles, explain your answer to part (b).

6.89 When simple sugars, called *monosaccharides,* link together, they form a variety of complex sugars and, ultimately, *polysaccharides,* such as starch, glycogen, and cellulose. Glucose and fructose have the same formula, $C_6H_{12}O_6$, but different arrangements of atoms. They link together to form a molecule of sucrose (table sugar) and a molecule of liquid water. The ΔH^0_f values of glucose, fructose, and sucrose are −1273 kJ/mol, −1266 kJ/mol, and −2226 kJ/mol, respectively. Write a balanced equation for this reaction and calculate ΔH^0_{rxn}.

6.90 Physicians and nutritional biochemists recommend eating vegetable oils rather than animal fats to lower risks of heart disease. In olive oil, one of the healthier choices, the main fatty acid is oleic acid ($C_{18}H_{34}O_2$), whose $\Delta H^0_{comb} = -1.11\times10^4$ kJ/mol. Calculate ΔH^0_f of oleic acid. [Assume $H_2O(g)$.]

6.91 Oxidation of gaseous ClF by F_2 yields liquid ClF_3, an important fluorinating agent. Use the following thermochemical equations to calculate ΔH^0_{rxn} for the production of ClF_3:

(1) $2ClF(g) + O_2(g) \longrightarrow Cl_2O(g) + OF_2(g)$ $\Delta H^0 = 167.5$ kJ
(2) $2F_2(g) + O_2(g) \longrightarrow 2OF_2(g)$ $\Delta H^0 = -43.5$ kJ
(3) $2ClF_3(l) + 2O_2(g) \longrightarrow Cl_2O(g) + 3OF_2(g)$ $\Delta H^0 = 394.1$ kJ

6.92 Silver bromide is used to coat ordinary black-and-white photographic film, while high-speed film uses silver iodide.
(a) When 50.0 mL of 5.0 g/L $AgNO_3$ is added to a coffee-cup calorimeter containing 50.0 mL of 5.0 g/L NaI, with both solutions at 25°C, what mass of AgI forms?
(b) Use Appendix B to find ΔH^0_{rxn}.
(c) What is ΔT_{soln} (assume the volumes are additive and the solution has the density and specific heat capacity of water)?

6.93 The calorie (4.184 J) was originally defined as the quantity of energy required to raise the temperature of 1.00 g of liquid water 1.00°C. The British thermal unit (Btu) is defined as the quantity of energy required to raise the temperature of 1.00 lb of liquid water 1.00°F.
(a) How many joules are in 1.00 British thermal unit (1 lb = 453.6 g; a change of 1.0°C = 1.8°F)?
(b) The "therm" is a unit of energy consumption that is used by natural gas companies in the United States and is defined as 100,000 Btu. How many joules are in 1.00 therm?
(c) How many moles of methane must be burned to give 1.00 therm of energy? (Assume water forms as a gas.)
(d) If natural gas costs $0.46 per therm, what is the cost per mole of methane? (Assume natural gas is pure methane.)
(e) How much would it cost to warm 308 gal of water in a hot tub from 15.0°C to 40.0°C (1 gal = 3.78 L)?

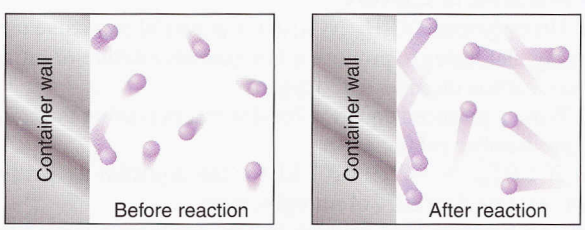
6.94 Whenever organic matter is decomposed under oxygen-free (anaerobic) conditions, methane is one of the products. Thus, enormous deposits of natural gas, which is almost entirely methane, exist as a major source of fuel for home and industry.
(a) It is estimated that known sources of natural gas can produce 5,600 EJ of energy (1 EJ = 10^{18} J). Current total global energy usage is 4.0×10^2 EJ per year. Find the mass (in kg) of known sources of natural gas (ΔH^0_{comb} of CH_4 = −802 kJ/mol).
(b) For how many years could these sources supply the world's total energy needs?
(c) What volume (in ft^3) of natural gas is required to heat 1.00 qt of water from 20.0°C to 100.0°C (d of H_2O = 1.00 g/mL; d of CH_4 at STP = 0.72 g/L)?
(d) The fission of 1 mol of uranium (about 4×10^{-4} ft^3) in a nuclear reactor produces 2×10^{13} J. What volume (in ft^3) of natural gas would produce the same amount of energy?

6.95 The heat of atomization (ΔH^0_{atom}) is the heat needed to form separated gaseous atoms from a substance in its standard state. The equation for the atomization of graphite is

$$C(graphite) \longrightarrow C(g)$$

Use Hess's law to calculate ΔH^0_{atom} of graphite from these data:
(1) ΔH^0_f of CH_4 = −74.9 kJ/mol
(2) ΔH^0_{atom} of CH_4 = 1660 kJ/mol
(3) ΔH^0_{atom} of H_2 = 432 kJ/mol

6.96 A reaction is carried out in a steel vessel within a chamber filled with argon gas. Below are molecular views of the argon adjacent to the surface of the reaction vessel before and after the reaction. Was the reaction exothermic or endothermic? Explain.



6.97 For each of the following events, the system is in *italics.* State whether heat, work, or both is (are) transferred and specify the direction of each transfer.
(a) You pump air into an automobile *tire.*
(b) A *tree* rots in a forest.
(c) You strike a *match.*
(d) You cool juice in an *ice chest.*
(e) You cook *food* on a kitchen range.

6.98 To make use of ionic hydrates for storing solar energy (see Chemical Connections, p. 247), you use 500.0 kg of sodium sulfate decahydrate on your house roof. Assuming complete reaction and 100% efficiency of heat transfer, how much heat (in kJ) is released to your house at night?

6.99 Benzene (C_6H_6) and acetylene (C_2H_2) have the same empirical formula, CH. Which releases more energy per mole of CH (ΔH^0_f of gaseous C_6H_6 = 82.9 kJ/mol)?

6.100 Kerosene, a common space-heater fuel, is a mixture of hydrocarbons whose "average" formula is $C_{12}H_{26}$.
(a) Write a balanced equation, using the simplest whole-number coefficients, for the complete combustion of kerosene to gases.
(b) If $\Delta H^0_{comb} = -1.50\times10^4$ kJ for the equation as written in part (a), determine ΔH^0_f of kerosene.
(c) Calculate the heat produced by combustion of 0.50 gal of kerosene (d of kerosene = 0.749 g/mL).
(d) How many gallons of kerosene must be burned for a kerosene furnace to produce 1250. Btu (1 Btu = 1.055 kJ)?

6.101 Coal gasification is a multistep process to convert coal into gaseous fuels (see Chemical Connections, p. 245). In one step, a certain coal sample reacts with superheated steam:

$$C(coal) + H_2O(g) \longrightarrow CO(g) + H_2(g) \qquad \Delta H^0_{rxn} = 129.7\ kJ$$

(a) Combine this reaction with the following two to write an overall reaction for the production of methane:

$$CO(g) + H_2O(g) \longrightarrow CO_2(g) + H_2(g)$$
$$CO(g) + 3H_2(g) \longrightarrow CH_4(g) + H_2O(g)$$

(b) Calculate ΔH^0_{rxn} for this overall change.

(c) Using the value in (b) and calculating the ΔH^0_{comb} of methane, find the total heat for gasifying 1.00 kg of coal and burning the methane formed (assume water forms as a gas and $\mathcal{M}$ of coal = 12.00 g/mol).

6.102 Phosphorus pentachloride is used in the industrial preparation of organic phosphorus compounds. Equation 1 shows its preparation from PCl_3 and Cl_2:

(1) $PCl_3(l) + Cl_2(g) \longrightarrow PCl_5(s)$

Use equations 2 and 3 to calculate ΔH_{rxn} of equation 1:

(2) $P_4(s) + 6Cl_2(g) \longrightarrow 4PCl_3(l) \qquad \Delta H = -1280\ kJ$

(3) $P_4(s) + 10Cl_2(g) \longrightarrow 4PCl_5(s) \qquad \Delta H = -1774\ kJ$

6.103 Consider the following hydrocarbon fuels:

(I) $CH_4(g)$ (II) $C_2H_4(g)$ (III) $C_2H_6(g)$

(a) Rank them in terms of heat released (a) per mole and (b) per gram. [Assume $H_2O(g)$ forms and combustion is complete.]

6.104 A typical candy bar weighs about 2 oz (1.00 oz = 28.4 g).

(a) Assuming that a candy bar is 100% sugar and that 1.0 g of sugar is equivalent to about 4.0 Calories of energy, calculate the energy (in kJ) contained in a typical candy bar.

(b) Assuming that your mass is 58 kg and you convert chemical potential energy to work with 100% efficiency, how high would you have to climb to work off the energy in a candy bar? (Potential energy = mass × g × height, where g = 9.8 m/s^2.)

(c) Why is your actual conversion of potential energy to work less than 100% efficient?

6.105 Silicon tetrachloride is produced annually on the multikiloton scale for making transistor-grade silicon. It can be made directly from the elements (reaction 1) or, more cheaply, by heating sand and graphite with chlorine gas (reaction 2). If water is present in reaction 2, some tetrachloride may be lost in an unwanted side reaction (reaction 3):

(1) $Si(s) + 2Cl_2(g) \longrightarrow SiCl_4(g)$

(2) $SiO_2(s) + 2C(graphite) + 2Cl_2(g) \longrightarrow SiCl_4(g) + 2CO(g)$

(3) $SiCl_4(g) + 2H_2O(g) \longrightarrow SiO_2(s) + 4HCl(g) \qquad \Delta H^0_{rxn} = -139.5\ kJ$

(a) Use reaction 3 to calculate the heats of reaction of reactions 1 and 2. (b) What is the heat of reaction for the new reaction that is the sum of reactions 2 and 3?

6.106 Use the following information to find ΔH^0_f of gaseous HCl:

$$N_2(g) + 3H_2(g) \longrightarrow 2NH_3(g) \qquad \Delta H^0_{rxn} = -91.8\ kJ$$
$$N_2(g) + 4H_2(g) + Cl_2(g) \longrightarrow 2NH_4Cl(s) \qquad \Delta H^0_{rxn} = -628.8\ kJ$$
$$NH_3(g) + HCl(g) \longrightarrow NH_4Cl(s) \qquad \Delta H^0_{rxn} = -176.2\ kJ$$

6.107 You want to determine ΔH^0 for the reaction

$$Zn(s) + 2HCl(aq) \longrightarrow ZnCl_2(aq) + H_2(g)$$

(a) To do so, you first determine the heat capacity of a calorimeter using the following reaction, whose ΔH is known:

$$NaOH(aq) + HCl(aq) \longrightarrow NaCl(aq) + H_2O(l) \qquad \Delta H^0 = -57.32\ kJ$$

Calculate the heat capacity of the calorimeter from these data:

Amounts used: 50.0 mL of 2.00 M HCl and 50.0 mL of 2.00 M NaOH

Initial T of both solutions: 16.9°C

Maximum T recorded during reaction: 30.4°C

Density of resulting NaCl solution: 1.04 g/mL

c of 1.00 M NaCl(aq) = 3.93 J/g·K

(b) Use the result from part (a) and the following data to determine ΔH^0_{rxn} for the reaction between zinc and HCl(aq):

Amounts used: 100.0 mL of 1.00 M HCl and 1.3078 g of Zn

Initial T of HCl solution and Zn: 16.8°C

Maximum T recorded during reaction: 24.1°C

Density of 1.0 M HCl solution = 1.015 g/mL

c of resulting $ZnCl_2(aq)$ = 3.95 J/g·K

(c) Given the values below, what is the error in your experiment?

$$\Delta H^0_f \text{ of HCl}(aq) = -1.652\times10^2\ kJ/mol$$
$$\Delta H^0_f \text{ of ZnCl}_2(aq) = -4.822\times10^2\ kJ/mol$$

6.108 One mole of nitrogen gas confined within a cylinder by a piston is heated from 0°C to 819°C at 1.00 atm.

(a) Calculate the work of expansion of the gas in joules (1 J = 9.87×10^{-3} atm·L). Assume all the energy is used to do work.

(b) What would be the temperature change if the gas were heated with the same amount of energy in a container of fixed volume? (Assume the specific heat capacity of N_2 is 1.00 J/g·K.)

6.109 The chemistry of nitrogen oxides is very versatile. Given the following reactions and their standard enthalpy changes,

(1) $NO(g) + NO_2(g) \longrightarrow N_2O_3(g) \qquad \Delta H^0_{rxn} = -39.8\ kJ$

(2) $NO(g) + NO_2(g) + O_2(g) \longrightarrow N_2O_5(g) \qquad \Delta H^0_{rxn} = -112.5\ kJ$

(3) $2NO_2(g) \longrightarrow N_2O_4(g) \qquad \Delta H^0_{rxn} = -57.2\ kJ$

(4) $2NO(g) + O_2(g) \longrightarrow 2NO_2(g) \qquad \Delta H^0_{rxn} = -114.2\ kJ$

(5) $N_2O_5(g) \longrightarrow N_2O_5(s) \qquad \Delta H^0_{rxn} = -54.1\ kJ$

calculate the heat of reaction for

$$N_2O_3(g) + N_2O_5(s) \longrightarrow 2N_2O_4(g)$$

6.110 Electric generating plants transport large amounts of hot water through metal pipes, and oxygen dissolved in the water can cause a major corrosion problem. Hydrazine (N_2H_4) added to the water avoids the problem by reacting with the oxygen:

$$N_2H_4(aq) + O_2(g) \longrightarrow N_2(g) + 2H_2O(l)$$

About 4×10^7 kg of hydrazine is produced every year by reacting ammonia with sodium hypochlorite in the *Raschig process*:

$$2NH_3(aq) + NaOCl(aq) \longrightarrow N_2H_4(aq) + NaCl(aq) + H_2O(l) \qquad \Delta H^0_{rxn} = -151\ kJ$$

(a) If ΔH^0_f of NaOCl(aq) = −346 kJ/mol, find ΔH^0_f of $N_2H_4(aq)$.

(b) What is the heat released when aqueous N_2H_4 is added to 5.00×10^3 L of plant water that is 2.50×10^{-4} M O_2?

6.111 Liquid methanol (CH_3OH) is used as an alternative fuel in truck engines. An industrial method for preparing it uses the catalytic hydrogenation of carbon monoxide:

$$CO(g) + 2H_2(g) \xrightarrow{\text{catalyst}} CH_3OH(l)$$

How much heat (in kJ) is released when 15.0 L of CO at 85°C and 112 kPa reacts with 18.5 L of H_2 at 75°C and 744 torr?

6.112 (a) How much heat is released when 25.0 g of methane burns in excess O_2 to form gaseous products?

(b) Calculate the temperature of the product mixture if the methane and air are both at an initial temperature of 0.0°C. Assume a stoichiometric ratio of methane to oxygen from the air, with air being 21% O_2 by volume (c of CO_2 = 57.2 J/mol·K; c of $H_2O(g)$ = 36.0 J/mol·K; c of N_2 = 30.5 J/mol·K).

A Spectral Spectacular Why do the exploding compounds in a fireworks display emit only certain colors of light? As you'll learn in this chapter, the answer has revolutionized our conceptions of matter and energy and of the amazing atoms that make up the world around us and the universe beyond.

Shapes of Atomic Orbitals
Energy Levels of the Hydrogen Atom

Over a few remarkable decades—from around 1890 to 1930—a revolution took place in how we view the makeup of the universe. But revolutions in science are not the violent upheavals of political overthrow. Rather, flaws appear in an established model as conflicting evidence mounts, a startling discovery or two widens the flaws into cracks, and the conceptual structure crumbles gradually from its inconsistencies. New insight, verified by experiment, then guides the building of a model more consistent with reality. So it was when Lavoisier's theory of combustion superseded the phlogiston model, when Dalton's atomic theory established the idea of individual units of matter, and when Rutherford's nuclear model substituted atoms with rich internal structure for "billiard balls" or "plum puddings." In this chapter, you will see this process unfold again with the development of modern atomic theory.

Almost as soon as Rutherford proposed his nuclear model, a major problem arose. A nucleus and an electron attract each other, so if they are to remain apart, the energy of the electron's motion (kinetic energy) must balance the energy of attraction (potential energy). However, the laws of classical physics had established that a negative particle moving in a curved path around a positive one *must* emit radiation and thus lose energy. If this requirement applied to atoms, why didn't the orbiting electron lose energy continuously and spiral into the nucleus? Clearly, if electrons behaved the way classical physics predicted, all atoms would have collapsed eons ago! The behavior of subatomic matter seemed to violate real-world experience and accepted principles.

The breakthroughs that soon followed Rutherford's model forced a complete rethinking of the classical picture of matter and energy. In the macroscopic world, the two are distinct. Matter occurs in chunks you can hold and weigh, and you can change the amount of matter in a sample piece by piece. In contrast, energy is "massless," and its quantity changes in a continuous manner. Matter moves in specific paths, whereas light and other types of energy travel in diffuse waves. As soon as 20^{th}-century scientists probed the subatomic world, however, these clear distinctions between particulate matter and wavelike energy began to fade.

IN THIS CHAPTER . . . We discuss *quantum mechanics,* the theory that explains our current picture of atomic structure. We consider the wave properties of energy and then examine the theories and experiments that led to a quantized, or particulate, model of light. We see why the light emitted by excited hydrogen (H) atoms—the *atomic spectrum*—suggests an atom with distinct energy levels, and we look briefly at how atomic spectra are applied to chemical analysis. Wave-particle duality, which reveals two faces of matter and of energy, leads us to the current model of the H atom and the quantum numbers that identify the regions of space an electron occupies in an atom. In Chapter 8, we'll consider atoms that have more than one electron and relate electron number and distribution to chemical behavior.

7.1 THE NATURE OF LIGHT

Visible light is one type of **electromagnetic radiation** (also called *electromagnetic energy* or *radiant energy*). Other familiar types include x-rays, microwaves, and radio waves. All electromagnetic radiation consists of energy propagated by means of electric and magnetic fields that alternately increase and decrease in intensity as they move through space. This classical wave model distinguishes clearly between waves and particles; it is essential for understanding why rainbows form, how magnifying glasses work, why objects look distorted under water, and many other everyday observations. But, it cannot explain observations on the atomic scale because, in that unfamiliar realm, energy behaves as though it consists of particles!

Concepts & Skills to Review

before you study this chapter

- discovery of the electron and atomic nucleus (Section 2.4)
- major features of atomic structure (Section 2.5)
- changes in energy state of a system (Section 6.1)

Hooray for the Human Mind The invention of the car, radio, and airplane fostered a feeling of unlimited human ability, and the discovery of x-rays, radioactivity, the electron, and the atomic nucleus led to the sense that the human mind would soon unravel all of nature's mysteries. Indeed, some people were convinced that few, if any, mysteries remained.

1895 Röntgen discovers x-rays.
1896 Becquerel discovers radioactivity.
1897 Thomson discovers the electron.
1898 Curie discovers radium.
1900 Freud proposes theory of the unconscious mind.
1900 Planck develops quantum theory.
1901 Marconi invents the radio.
1903 Wright brothers fly an airplane.
1905 Ford uses assembly line to build cars.
1905 Rutherford explains radioactivity.
1905 Einstein publishes relativity and photon theories.
1906 St. Denis develops modern dance.
1908 Matisse and Picasso develop modern art.
1909 Schoenberg and Berg develop modern music.
1911 Rutherford presents nuclear model.
1913 Bohr proposes atomic model.
1914 to 1918 World War I is fought.
1923 Compton demonstrates photon momentum.
1924 De Broglie publishes wave theory of matter.
1926 Schrödinger develops wave equation.
1927 Heisenberg presents uncertainty principle.
1932 Chadwick discovers the neutron.

The Wave Nature of Light

The wave properties of electromagnetic radiation are described by two interdependent variables, as Figure 7.1 shows:

- **Frequency** (ν, Greek *nu*) is the number of cycles the wave undergoes per second and is expressed in units of 1/second [s^{-1}; also called *hertz* (Hz)].
- **Wavelength** (λ, Greek *lambda*) is the distance between any point on a wave and the corresponding point on the next crest (or trough) of the wave, that is, the distance the wave travels during one cycle. Wavelength is expressed in meters and often, for very short wavelengths, in nanometers (nm, 10^{-9} m), picometers (pm, 10^{-12} m), or the non-SI unit angstroms (Å, 10^{-10} m).

The speed of the wave, the distance traveled per unit time (in units of meters per second), is the product of its frequency (cycles per second) and its wavelength (meters per cycle):

$$\text{Units for speed of wave: } \frac{\cancel{\text{cycles}}}{\text{s}} \times \frac{\text{m}}{\cancel{\text{cycle}}} = \frac{\text{m}}{\text{s}}$$

In a vacuum, all types of electromagnetic radiation travel at 2.99792458×10^8 m/s (3.00×10^8 m/s to three significant figures), a constant called the **speed of light (*c*):**

$$c = \nu \times \lambda \tag{7.1}$$

As Equation 7.1 shows, the product of ν and λ is a constant. Thus, the individual terms have a reciprocal relationship to each other: *radiation with a high frequency has a short wavelength, and vice versa.*

Another characteristic of a wave is its **amplitude,** the height of the crest (or depth of the trough) of each wave (Figure 7.2). The amplitude of an electromagnetic wave is a measure of the strength of its electric and magnetic fields. Thus, amplitude is related to the *intensity* of the radiation, which we perceive as brightness in the case of visible light. Light of a particular color, fire-engine red for instance, has a specific frequency and wavelength, but it can be dimmer (lower amplitude) or brighter (higher amplitude).

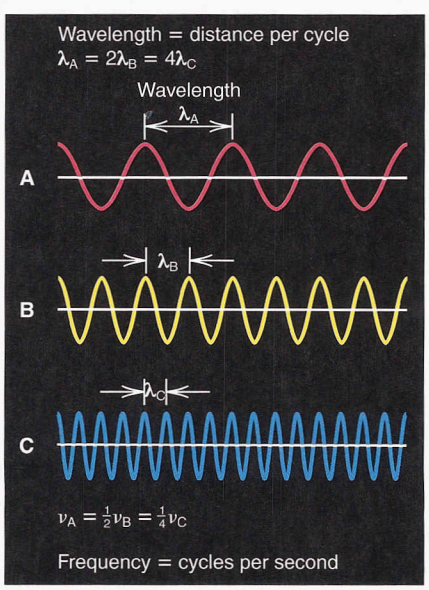

Figure 7.1 Frequency and wavelength. Three waves with different wavelengths (λ) and thus different frequencies (ν) are shown. Note that *as the wavelength decreases, the frequency increases, and vice versa.*

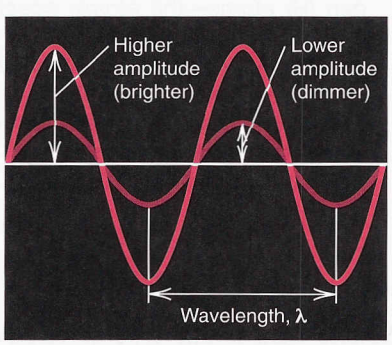

Figure 7.2 Amplitude (intensity) of a wave. Amplitude is represented by the height of the crest (or depth of the trough) of the wave. The two waves shown have the same wavelength (color) but different amplitudes and, therefore, different brightnesses (intensities).

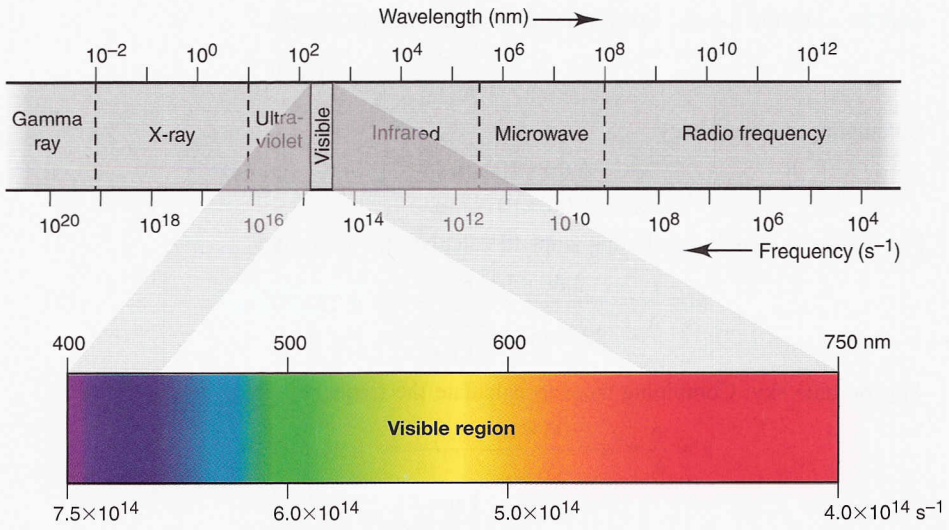

Figure 7.3 Regions of the electromagnetic spectrum. The electromagnetic spectrum extends from the very short wavelengths (very high frequencies) of gamma rays through the very long wavelengths (very low frequencies) of radio waves. The relatively narrow visible region is expanded (and the scale made linear) to show the component colors.

The Electromagnetic Spectrum Visible light represents a small portion of the continuum of radiant energy known as the **electromagnetic spectrum** (Figure 7.3). *All the waves in the spectrum travel at the same speed through a vacuum but differ in frequency and, therefore, wavelength.* Some regions of the spectrum are utilized by particular devices; for example, the long-wavelength, low-frequency radiation is used by microwave ovens and radios. Note that each region meets the next. For instance, the **infrared (IR)** region meets the microwave region on one end and the visible region on the other.

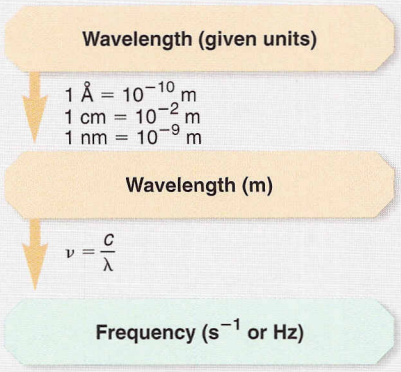
We perceive different wavelengths (or frequencies) of *visible* light as different colors, from red ($\lambda \approx 750$ nm) to violet ($\lambda \approx 400$ nm). Light of a single wavelength is called *monochromatic* (Greek, "one color"), whereas light of many wavelengths is *polychromatic*. White light is polychromatic. The region adjacent to visible light on the short-wavelength end consists of **ultraviolet (UV)** radiation (also called *ultraviolet light*). Still shorter wavelengths (higher frequencies) make up the x-ray and gamma (γ) ray regions. Thus, a TV signal, the green light from a traffic signal, and a gamma ray emitted by a radioactive element all travel at the same speed but differ in their frequency (and wavelength).

Electromagnetic Emissions Everywhere We are bathed in electromagnetic radiation from the Sun. Radiation from human activities bombards us as well: radio and TV signals; microwaves from traffic monitors and telephone relay stations; from lightbulbs, x-ray equipment, car motors, and so forth. Natural sources on Earth bombard us also: lightning, radioactivity, and even the glow of fireflies! And our knowledge of the distant universe comes from radiation entering our light, x-ray, and radio telescopes.

SAMPLE PROBLEM 7.1 Interconverting Wavelength and Frequency

Problem A dental hygienist uses x-rays ($\lambda = 1.00$ Å) to take a series of dental radiographs while the patient listens to a radio station ($\lambda = 325$ cm) and looks out the window at the blue sky ($\lambda = 473$ nm). What is the frequency (in s^{-1}) of the electromagnetic radiation from each source? (Assume that the radiation travels at the speed of light, 3.00×10^{8} m/s.)

Plan We are given the wavelengths, so we use Equation 7.1 to find the frequencies. However, we must first convert the wavelengths to meters because c has units of m/s.



Solution For the x-rays: Converting from angstroms to meters,

$$\lambda = 1.00\ \text{Å} \times \frac{10^{-10}\ \text{m}}{1\ \text{Å}} = 1.00\times10^{-10}\ \text{m}$$

Calculating the frequency:

$$\nu = \frac{c}{\lambda} = \frac{3.00\times10^{8}\ \text{m/s}}{1.00\times10^{-10}\ \text{m}} = 3.00\times10^{18}\ \text{s}^{-1}$$

For the radio signal: Combining steps to calculate the frequency,

$$\nu = \frac{c}{\lambda} = \frac{3.00\times10^{8}\ \text{m/s}}{325\ \text{cm} \times \dfrac{10^{-2}\ \text{m}}{1\ \text{cm}}} = 9.23\times10^{7}\ \text{s}^{-1}$$

For the blue sky: Combining steps to calculate the frequency,

$$\nu = \frac{c}{\lambda} = \frac{3.00\times10^{8}\ \text{m/s}}{473\ \text{nm} \times \dfrac{10^{-9}\ \text{m}}{1\ \text{nm}}} = 6.34\times10^{14}\ \text{s}^{-1}$$

Check The orders of magnitude are correct for the regions of the electromagnetic spectrum (see Figure 7.3): x-rays (10^{19} to 10^{16} s^{-1}), radio waves (10^{9} to 10^{4} s^{-1}), and visible light (7.5×10^{14} to 4.0×10^{14} s^{-1}).

Comment The radio station here is broadcasting at 92.3×10^{6} s^{-1}, or 92.3 million Hz (92.3 MHz), about midway in the FM range.

FOLLOW-UP PROBLEM 7.1 Some diamonds appear yellow because they contain nitrogen compounds that absorb purple light of frequency 7.23×10^{14} Hz. Calculate the wavelength (in nm and Å) of the absorbed light.

The Distinction Between Energy and Matter In the everyday world around us, energy and matter behave very differently. Let's examine some important observations about light and see how they contrast with the behavior of particles. Light of a given wavelength travels at different speeds through different transparent media—vacuum, air, water, quartz, and so forth. Therefore, when a light wave passes from one medium into another, say, from air to water, the speed of the wave changes. Figure 7.4A shows the phenomenon known as **refraction.** If the

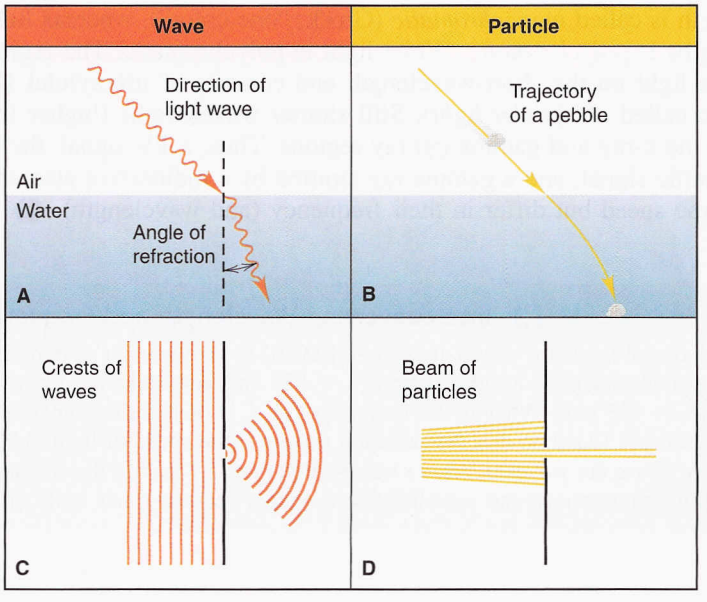


Figure 7.4 Different behaviors of waves and particles. A, A wave passing from air into water is *refracted* (bent at an angle). **B,** In contrast, a particle of matter (such as a pebble) entering a pond moves in a curved path, because gravity and the greater resistance (drag) of the water slow it down gradually. **C,** A wave is *diffracted* through a small opening, which gives rise to a circular wave on the other side. (The lines represent the crests of water waves as seen from above.) **D,** In contrast, when a collection of moving particles encounters a small opening, as when a handful of sand is thrown at a hole in a fence, some particles move through the opening and continue along their individual paths.

wave strikes the boundary, say, between air and water, at an angle other than 90°, the change in speed causes a change in direction, and the wave continues at a different angle. The new angle (angle of refraction) depends on the materials on either side of the boundary and the wavelength of the light. In the process of *dispersion,* white light separates (disperses) into its component colors, as when it passes through a prism, because each incoming wavelength is refracted at a slightly different angle.

In contrast, a particle, like a pebble, does not undergo refraction when passing from one medium to another. Figure 7.4B shows that when a pebble thrown through the air enters a pond, its speed changes abruptly and then it continues to slow down gradually in a curved path.

When a wave strikes the edge of an object, it bends around it in a phenomenon called **diffraction.** If the wave passes through a slit about as wide as its wavelength, it bends around both edges of the slit and forms a semicircular wave on the other side of the opening, as shown in Figure 7.4C.

Once again, particles act very differently. Figure 7.4D shows that if you throw a collection of particles, like a handful of sand, at a small opening, some particles hit the edge, while others go through the opening and continue linearly in a narrower group.

If waves of light pass through two adjacent slits, the emerging circular waves interact with each other through the process of *interference*. If the crests of the waves coincide (*in phase*), they interfere *constructively* and the amplitudes add together. If the crests coincide with troughs (*out of phase*), they interfere *destructively* and the amplitudes cancel. The result is a diffraction pattern of brighter and darker regions (Figure 7.5). In contrast, particles passing through adjacent openings continue in straight paths, some colliding with each other and moving at different angles.

At the end of the 19th century, all everyday and laboratory experience seemed to confirm these classical distinctions between the wave nature of energy and the particle nature of matter.

Rainbows and Diamonds You can see a rainbow only when the Sun is at your back. Light entering the near surface of a water droplet is dispersed and reflected off the far surface. Because red light is bent least, it reaches your eye from droplets higher in the sky, whereas violet appears from lower droplets. The colors in a diamond's sparkle are due to its facets, which are cleaved at angles that disperse and reflect the incoming light, lengthening its path enough for the different wavelengths to separate.

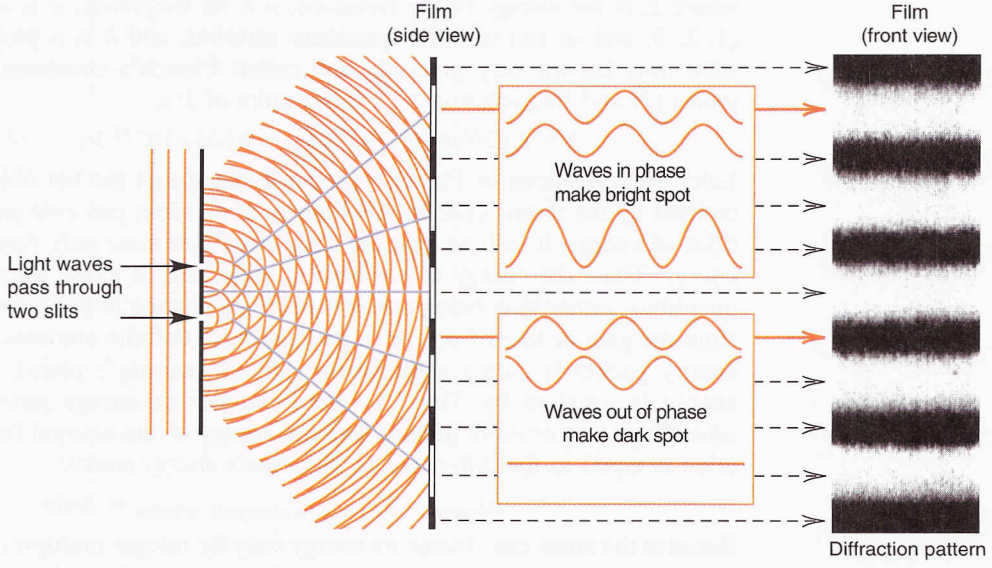

Figure 7.5 The diffraction pattern caused by light passing through two adjacent slits. As light waves pass through two closely spaced slits, they emerge as circular waves and interfere with each other. They create a diffraction (interference) pattern of bright and dark regions on a sheet of film. Bright regions appear where crests coincide and the amplitudes combine with each other (in phase); dark regions appear where crests meet troughs and the amplitudes cancel each other (out of phase).

The Particle Nature of Light

Three phenomena involving matter and light confounded physicists at the turn of the 20th century: (1) blackbody radiation, (2) the photoelectric effect, and (3) atomic spectra. Explaining these phenomena required a radically new picture of energy. We discuss the first two here and the third in the next section.

Blackbody Radiation and the Quantization of Energy When a solid object is heated to about 1000 K, it begins to emit visible light, as you can see in the soft red glow of smoldering coal (Figure 7.6, *left*). At about 1500 K, the light is brighter and more orange, like that from an electric heating coil (Figure 7.6, *center*). At temperatures greater than 2000 K, the light is still brighter and whiter, as seen in the filament of a lightbulb (Figure 7.6, *right*). These changes in intensity and wavelength of emitted light as an object is heated are characteristic of *blackbody radiation,* light given off by a hot *blackbody.** All attempts to account for these observed changes by applying classical electromagnetic theory failed.

Smoldering coal | Electric heating element | Lightbulb filament

Figure 7.6 Blackbody radiation. Familiar examples of the change in intensity and wavelength of light emitted by heated objects.

In 1900, the German physicist Max Planck (1858–1947) developed a formula that fit the data perfectly; to find a physical explanation for his formula, however, Planck was forced to make a radical assumption, which eventually led to an entirely new view of energy. He proposed that the hot, glowing object could emit (or absorb) only *certain quantities* of energy:

$$E = nh\nu$$

where E is the energy of the radiation, ν is its frequency, n is a positive integer (1, 2, 3, and so on) called a **quantum number,** and h is a proportionality constant now known very precisely and called **Planck's constant.** With energy in joules (J) and frequency in s^{-1}, h has units of J·s:

$$h = 6.62606876\times10^{-34}\ \text{J·s} = 6.626\times10^{-34}\ \text{J·s} \qquad (4\ \text{sf})$$

Later interpretations of Planck's proposal stated that the hot object's radiation is emitted by the atoms contained within it. If an atom can *emit* only certain quantities of energy, it follows that *the atom itself can have only certain quantities of energy.* Thus, the energy of an atom is *quantized:* it exists only in certain fixed quantities, rather than being continuous. Each change in the atom's energy results from the gain or loss of one or more "packets," definite amounts, of energy. Each energy packet is called a **quantum** ("fixed quantity"; plural, *quanta*), and its energy is equal to $h\nu$. Thus, *an atom changes its energy state by emitting (or absorbing) one or more quanta,* and the energy of the emitted (or absorbed) radiation is equal to the *difference in the atom's energy states:*

$$\Delta E_{\text{atom}} = E_{\text{emitted (or absorbed) radiation}} = \Delta nh\nu$$

Because the atom can change its energy only by integer multiples of $h\nu$, the smallest change occurs when an atom in a given energy state changes to an adjacent state, that is, when $\Delta n = 1$:

$$\Delta E = h\nu \qquad (7.2)$$

*A blackbody is an idealized object that absorbs all the radiation incident on it. A hollow cube with a small hole in one wall approximates a blackbody.

The Photoelectric Effect and the Photon Theory of Light Despite the idea that energy is quantized, Planck and other physicists continued to picture the emitted energy as traveling in waves. However, the wave model could not explain the **photoelectric effect,** the flow of current when monochromatic light of sufficient frequency shines on a metal plate (Figure 7.7). The existence of the current was not puzzling: it could be understood as arising when the light transfers energy to the electrons at the metal surface, which break free and are collected by the positive electrode. However, the photoelectric effect had certain confusing features, in particular, the *presence of a threshold frequency* and the *absence of a time lag:*

1. *Presence of a threshold frequency.* Light shining on the metal must have a minimum *frequency,* or no current flows. (Different metals have different minimum frequencies.) The wave theory, however, associates the energy of the light with the *amplitude* (intensity) of the wave, not with its frequency (color). Thus, the wave theory predicts that an electron would break free when it absorbed enough energy from light of *any* color.
2. *Absence of a time lag.* Current flows the moment light of this minimum frequency shines on the metal, regardless of the light's intensity. The wave theory, however, predicts that in dim light there would be a time lag before the current flowed, because the electrons had to absorb enough energy to break free.

Carrying Planck's idea of quantized energy further, Einstein proposed that light itself is particulate, that is, quantized into small "bundles" of electromagnetic energy, which were later called **photons.** In terms of Planck's work, we can say that each atom changes its energy whenever it absorbs or emits one photon, one "particle" of light, whose energy is fixed by its *frequency:*

$$E_{\text{photon}} = h\nu = \Delta E_{\text{atom}}$$

Let's see how Einstein's photon theory explains the photoelectric effect:

1. *Explanation of the threshold frequency.* According to the photon theory, a beam of light consists of an enormous number of photons. Light intensity (brightness) is related to the number of photons striking the surface per unit time, but *not* to their energy. Therefore, a photon of a certain minimum *energy* must be absorbed for an electron to be freed. Since energy depends on frequency ($h\nu$), the theory predicts a threshold frequency.
2. *Explanation of the time lag.* An electron cannot "save up" energy from several photons below the minimum energy until it has enough to break free. Rather, one electron breaks free the moment it absorbs one photon of *enough* energy. The current is weaker in dim light than in bright light because fewer photons of enough energy are present, so fewer electrons break free per unit time. But some current flows the moment photons reach the metal plate.

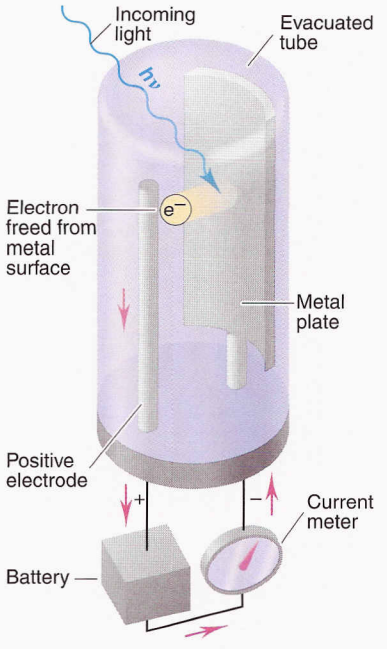

Figure 7.7 Demonstration of the photoelectric effect. When monochromatic light of high enough frequency strikes the metal plate, electrons are freed from the plate and travel to the positive electrode, creating a current.

Ping-Pong Photons Consider this analogy for the fact that light of insufficient energy can't free an electron from the metal surface. If one Ping-Pong ball doesn't have enough energy to knock a book off a shelf, neither does a series of Ping-Pong balls, because the book can't save up the energy from the individual impacts. But one baseball traveling at the same speed does have enough energy.

SAMPLE PROBLEM 7.2 Calculating the Energy of Radiation from Its Wavelength

Problem A cook uses a microwave oven to heat a meal. The wavelength of the radiation is 1.20 cm. What is the energy of one photon of this microwave radiation?

Plan We know λ in centimeters (1.20 cm) so we convert to meters, find the frequency with Equation 7.1, and then find the energy of one photon with Equation 7.2.

Solution Combining steps to find the energy:

$$E = h\nu = \frac{hc}{\lambda} = \frac{(6.626\times10^{-34}\ \text{J·s})(3.00\times10^{8}\ \text{m/s})}{(1.20\ \text{cm})\left(\dfrac{10^{-2}\ \text{m}}{1\ \text{cm}}\right)} = 1.66\times10^{-23}\ \text{J}$$

Check Checking the order of magnitude gives $\dfrac{10^{-33}\ \text{J·s}\times10^{8}\ \text{m/s}}{10^{-2}\ \text{m}} = 10^{-23}\ \text{J}$.

FOLLOW-UP PROBLEM 7.2 Calculate the energies of one photon of ultraviolet ($\lambda = 1\times10^{-8}$ m), visible ($\lambda = 5\times10^{-7}$ m), and infrared ($\lambda = 1\times10^{-4}$ m) light. What do the answers indicate about the relationship between the wavelength and energy of light?

Planck's quantum theory and Einstein's photon theory assigned properties to energy that, until then, had always been reserved for matter: fixed quantity and discrete particles. These properties have since proved essential to explaining the interactions of matter and energy at the atomic level. But how can a particulate model of energy be made to fit the facts of diffraction and refraction, phenomena explained only in terms of waves? As you'll see shortly, the photon model does not *replace* the wave model. Rather, we have to accept *both* to understand reality. Before we discuss this astonishing notion, however, let's see how the new idea of quantized energy led to a key understanding about atomic behavior.

SECTION SUMMARY

Electromagnetic radiation travels in waves of specific wavelength (λ) and frequency (ν). All electromagnetic waves travel through a vacuum at the speed of light, c (3.00×10^8 m/s), which is equal to $\nu \times \lambda$. The intensity (brightness) of a light wave is related to its amplitude. The electromagnetic spectrum ranges from very long radio waves to very short gamma rays and includes the visible region [750 nm (red) to 400 nm (violet)]. Refraction and diffraction indicate that electromagnetic radiation is wavelike, but blackbody radiation and the photoelectric effect indicate that it is particle-like. Light exists as photons (quanta) that have an energy proportional to the frequency. According to quantum theory, an atom has only certain quantities of energy ($E = nh\nu$), which it can change only by absorbing or emitting a photon.

7.2 ATOMIC SPECTRA

The third key observation about matter and energy that late 19th-century physicists could not explain involved the light emitted when an element is vaporized and then thermally or electrically excited, as you see in a neon sign. Figure 7.8A shows the result when light from excited hydrogen atoms passes through a nar-

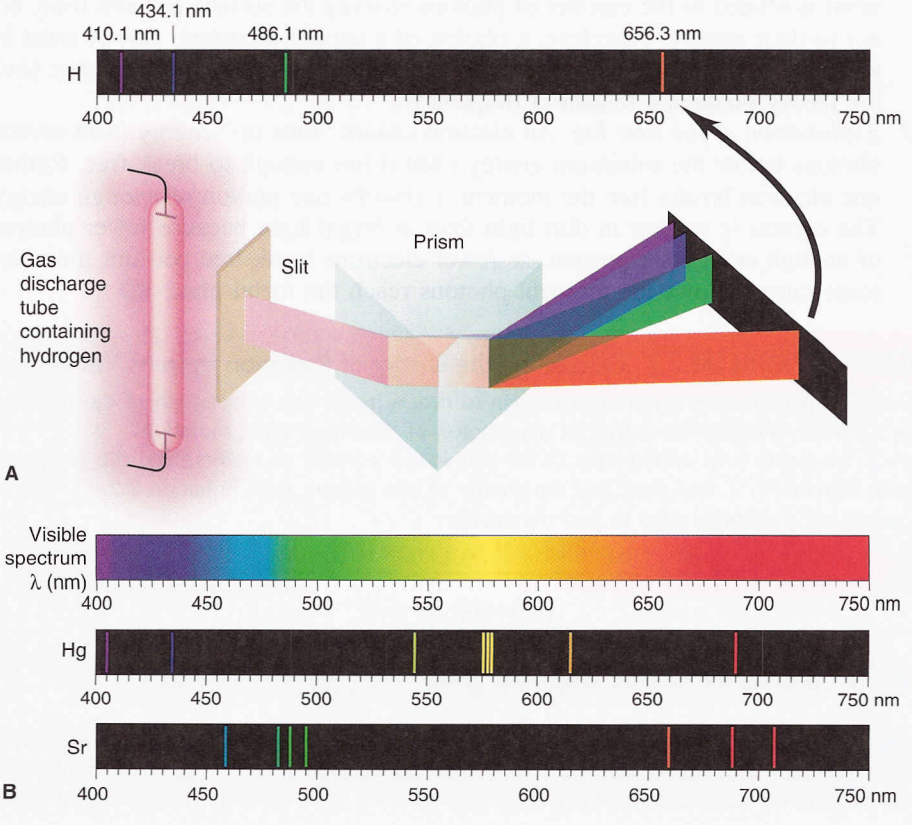

Figure 7.8 The line spectra of several elements. A, A sample of gaseous H_2 is dissociated into atoms and excited by an electric discharge. The emitted light passes through a slit and a prism, which disperses the light into individual wavelengths. The line spectrum of atomic H is shown *(top)*. **B,** The continuous spectrum of white light is compared with the line spectra of mercury and strontium. Note that each line spectrum is different from the others.

Animation: Atomic Line Spectra
Online Learning Center

row slit and is then refracted by a prism. Note that this light does not create a *continuous spectrum,* or rainbow, as sunlight does. Instead, it creates a **line spectrum,** a series of fine lines of individual colors separated by colorless (black) spaces.* The wavelengths of these spectral lines are characteristic of the element producing them (Figure 7.8B).

Spectroscopists studying the spectrum of atomic hydrogen had identified several series of such lines in different regions of the electromagnetic spectrum. Figure 7.9 shows three of these series of lines. Equations of the following general form, called the *Rydberg equation,* were found to predict the position and wavelength of any line in a given series:

$$\frac{1}{\lambda} = R\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right) \tag{7.3}$$

where λ is the wavelength of a spectral line, n_1 and n_2 are positive integers with $n_2 > n_1$, and R is the Rydberg constant ($1.096776 \times 10^7\ m^{-1}$). For the visible series of lines, $n_1 = 2$:

$$\frac{1}{\lambda} = R\left(\frac{1}{2^2} - \frac{1}{n_2^2}\right), \quad \text{with } n_2 = 3, 4, 5, \ldots$$

The Rydberg equation and the value of the constant are based on data rather than theory. No one knew *why* the spectral lines of hydrogen appear in this pattern. (Problems 7.23 and 7.24 are two of several that apply the Rydberg equation.)

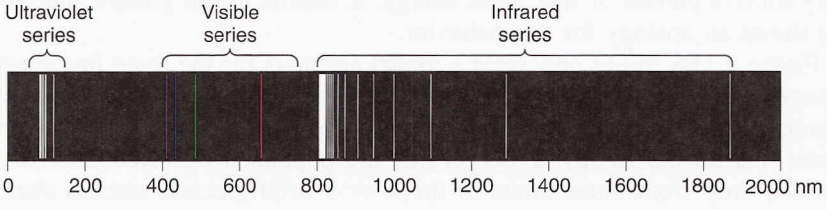

Figure 7.9 Three series of spectral lines of atomic hydrogen. These series appear in different regions of the electromagnetic spectrum. The hydrogen spectrum shown in Figure 7.8A is the visible series.

Animation: Emission Spectra
Online Learning Center

The observation of line spectra did not correlate with classical theory for one major reason. As was mentioned in the chapter introduction, as the electron spiraled into the nucleus, it should emit radiation. Moreover, the frequency of the radiation should be related to the time of revolution. On the spiral path inward, the time should decrease smoothly, so the frequency of the radiation should change smoothly and create a continuous spectrum. Rutherford's nuclear model seemed totally at odds with these atomic spectra.

The Bohr Model of the Hydrogen Atom

Soon after the nuclear model was proposed, Niels Bohr (1885–1962), a young Danish physicist working in Rutherford's laboratory, suggested a model for the H atom that predicted the existence of line spectra. In his model, Bohr used Planck's and Einstein's ideas about quantized energy and proposed three postulates:

1. *The H atom has only certain allowable energy levels,* which Bohr called **stationary states.** Each of these states is associated with a fixed circular orbit of the electron around the nucleus.

2. *The atom does* ***not*** *radiate energy while in one of its stationary states.* That is, even though it violates the ideas of classical physics, the atom does not change energy while the electron moves *within* an orbit.

*The appearance of the spectrum as a series of lines results from the construction of the apparatus. If the light passed through a small hole, rather than a narrow slit, the spectrum would appear as a circular field of dots rather than a horizontal series of lines. The key point is that *the spectrum is discrete, rather than continuous.*

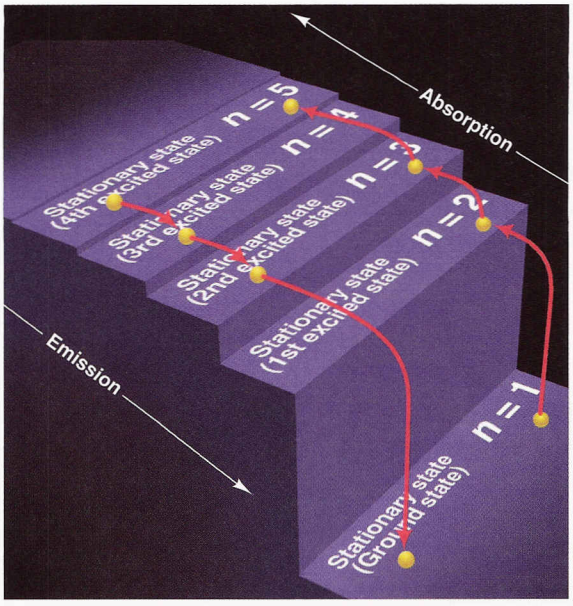

Figure 7.10 Quantum staircase. In this analogy for the energy levels of the hydrogen atom, an electron can absorb a photon and jump up to a higher "step" (stationary state) or emit a photon and jump down to a lower one. But the electron cannot lie between two steps.

3. *The atom changes to another stationary state* (the electron moves to another orbit) *only by absorbing or emitting a photon whose energy equals the difference in energy between the two states:*

$$E_{\text{photon}} = E_{\text{state A}} - E_{\text{state B}} = h\nu$$

where the energy of state A is higher than that of state B. A spectral line results when a photon of specific energy (and thus specific frequency) is *emitted* as the electron moves from a higher energy state to a lower one. Therefore, Bohr's model explains that an atomic spectrum is not continuous because *the atom's energy has only certain discrete levels, or states.*

In Bohr's model, the quantum number n (1, 2, 3, . . .) is associated with the radius of an electron orbit, which is directly related to the electron's energy: *the lower the n value, the smaller the radius of the orbit, and the lower the energy level.* When the electron is in the first orbit ($n = 1$), the orbit closest to the nucleus, the H atom is in its lowest (first) energy level, called the **ground state.** If the H atom absorbs a photon whose energy equals the *difference* between the first and second energy levels, the electron moves to the second orbit ($n = 2$), the next orbit out from the nucleus. When the electron is in the second or any higher orbit, the atom is said to be in an **excited state.** If the H atom in the first excited state (the electron in the second orbit) emits a photon of that same energy, it returns to the ground state. Figure 7.10 shows an analogy for this behavior.

Figure 7.11A shows how Bohr's model accounts for the three line spectra of hydrogen. When a sample of gaseous H atoms is excited, different atoms absorb different quantities of energy. Each atom has one electron, but so many atoms are present that all the energy levels (orbits) are populated by electrons. When the electrons drop from outer orbits to the $n = 3$ orbit (second excited state), the emitted photons create the infrared series of lines. The visible series arises when electrons drop to the $n = 2$ orbit (first excited state). Figure 7.11B shows that the ultraviolet series arises when electrons drop to the $n = 1$ orbit (ground state).

Limitations of the Bohr Model Despite its great success in accounting for the spectral lines of the H atom, the Bohr model failed to predict the spectrum of any other atom, even that of helium, the next simplest element. In essence, the Bohr model is a one-electron model. It works beautifully for the H atom and for other one-electron species, such as several created in the lab or seen in the spectra of stars: He^+ ($Z = 2$), Li^{2+} ($Z = 3$), Be^{3+} ($Z = 4$), B^{4+} ($Z = 5$), C^{5+} ($Z = 6$), N^{6+} ($Z = 7$), and O^{7+} ($Z = 8$). But it does not work for atoms with more than one electron because in these systems, additional nucleus-electron attractions and electron-electron repulsions are present. Moreover, as you'll soon see, electron movement in any real atom is far less clearly defined than the fixed orbits of the model. As a picture of the atom, the Bohr model is incorrect, but we still use the terms "ground state" and "excited state" and retain one of Bohr's central ideas in our current model: *the energy of an atom occurs in discrete levels.*

The Energy States of the Hydrogen Atom

A very useful result from Bohr's work is an equation for calculating the energy levels of an atom, which he derived from the classical principles of electrostatic attraction and circular motion:

$$E = -2.18\times10^{-18}\ \text{J}\left(\frac{Z^2}{n^2}\right)$$

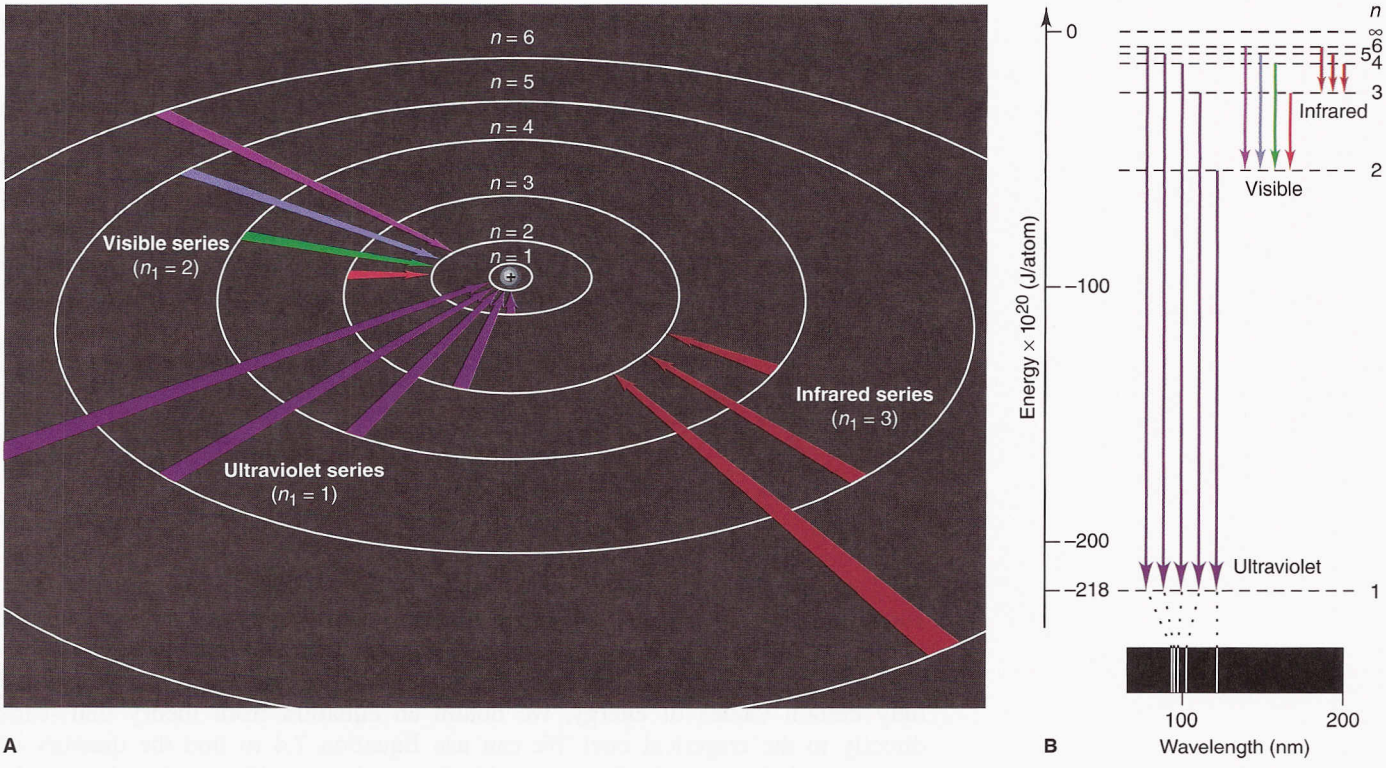

Figure 7.11 The Bohr explanation of three series of spectral lines. **A,** According to the Bohr model, when an electron drops from an outer orbit to an inner one, the atom emits a photon of specific energy that gives rise to a spectral line. In a given series, each electron drop, and thus each emission, has the same inner orbit, that is, the same value of n_1 in the Rydberg equation (see Equation 7.3). (The orbit radius is proportional to n^2. Only the first six orbits are shown.) **B,** An energy diagram shows how the ultraviolet series arises. Within each series, the greater the *difference* in orbit radii, the greater the difference in energy levels (depicted as a downward arrow), and the higher the energy of the photon emitted. For example, in the ultraviolet series, in which $n_1 = 1$, a drop from $n = 5$ to $n = 1$ emits a photon with more energy (shorter λ, higher ν) than a drop from $n = 2$ to $n = 1$. [The axis shows negative values because $n = \infty$ (the electron completely separated from the nucleus) is *defined* as the atom with zero energy.]

where Z is the charge of the nucleus. For the H atom, $Z = 1$, so we have

$$E = -2.18\times10^{-18}\ \text{J}\left(\frac{1^2}{n^2}\right) = -2.18\times10^{-18}\ \text{J}\left(\frac{1}{n^2}\right)$$

Therefore, the energy of the ground state ($n = 1$) is

$$E = -2.18\times10^{-18}\ \text{J}\left(\frac{1}{1^2}\right) = -2.18\times10^{-18}\ \text{J}$$

Don't be confused by the negative sign for the energy values (see the axis in Figure 7.11B). It appears because we *define* the zero point of the atom's energy when *the electron is completely removed from the nucleus.* Thus, $E = 0$ when $n = \infty$, so $E < 0$ for any smaller n. As an analogy, consider a book resting on the floor. You can define the zero point of the book's potential energy in many ways. If you define zero when the book is on the floor, the energy is positive when the book is on a tabletop. But, if you define zero when the book is on a tabletop, the energy is negative when the book lies on the floor; the latter case is analogous to the energy of the H atom (Figure 7.12).

Since n is in the denominator of the energy equation, as the electron moves closer to the nucleus (n decreases), the atom becomes more stable (less energetic) and its energy becomes a *larger negative number.* As the electron moves away from the nucleus (n increases), the atom's energy increases (becomes a smaller negative number).

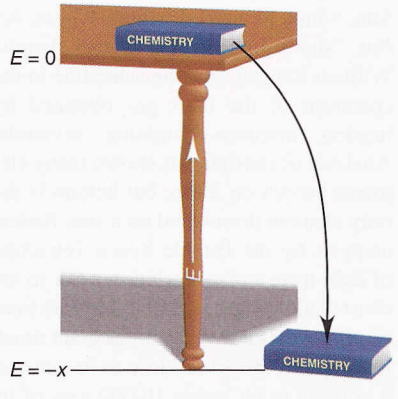

Figure 7.12 A tabletop analogy for the H atom's energy.

This equation is easily adapted to find the energy difference between any two levels:

$$\Delta E = E_{\text{final}} - E_{\text{initial}} = -2.18\times10^{-18}\ \text{J}\left(\frac{1}{n^2_{\text{final}}} - \frac{1}{n^2_{\text{initial}}}\right) \tag{7.4}$$

With it, we can predict the wavelengths of the spectral lines of the H atom. (In fact, Bohr obtained a value for the Rydberg constant that differed from the spectroscopists' value by only 0.05%!) Note that if we combine Equation 7.4 with Planck's expression for the change in an atom's energy (Equation 7.2), we obtain the Rydberg equation (Equation 7.3):

$$\Delta E = h\nu = \frac{hc}{\lambda} = -2.18\times10^{-18}\ \text{J}\left(\frac{1}{n^2_{\text{final}}} - \frac{1}{n^2_{\text{initial}}}\right)$$

$$\text{Therefore, } \frac{1}{\lambda} = -\frac{2.18\times10^{-18}\ \text{J}}{hc}\left(\frac{1}{n^2_{\text{final}}} - \frac{1}{n^2_{\text{initial}}}\right)$$

$$= -\frac{2.18\times10^{-18}\ \text{J}}{(6.626\times10^{-34}\ \text{J·s})(3.00\times10^{8}\ \text{m/s})}\left(\frac{1}{n^2_{\text{final}}} - \frac{1}{n^2_{\text{initial}}}\right)$$

$$= -1.10\times10^{7}\ \text{m}^{-1}\left(\frac{1}{n^2_{\text{final}}} - \frac{1}{n^2_{\text{initial}}}\right)$$

where $n_{\text{final}} = n_2$, $n_{\text{initial}} = n_1$, and $1.10\times10^7\ \text{m}^{-1}$ is the Rydberg constant ($1.096776\times10^7\ \text{m}^{-1}$) to three significant figures. Thus, from classical relationships of charge and of motion combined with the idea that the H atom can have only certain values of energy, we obtain an equation from theory that leads directly to the empirical one! We can use Equation 7.4 to find the quantity of energy needed to completely remove the electron from an H atom. In other words, what is ΔE for the following change?

$$\text{H}(g) \longrightarrow \text{H}^+(g) + \text{e}^-$$

We substitute $n_{\text{final}} = \infty$ and $n_{\text{initial}} = 1$ and obtain

$$\Delta E = E_{\text{final}} - E_{\text{initial}} = -2.18\times10^{-18}\ \text{J}\left(\frac{1}{\infty^2} - \frac{1}{1^2}\right)$$

$$= -2.18\times10^{-18}\ \text{J}(0 - 1) = 2.18\times10^{-18}\ \text{J}$$

ΔE is positive because energy is *absorbed* to remove the electron from the vicinity of the nucleus. For 1 mol of H atoms,

$$\Delta E = \left(2.18\times10^{-18}\ \frac{\text{J}}{\text{atom}}\right)\left(6.022\times10^{23}\ \frac{\text{atoms}}{\text{mol}}\right)\left(\frac{1\ \text{kJ}}{10^3\ \text{J}}\right) = 1.31\times10^3\ \text{kJ/mol}$$

This is the *ionization energy* of the H atom, the quantity of energy required to form 1 mol of gaseous H^+ ions from 1 mol of gaseous H atoms. We return to this idea in Chapter 8.

Spectroscopic analysis of the H atom led to the Bohr model, the first step toward our current model of the atom. From its use by 19th-century chemists as a means of identifying elements and compounds, spectrometry has developed into a major tool of modern chemistry (see Tools of the Laboratory).

What Are Stars and Planets Made Of?

In 1868, the French astronomer Pierre Janssen noted a bright yellow line in the solar emission spectrum and thought it was emitted by an element unique to the Sun, which he named helium (Greek *helios*, "sun"). In 1888, the British chemist William Ramsay saw the same line in the spectrum of the inert gas obtained by heating uranium-containing minerals. Analysis of starlight has shown many elements known on Earth, but helium is the only element discovered on a star. Recent analysis by the Hubble Space Telescope of light from a planet orbiting a star in the constellation Pegasus, 150 light-years from Earth, reveals a hydrogen-gas giant much like Jupiter, except so close to its sun that it appears to be losing 10,000 tons of its atmosphere every second!

SECTION SUMMARY

To explain the line spectrum of atomic hydrogen, Bohr proposed that the atom's energy is quantized because the electron's motion is restricted to fixed orbits. The electron can move from one orbit to another only if the atom absorbs or emits a photon whose energy equals the difference in energy levels (orbits). Line spectra are produced because these energy changes correspond to photons of specific wavelength. Bohr's model predicted the hydrogen atomic spectrum but could not predict that of any other atom because electrons influence one another. Despite this, Bohr's idea that atoms have quantized energy levels is a cornerstone of our current atomic model. Spectrophotometry is an instrumental technique in which emission and absorption spectra are used to identify and measure concentrations of substances.

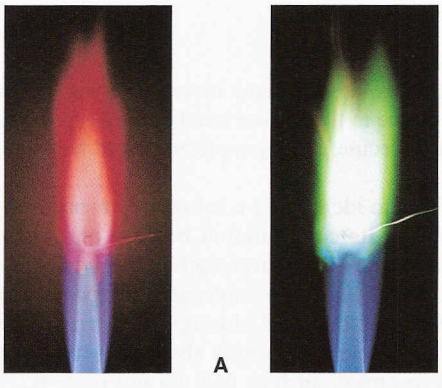
Spectrophotometry in Chemical Analysis

The use of spectral data to identify and quantify substances is essential to modern chemical analysis. The terms *spectroscopy, spectrometry,* and **spectrophotometry** denote a large group of instrumental techniques that obtain spectra corresponding to a substance's atomic and molecular energy levels.

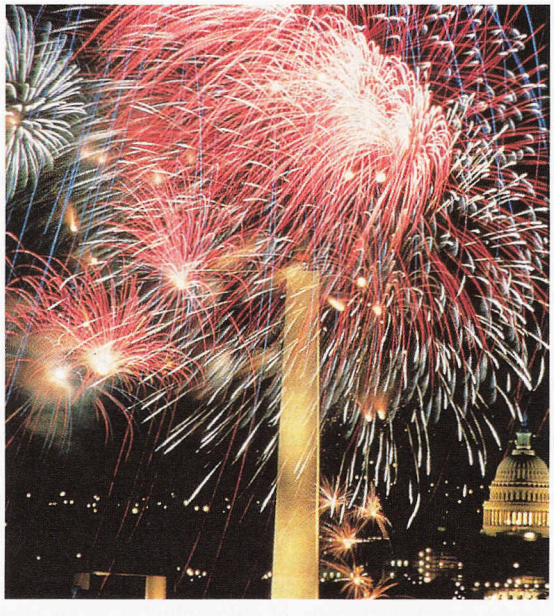
The two types of spectra most often obtained are emission and absorption spectra. An **emission spectrum,** such as the H atom line spectrum, is produced when atoms in an excited state *emit* photons characteristic of the element as they return to lower energy states. Some elements produce a very intense spectral line (or several closely spaced ones) that serves as a marker of their presence. Such an intense line is the basis of **flame tests,** rapid qualitative procedures performed by placing a granule of an ionic compound or a drop of its solution in a flame (Figure B7.1, A). Some of the colors of fireworks and flares are due to emissions from the same elements shown in the flame tests: crimson from strontium salts and blue-green from copper salts (Figure B7.1, B). The characteristic colors of sodium-vapor and mercury-vapor streetlamps, seen in many towns and cities, are due to one or a few prominent lines in their emission spectra.

An **absorption spectrum** is produced when atoms *absorb* photons of certain wavelengths and become excited from lower to higher energy states. Therefore, the absorption spectrum of an element appears as dark lines against a bright background. When white light passes through sodium vapor, for example, it gives rise to a sodium absorption spectrum, and the dark lines appear at the same wavelengths as those for the yellow-orange lines in the sodium emission spectrum (Figure B7.2).

(continued)



A



B

Figure B7.1 Flame tests and fireworks. A, In general, the color of the flame is created by a strong emission in the line spectrum of the element and therefore is often taken as preliminary evidence of the presence of the element in a sample. Shown here are the crimson of strontium and the blue-green of copper. **B,** The same emissions from compounds that contain these elements often appear in the brilliant displays of fireworks.

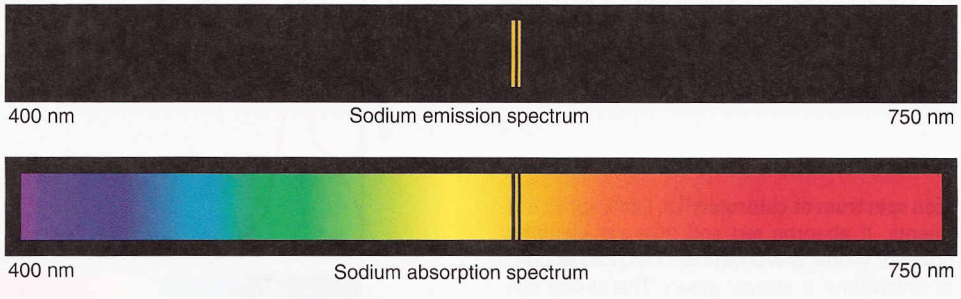


Figure B7.2 Emission and absorption spectra of sodium atoms. The wavelengths of the bright emission lines correspond to those of the dark absorption lines because both are created by the same energy change: $\Delta E_{emission} = -\Delta E_{absorption}$. (Only the two most intense lines in the Na spectra are shown.)

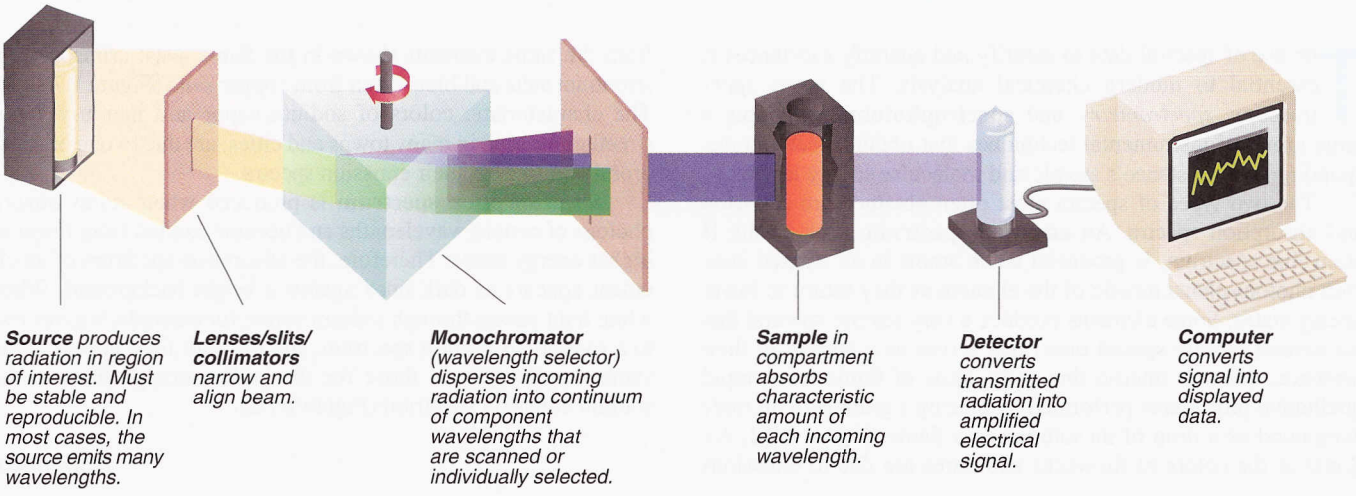

Figure B7.3 The main components of a typical spectrometer.

Instruments based on absorption spectra are much more common than those based on emission spectra, for several reasons. When a solid, liquid, or dense gas is excited, it *emits* so many lines that the spectrum is a continuum (recall the continuum of colors in sunlight). Absorption is also less destructive of fragile organic and biological molecules.

Despite differences that depend on the region of the electromagnetic spectrum used to irradiate the sample, all modern spectrometers have components that perform the same basic functions (Figure B7.3). (We discuss infrared spectroscopy and nuclear magnetic resonance spectroscopy in later chapters.)

Visible light is often used to study colored substances, which absorb only some of the wavelengths from white light. A leaf looks green, for example, because its chlorophyll absorbs red and blue wavelengths strongly and green weakly, so most of the green light is reflected. The absorption spectrum of chlorophyll *a* in ether solution appears in Figure B7.4.

The overall shape of the curve and the wavelengths of the major peaks are characteristic of chlorophyll *a*, so its spectrum serves as a means of identifying it from an unknown source. The curve varies in height because chlorophyll *a* absorbs incoming wavelengths to different extents. The absorptions appear as broad bands, rather than as the distinct lines we saw earlier for individual gaseous atoms, because dissolved substances, as well as pure solids and liquids, absorb many more wavelengths. This broader absorbance is due to the greater numbers and types of energy levels within a molecule, among molecules, and between molecules and solvent.

In addition to identifying a substance, a spectrometer can be used to measure its concentration because *the absorbance, the amount of light of a given wavelength absorbed by a substance, is proportional to the number of molecules*. Suppose you want to determine the concentration of chlorophyll in an ether solution of leaf extract. You select a strongly absorbed wavelength from the chlorophyll spectrum (such as 663 nm in Figure B7.4), measure the absorbance of the leaf-extract solution, and compare it with the absorbances of a series of ether solutions with known chlorophyll concentrations.

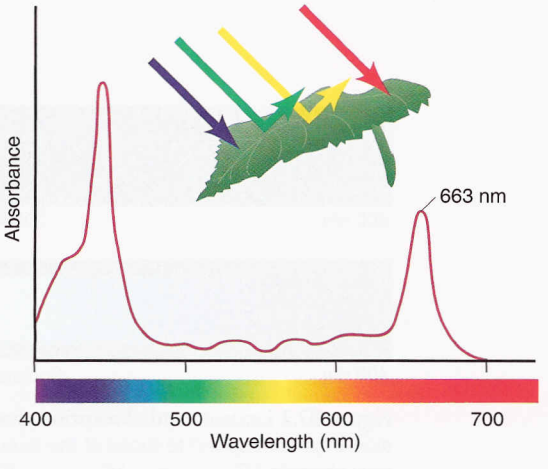

Figure B7.4 The absorption spectrum of chlorophyll *a*. Chlorophyll *a* is one of several leaf pigments. It absorbs red and blue wavelengths strongly but almost no green or yellow wavelengths. Thus, leaves containing large amounts of chlorophyll *a* appear green. The strong absorption at 663 nm can be used to quantify the amount of chlorophyll *a* present in a plant extract.

7.3 THE WAVE-PARTICLE DUALITY OF MATTER AND ENERGY

The year 1905 was a busy one for Albert Einstein. In addition to presenting the photon theory of light and explaining the photoelectric effect, he found time to explain Brownian motion (Chapter 13), which helped establish the molecular view of matter, and to introduce a new branch of physics with his theory of relativity. One of its many startling revelations was that matter and energy are alternate forms of the same entity. This idea is embodied in his famous equation $E = mc^2$, which relates the quantity of energy equivalent to a given mass, and vice versa. Relativity theory does not depend on quantum theory, but together they have completely blurred the sharp divisions we normally perceive between matter (chunky and massive) and energy (diffuse and massless).

The early proponents of quantum theory demonstrated that *energy is particle-like*. Physicists who developed the theory turned this proposition upside down and showed that *matter is wavelike*. Strange as this idea may seem, it is the key to our modern atomic model.

"He'll Never Make a Success of Anything" This comment, attributed to the principal of young Albert Einstein's primary school, remains a classic of misperception. Contrary to myth, the greatest physicist of the 20th century (some say of all time) was not a poor student but an independent one, preferring his own path to that prescribed by authority—a trait that gave him the intense focus characteristic of all his work. A friend recalls finding him in his small apartment, rocking his baby in its carriage with one hand while holding a pencil stub and scribbling on a pad with the other. At age 26, he was working on one of the four papers he published in 1905 that would revolutionize the way the universe is perceived and lead to his 1921 Nobel Prize.

The Wave Nature of Electrons and the Particle Nature of Photons

Bohr's efforts were a perfect case of fitting theory to data: he *assumed* that an atom has only certain allowable energy levels in order to *explain* the observed line spectrum. However, his assumption had no basis in physical theory. Then, in the early 1920s, a young French physics student named Louis de Broglie proposed a startling reason for fixed energy levels: *if energy is particle-like, perhaps matter is wavelike*. De Broglie had been thinking of other systems that display only certain allowed motions, such as the wave of a plucked guitar string. Figure 7.13 shows that, because the ends of the string are fixed, only certain vibrational frequencies (and wavelengths) are possible. De Broglie reasoned that *if electrons have wavelike motion* and are restricted to orbits of fixed radii, that would explain why they have only certain possible frequencies and energies.

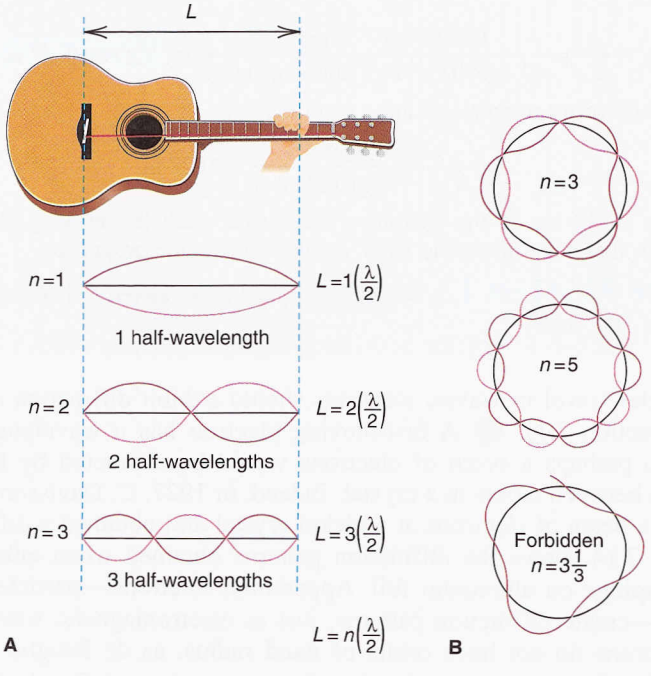

Figure 7.13 Wave motion in restricted systems. A, In a musical analogy to electron waves, one half-wavelength ($\lambda/2$) is the "quantum" of the guitar string's vibration. The string length L is fixed, so the only allowed vibrations occur when L is a whole-number multiple (n) of $\lambda/2$. **B,** If an electron occupies a circular orbit, only whole numbers of wavelengths are allowed ($n = 3$ and $n = 5$ are shown). A wave with a fractional number of wavelengths (such as $n = 3\frac{1}{3}$) is "forbidden" because it rapidly dies out through overlap of crests and troughs.

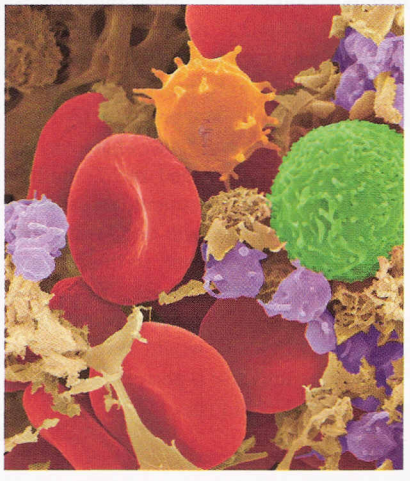
Combining the equation for mass-energy equivalence ($E = mc^2$) with that for the energy of a photon ($E = h\nu = hc/\lambda$), de Broglie derived an equation for the wavelength of any particle of mass m—whether planet, baseball, or electron—moving at speed u:

$$\lambda = \frac{h}{mu} \tag{7.5}$$

According to this equation for the **de Broglie wavelength,** *matter behaves as though it moves in a wave.* Note also that an object's wavelength is *inversely* proportional to its mass, so heavy objects such as planets and baseballs have wavelengths that are *many* orders of magnitude smaller than the object itself, as you can see in Table 7.1.

Table 7.1 The de Broglie Wavelengths of Several Objects

Substance	Mass (g)	Speed (m/s)	λ (m)
Slow electron	9×10^{-28}	1.0	7×10^{-4}
Fast electron	9×10^{-28}	5.9×10^{6}	1×10^{-10}
Alpha particle	6.6×10^{-24}	1.5×10^{7}	7×10^{-15}
One-gram mass	1.0	0.01	7×10^{-29}
Baseball	142	25.0	2×10^{-34}
Earth	6.0×10^{27}	3.0×10^{4}	4×10^{-63}



The Electron Microscope In a transmission electron microscope, a beam is focused by a lens and passes through a thin section of the specimen to a second lens. The resulting image is then magnified by a third lens to a final image. The differences between this and a light microscope are that the "beam" consists of high-speed electrons and the "lenses" are electromagnetic fields, which can be adjusted to give up to 200,000-fold magnification and 0.5-nm resolution. In a scanning electron microscope, the electron beam scans the specimen, knocking electrons from it, which creates a current that varies with surface irregularities. The current generates an image that looks like the object's surface, as in this false-color micrograph of various types of blood cells (×1200). The great advantage of electron microscopes is that high-speed electrons have wavelengths much smaller than those of visible light and, thus, allow much higher image resolution.

SAMPLE PROBLEM 7.3 Calculating the de Broglie Wavelength of an Electron

Problem Find the de Broglie wavelength of an electron with a speed of 1.00×10^{6} m/s (electron mass = 9.11×10^{-31} kg; $h = 6.626\times10^{-34}$ kg·m^2/s).

Plan We know the speed (1.00×10^{6} m/s) and mass (9.11×10^{-31} kg) of the electron, so we substitute these into Equation 7.5 to find λ.

Solution

$$\lambda = \frac{h}{mu} = \frac{6.626\times10^{-34}\ \text{kg·m}^2/\text{s}}{(9.11\times10^{-31}\ \text{kg})(1.00\times10^{6}\ \text{m/s})} = 7.27\times10^{-10}\ \text{m}$$

Check The order of magnitude and units seem correct:

$$\lambda \approx \frac{10^{-33}\ \text{kg·m}^2/\text{s}}{(10^{-30}\ \text{kg})(10^{6}\ \text{m/s})} = 10^{-9}\ \text{m}$$

Comment As you'll see in the upcoming discussion, such fast-moving electrons, with wavelengths in the range of atomic sizes, exhibit remarkable properties.

FOLLOW-UP PROBLEM 7.3 What is the speed of an electron that has a de Broglie wavelength of 100. nm?

If particles travel in waves, electrons should exhibit diffraction and interference (see Section 7.1). A fast-moving electron has a wavelength of about 10^{-10} m, so perhaps a beam of electrons would be diffracted by the similarly sized spaces between atoms in a crystal. Indeed, in 1927, C. Davisson and L. Germer guided a beam of electrons at a nickel crystal and obtained a diffraction pattern. Figure 7.14 shows the diffraction patterns obtained when either x-rays or electrons impinge on aluminum foil. Apparently, electrons—particles with mass and charge—create diffraction patterns, just as electromagnetic waves do! Even though electrons do not have orbits of fixed radius, as de Broglie thought, the energy levels of the atom *are* related to the wave nature of the electron.

If electrons have properties of energy, do photons have properties of matter? The de Broglie equation suggests that we can calculate the momentum (p), the product of mass and speed, for a photon of a given wavelength. Substituting the speed of light (c) for speed u in Equation 7.5 and solving for p gives

$$\lambda = \frac{h}{mc} = \frac{h}{p} \quad \text{and} \quad p = \frac{h}{\lambda}$$

Notice the inverse relationship between p and λ. This means that shorter wavelength (higher energy) photons have greater momentum. Thus, a decrease in a photon's momentum should appear as an increase in its wavelength. In 1923, Arthur Compton directed a beam of x-ray photons at a sample of graphite and observed that the wavelength of the reflected photons increased. This result means that the photons transferred some of their momentum to the electrons in the carbon atoms of the graphite, just as colliding billiard balls transfer momentum to one another. In this experiment, photons behave as particles with momentum!

To scientists of the time, these results were very unsettling. Classical experiments had shown matter to be particle-like and energy to be wavelike, but these new studies showed that every characteristic trait used to define the one now also defined the other. Figure 7.15 summarizes the conceptual and experimental breakthroughs that led to this juncture.

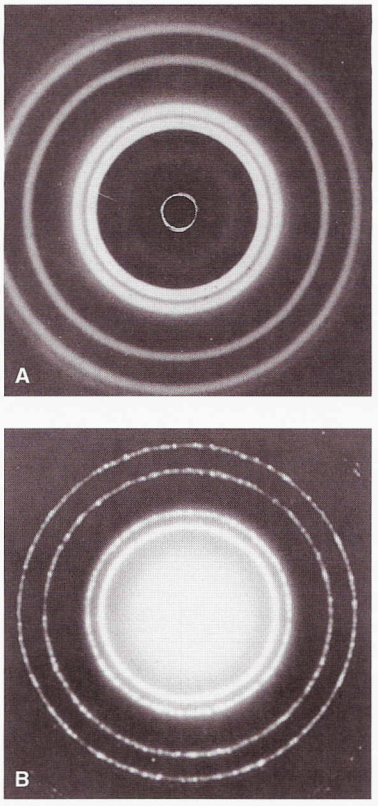


Figure 7.14 Comparing diffraction patterns of x-rays and electrons. A, X-ray diffraction pattern of aluminum. **B,** Electron diffraction pattern of aluminum. This behavior implies that both x-rays, which are electromagnetic radiation, and electrons, which are particles, travel in waves.

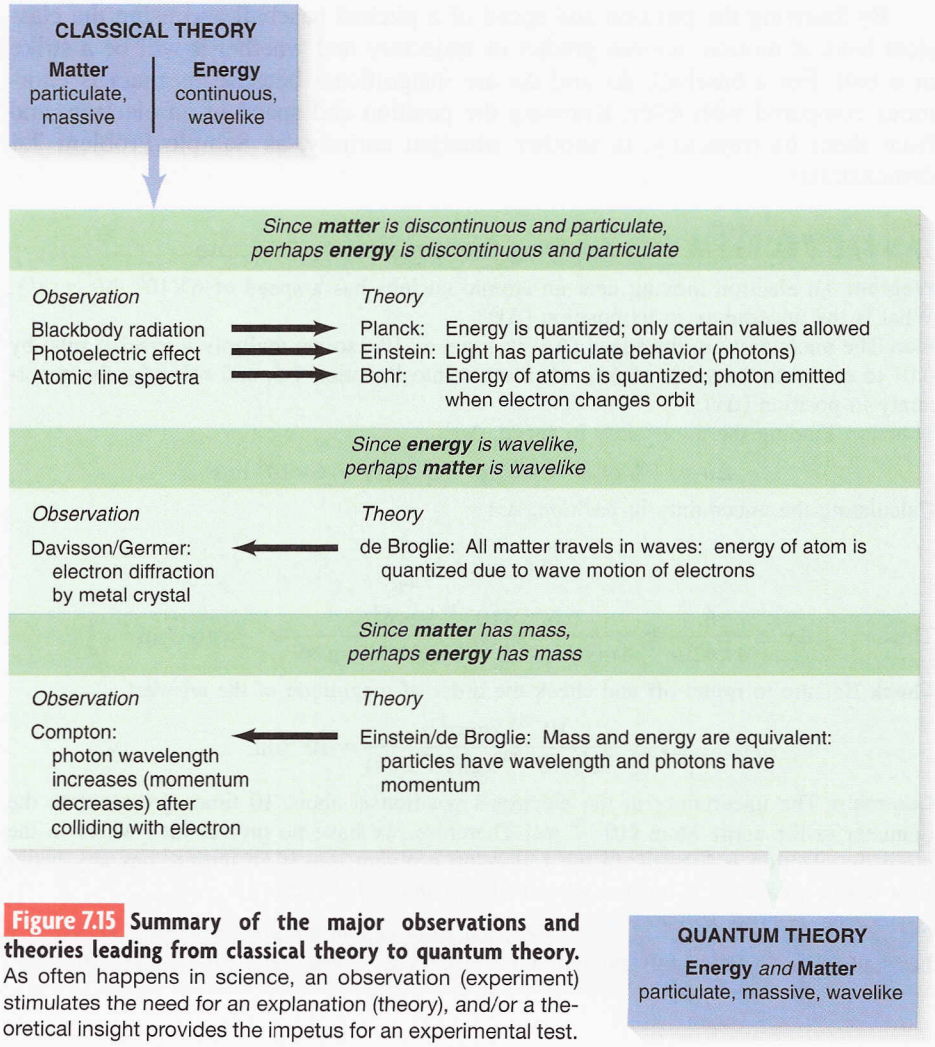

Figure 7.15 Summary of the major observations and theories leading from classical theory to quantum theory. As often happens in science, an observation (experiment) stimulates the need for an explanation (theory), and/or a theoretical insight provides the impetus for an experimental test.

The truth is that *both* matter and energy show *both* behaviors: each possesses both "faces." In some experiments, we observe one face; in other experiments, we observe the other face. The distinction between a particle and a wave is meaningful only in the macroscopic world, *not* in the atomic world. The distinction between matter and energy is in our minds and our limiting definitions, not inherent in nature. This dual character of matter and energy is known as the **wave-particle duality.**

The Heisenberg Uncertainty Principle

In the classical view of the world, a moving particle has a definite location at any instant, whereas a wave is spread out in space. If an electron has the properties of *both* a particle and a wave, what can we determine about its position in the atom? In 1927, the German physicist Werner Heisenberg postulated the **uncertainty principle,** which states that it is impossible to know the exact position *and* momentum (mass times speed) of a particle simultaneously. For a particle with constant mass m, the principle is expressed mathematically as

$$\Delta x \cdot m\Delta u \geq \frac{h}{4\pi} \tag{7.6}$$

where Δx is the uncertainty in position and Δu is the uncertainty in speed. The more accurately we know the position of the particle (smaller Δx), the less accurately we know its speed (larger Δu), and vice versa.

By knowing the position and speed of a pitched baseball and using the classical laws of motion, we can predict its trajectory and whether it will be a strike or a ball. For a baseball, Δx and Δu are insignificant because its mass is enormous compared with $h/4\pi$. Knowing the position and speed of an electron, and from them its trajectory, is another situation entirely, as Sample Problem 7.4 demonstrates.

SAMPLE PROBLEM 7.4 Applying the Uncertainty Principle

Problem An electron moving near an atomic nucleus has a speed of 6×10^6 m/s ± 1%. What is the uncertainty in its position (Δx)?

Plan The uncertainty in the speed (Δu) is given as 1%, so we multiply u (6×10^6 m/s) by 0.01 to calculate the value of Δu, substitute it into Equation 7.6, and solve for the uncertainty in position (Δx).

Solution Finding the uncertainty in speed, Δu:

$$\Delta u = 1\% \text{ of } u = 0.01(6\times10^6 \text{ m/s}) = 6\times10^4 \text{ m/s}$$

Calculating the uncertainty in position, Δx:

$$\Delta x \cdot m\Delta u \geq \frac{h}{4\pi}$$

Thus,
$$\Delta x \geq \frac{h}{4\pi m\Delta u} \geq \frac{6.626\times10^{-34}\ \text{kg}\cdot\text{m}^2/\text{s}}{4\pi(9.11\times10^{-31}\ \text{kg})(6\times10^4\ \text{m/s})} \geq 1\times10^{-9}\ \text{m}$$

Check Be sure to round off and check the order of magnitude of the answer:

$$\Delta x \geq \frac{10^{-33}\ \text{kg}\cdot\text{m}^2/\text{s}}{(10^1)(10^{-30}\ \text{kg})(10^5\ \text{m/s})} = 10^{-9}\ \text{m}$$

Comment The uncertainty in the electron's position is about 10 times greater than the diameter of the entire atom (10^{-10} m)! Therefore, we have no precise idea where in the atom the electron is located. In the follow-up problem, see if an umpire has any better idea where a baseball is located when calling balls and strikes.

FOLLOW-UP PROBLEM 7.4 How accurately can an umpire know the position of a baseball (mass = 0.142 kg) moving at 100.0 mi/h ± 1.00% (44.7 m/s ± 1.00%)?

As the results of Sample Problem 7.4 show, the uncertainty principle has profound implications for an atomic model. It means that *we cannot assign fixed paths for electrons,* such as the circular orbits of Bohr's model. As you'll see in the next section, the most we can ever hope to know is the *probability*—the odds—of finding an electron in a given region of space. However, we are not *sure* it is there any more than a gambler is sure of the next roll of the dice.

Uncertainty Is Unacceptable? Although the uncertainty principle is universally accepted by physicists today, Einstein found some aspects of it difficult to accept, as reflected in his famous statement that "God does not play dice with the universe." Rutherford was also skeptical. When Niels Bohr *(right),* who had become a champion of the new physics, delivered a lecture in Rutherford's laboratory on the principle, Rutherford *(left)* said, "You know, Bohr, your conclusions seem to me as uncertain as the premises on which they are built." Acceptance of radical ideas does not come easily, even among fellow geniuses.

SECTION SUMMARY

As a result of quantum theory and relativity theory, we can no longer view matter and energy as distinct entities. The de Broglie wavelength is the idea that electrons (and all matter) have wavelike motion. Allowed atomic energy levels are related to allowed wavelengths of the electron's motion. Electrons exhibit diffraction patterns, as do waves of energy, and photons exhibit transfer of momentum, as do particles of mass. The wave-particle duality of matter and energy exists at all scales but is observable only on the atomic scale. According to the uncertainty principle, we cannot know simultaneously the exact position and speed of an electron.

7.4 THE QUANTUM-MECHANICAL MODEL OF THE ATOM

Acceptance of the dual nature of matter and energy and of the uncertainty principle culminated in the field of **quantum mechanics,** which examines the wave nature of objects on the atomic scale. In 1926, Erwin Schrödinger derived an equation that is the basis for the quantum-mechanical model of the hydrogen atom. The model describes an atom that has certain allowed quantities of energy due to the allowed wavelike behavior of an electron whose exact location is impossible to know.

The Atomic Orbital and the Probable Location of the Electron

The electron's matter-wave occupies the three-dimensional space near the nucleus and experiences a continuous, but varying, influence from the nuclear charge. The **Schrödinger equation** is quite complex, but is represented as

$$\mathcal{H}\psi = E\psi$$

where E is the energy of the atom. The symbol ψ (Greek *psi,* pronounced "sigh") is called a **wave function,** a mathematical description of the state of the electron's matter-wave in terms of position in three dimensions. The symbol $\mathcal{H}$, called the Hamiltonian operator, represents a set of mathematical operations that, when carried out on a particular ψ, yields an allowed energy value.*

Each solution to the equation (that is, each energy state of the atom) is associated with a given wave function, also called an **atomic orbital.** It's important to keep in mind that an "orbital" in the quantum-mechanical model *bears no resemblance* to an "orbit" in the Bohr model: an *orbit* was, supposedly, a electron's path around the nucleus, whereas an *orbital* is a mathematical function with no direct physical meaning.

We cannot know precisely where the electron is at any moment, but we can describe where it *probably* is, that is, where it is most likely to be found, or where it spends most of its time. Although the wave function (atomic orbital) has no

*The complete form of the Schrödinger equation in terms of the three linear axes is

$$\left[-\frac{h^2}{8\pi^2 m_e}\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}+\frac{d^2}{dz^2}\right)+V(x,y,z)\right]\psi(x,y,z) = E\psi(x,y,z)$$

where ψ is the wave function; m_e is the electron's mass; E is the total quantized energy of the atomic system; and V is the potential energy at point (x,y,z).

direct physical meaning, the square of the wave function, ψ^2, is the *probability density,* a measure of the probability that the electron can be found within a particular tiny volume of the atom. (Whereas ψ can have positive or negative values, ψ^2 is always positive, which makes sense for a value that expresses a probability.) For a given energy level, we can depict this probability with an *electron probability density diagram,* or more simply, an **electron density diagram.** In Figure 7.16A, the value of ψ^2 for a given volume is represented pictorially by a certain density of dots: the greater the density of dots, the higher the probability of finding the electron within that volume.

Electron density diagrams are sometimes called **electron cloud** representations. If we *could* take a time-exposure photograph of the electron in wavelike motion around the nucleus, it would appear as a "cloud" of electron positions. The electron cloud is an *imaginary* picture of the electron changing its position rapidly over time; it does *not* mean that an electron is a diffuse cloud of charge. Note that *the electron probability density decreases with distance from the nucleus* along a line, *r.* The same concept is shown graphically in the plot of ψ^2 vs. *r* in Figure 7.16B. Note that due to the thickness of the printed line, the curve touches the axis; nevertheless, *the probability of the electron being far from the nucleus is very small, but not zero.*

The *total* probability of finding the electron at any distance *r* from the nucleus is also important. To find this, we mentally divide the volume around the nucleus into thin, concentric, spherical layers, like the layers of an onion (shown in cross section in Figure 7.16C), and ask in which *spherical layer* we are most likely to find the electron. This is the same as asking for the *sum of* ψ^2 *values* within each spherical layer. The steep falloff in probability density with distance (see Figure 7.16B) has an important effect. Near the nucleus, the volume of each layer increases faster than its probability density decreases. As a result, the *total* probability of finding the electron in the second layer is higher than in the first. Electron density drops off so quickly, however, that this effect soon diminishes with greater distance. Thus, even though the volume of each layer continues to increase, the total probability for a given layer gradually decreases. Because of

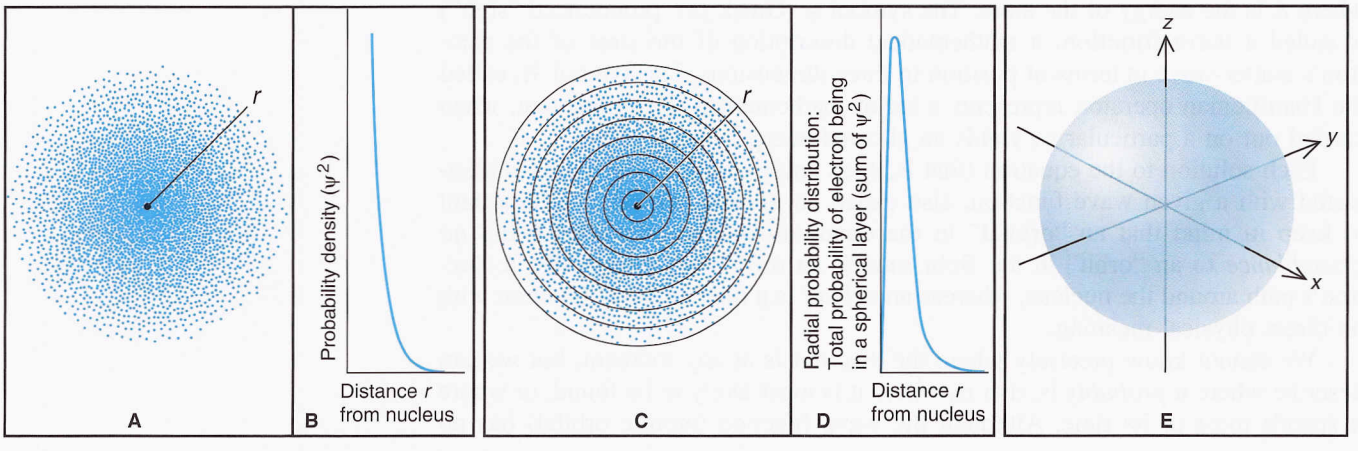

Figure 7.16 Electron probability density in the ground-state H atom. **A,** An electron density diagram shows a cross section of the H atom. The dots, each representing the probability density of the electron being within a tiny volume, decrease along a line outward from the nucleus. **B,** A plot of the data in **A** shows that the probability density (ψ^2) decreases with distance from the nucleus but does not reach zero (the thickness of the line makes it appear to do so). **C,** Dividing the atom's volume into thin, concentric, spherical layers (shown in cross section) and counting the dots within each layer gives the total probability of finding the electron within that layer. **D,** A radial probability distribution plot shows total electron density in each spherical layer vs. *r.* Since electron density decreases more slowly than the volume of each concentric layer increases, the plot shows a peak. **E,** A 90% probability contour shows the ground state of the H atom (orbital of lowest energy) and represents the volume in which the electron spends 90% of its time.

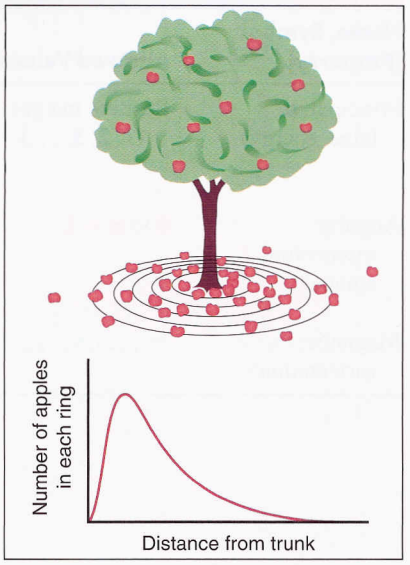
these opposing effects of decreasing probability density and increasing layer volume, the total probability peaks in a layer some distance from the nucleus. Figure 7.16D shows this as a **radial probability distribution plot.**

The peak of the radial probability distribution for the ground-state H atom appears at the same distance from the nucleus (0.529Å, or 5.29×10^{-11} m) as Bohr postulated for the closest orbit. Thus, at least for the ground state, the Schrödinger model predicts that the electron spends *most* of its time at the same distance that the Bohr model predicted it spent *all* of its time. The difference between "most" and "all" reflects the uncertainty of the electron's location in the Schrödinger model.

How far away from the nucleus can we find the electron? This is the same as asking "How large is the atom?" Recall from Figure 7.16B that the probability of finding the electron far from the nucleus is not zero. Therefore, we *cannot* assign a definite volume to an atom. However, we often visualize atoms with a 90% **probability contour,** such as in Figure 7.16E, which shows the volume within which the electron of the hydrogen atom spends 90% of its time.



A Radial Probability Distribution of Apples An analogy might clarify why the curve in the radial probability distribution plot peaks and then falls off. Picture fallen apples around the base of an apple tree: the density of apples is greatest near the trunk and decreases with distance. Divide the ground under the tree into foot-wide concentric rings and collect the apples within each ring. Apple density is greatest in the first ring, but the area of the second ring is larger, and so it contains a greater *total* number of apples. Farther out near the edge of the tree, rings have more area but lower apple "density," so the total number of apples decreases. A plot of "number of apples within a ring" vs. "distance of ring from trunk" shows a peak at some distance from the trunk, as in Figure 7.16D.

Quantum Numbers of an Atomic Orbital

So far we have discussed the electron density for the *ground* state of the H atom. When the atom absorbs energy, it exists in an *excited* state and the region of space occupied by the electron is described by a different atomic orbital (wave function). As you'll see, each atomic orbital has a distinctive radial probability distribution and 90% probability contour.

An atomic orbital is specified by three quantum numbers. One is related to the orbital's size, another to its shape, and the third to its orientation in space.* The quantum numbers have a hierarchical relationship: the size-related number limits the shape-related number, which limits the orientation-related number. Let's examine this hierarchy and then look at the shapes and orientations.

1. The **principal quantum number (n)** *is a positive integer* (1, 2, 3, and so forth). It indicates the relative *size* of the orbital and therefore the relative *distance from the nucleus* of the peak in the radial probability distribution plot. The principal quantum number specifies the *energy level* of the H atom: *the higher the n value, the higher the energy level.* When the electron occupies an orbital with $n = 1$, the H atom is in its ground state and has lower energy than when the electron occupies the $n = 2$ orbital (first excited state).

2. The **angular momentum quantum number (l)** *is an integer from* 0 *to* $n - 1$. It is related to the *shape* of the orbital and is sometimes called the *orbital-shape quantum number.* Note that the principal quantum number sets a limit on the values for the angular momentum quantum number; that is, n limits l. For an orbital with $n = 1$, l can have a value of only 0. For orbitals with $n = 2$, l can have a value of 0 or 1; for those with $n = 3$, l can be 0, 1, or 2; and so forth. Note that the number of possible l values equals the value of n.

3. The **magnetic quantum number (m_l)** *is an integer from* $-l$ *through* 0 *to* $+l$. It prescribes the *orientation* of the orbital in the space around the nucleus and is sometimes called the *orbital-orientation quantum number.* The possible values of an orbital's magnetic quantum number are set by its angular momentum quantum number; that is, l sets the possible values of m_l. An orbital with $l = 0$ can have only $m_l = 0$. However, an orbital with $l = 1$ can have any one of three m_l values, -1, 0, or $+1$; thus, there are three possible orbitals with $l = 1$, each with its own orientation. Note that the number of possible m_l values *equals* the number of orbitals, which is $2l + 1$ for a given l value.

*For ease in discussion, we refer to the size, shape, and orientation of an "atomic orbital," although we really mean the size, shape, and orientation of an "atomic orbital's radial probability distribution." This usage is common in both introductory and advanced texts.

Table 7.2 The Hierarchy of Quantum Numbers for Atomic Orbitals

Name, Symbol (Property)	Allowed Values	Quantum Numbers
Principal, n (size, energy)	Positive integer (1, 2, 3, . . .)	1 2 3
Angular momentum, l (shape)	0 to $n - 1$	0 0 1 0 1 2
Magnetic, m_l (orientation)	$-l, \ldots, 0, \ldots, +l$	0 0 −1 0 +1 0 −1 0 +1 −2 −1 0 +1 +2

Table 7.2 summarizes the relationships among the three quantum numbers. (In Chapter 8, we'll discuss a fourth quantum number that relates to a property of the electron itself.) The total number of orbitals for a given n value is n^2.

SAMPLE PROBLEM 7.5 Determining Quantum Numbers for an Energy Level

Problem What values of the angular momentum (l) and magnetic (m_l) quantum numbers are allowed for a principal quantum number (n) of 3? How many orbitals exist for $n = 3$?

Plan We determine allowable quantum numbers with the rules from the text: l values are integers from 0 to $n - 1$, and m_l values are integers from $-l$ to 0 to $+l$. One m_l value is assigned to each orbital, so the number of m_l values gives the number of orbitals.

Solution Determining l values: for $n = 3$, $l = 0, 1, 2$

Determining m_l for each l value:

For $l = 0$, $m_l = 0$

For $l = 1$, $m_l = -1, 0, +1$

For $l = 2$, $m_l = -2, -1, 0, +1, +2$

There are nine m_l values, so there are nine orbitals with $n = 3$.

Check Table 7.2 shows that we are correct. The total number of orbitals for a given n value is n^2, and for $n = 3$, $n^2 = 9$.

FOLLOW-UP PROBLEM 7.5 Specify the l and m_l values for $n = 4$.

The energy states and orbitals of the atom are described with specific terms and associated with one or more quantum numbers:

1. *Level.* The atom's energy **levels,** or *shells,* are given by the n value: the smaller the n value, the lower the energy level and the greater the probability of the electron being closer to the nucleus.

2. *Sublevel.* The atom's levels contain **sublevels,** or *subshells,* which designate the orbital shape. Each sublevel has a letter designation:

$l = 0$ is an s sublevel.
$l = 1$ is a p sublevel.
$l = 2$ is a d sublevel.
$l = 3$ is an f sublevel.

(The letters derive from the names of spectroscopic lines: *s*harp, *p*rincipal, *d*iffuse, and *f*undamental. Sublevels with l values greater than 3 are designated alphabetically: g sublevel, h sublevel, etc.) Sublevels are named by joining the n value and the letter designation. For example, the sublevel (subshell) with $n = 2$ and $l = 0$ is called the 2s sublevel.

3. *Orbital.* Each allowed combination of n, l, and m_l values specifies one of the atom's *orbitals*. Thus, the three quantum numbers that describe an orbital express its size (energy), shape, and spatial orientation. You can easily give the quantum numbers of the orbitals in any sublevel if you know the sublevel letter designation and the quantum number hierarchy. For example, the hierarchy prescribes that the $2s$ sublevel has only one orbital, and its quantum numbers are $n = 2$, $l = 0$, and $m_l = 0$. The $3p$ sublevel has three orbitals: one with $n = 3$, $l = 1$, and $m_l = -1$; another with $n = 3$, $l = 1$, and $m_l = 0$; and a third with $n = 3$, $l = 1$, and $m_l = +1$.

SAMPLE PROBLEM 7.6 Determining Sublevel Names and Orbital Quantum Numbers

Problem Give the name, magnetic quantum numbers, and number of orbitals for each sublevel with the given quantum numbers:

(a) $n = 3, l = 2$ **(b)** $n = 2, l = 0$ **(c)** $n = 5, l = 1$ **(d)** $n = 4, l = 3$

Plan To name the sublevel (subshell), we combine the n value and l letter designation. Since we know l, we can find the possible m_l values, whose total number equals the number of orbitals.

Solution

	n	l	Sublevel Name	Possible m_l Values	No. of Orbitals
(a)	3	2	$3d$	$-2, -1, 0, +1, +2$	5
(b)	2	0	$2s$	0	1
(c)	5	1	$5p$	$-1, 0, +1$	3
(d)	4	3	$4f$	$-3, -2, -1, 0, +1, +2, +3$	7

Check Check the number of orbitals in each sublevel using

$$\text{No. of orbitals} = \text{no. of } m_l \text{ values} = 2l + 1$$

FOLLOW-UP PROBLEM 7.6 What are the n, l, and possible m_l values for the $2p$ and $5f$ sublevels?

SAMPLE PROBLEM 7.7 Identifying Incorrect Quantum Numbers

Problem What is wrong with each of the following quantum number designations and/or sublevel names?

	n	l	m_l	Name
(a)	1	1	0	$1p$
(b)	4	3	+1	$4d$
(c)	3	1	−2	$3p$

Solution **(a)** A sublevel with $n = 1$ can have only $l = 0$, not $l = 1$. The only possible sublevel name is $1s$.

(b) A sublevel with $l = 3$ is an f sublevel, not a d sublevel. The name should be $4f$.

(c) A sublevel with $l = 1$ can have only m_l of $-1, 0, +1$, not -2.

Check Check that l is always less than n, and m_l is always $\geq -l$ and $\leq +l$.

FOLLOW-UP PROBLEM 7.7 Supply the missing quantum numbers and sublevel names.

	n	l	m_l	Name
(a)	?	?	0	$4p$
(b)	2	1	0	?
(c)	3	2	−2	?
(d)	?	?	?	$2s$

Shapes of Atomic Orbitals

Each sublevel of the H atom consists of a set of orbitals with characteristic shapes. As you'll see in Chapter 8, orbitals for the other atoms have similar shapes.

The *s* Orbital An orbital with $l = 0$ has a *spherical* shape with the nucleus at its center and is called an ***s* orbital.** The H atom's ground state, for example, has the electron in the 1*s* orbital, and *the electron probability density is highest at the nucleus.* Figure 7.17A shows this fact graphically *(top),* and an electron density *relief map (inset)* depicts this curve in three dimensions. The quarter-section of an electron cloud representation *(middle)* has the darkest shading at the nucleus. On the other hand, the radial probability distribution plot *(bottom),* which represents the probability of finding the electron (that is, where the electron spends

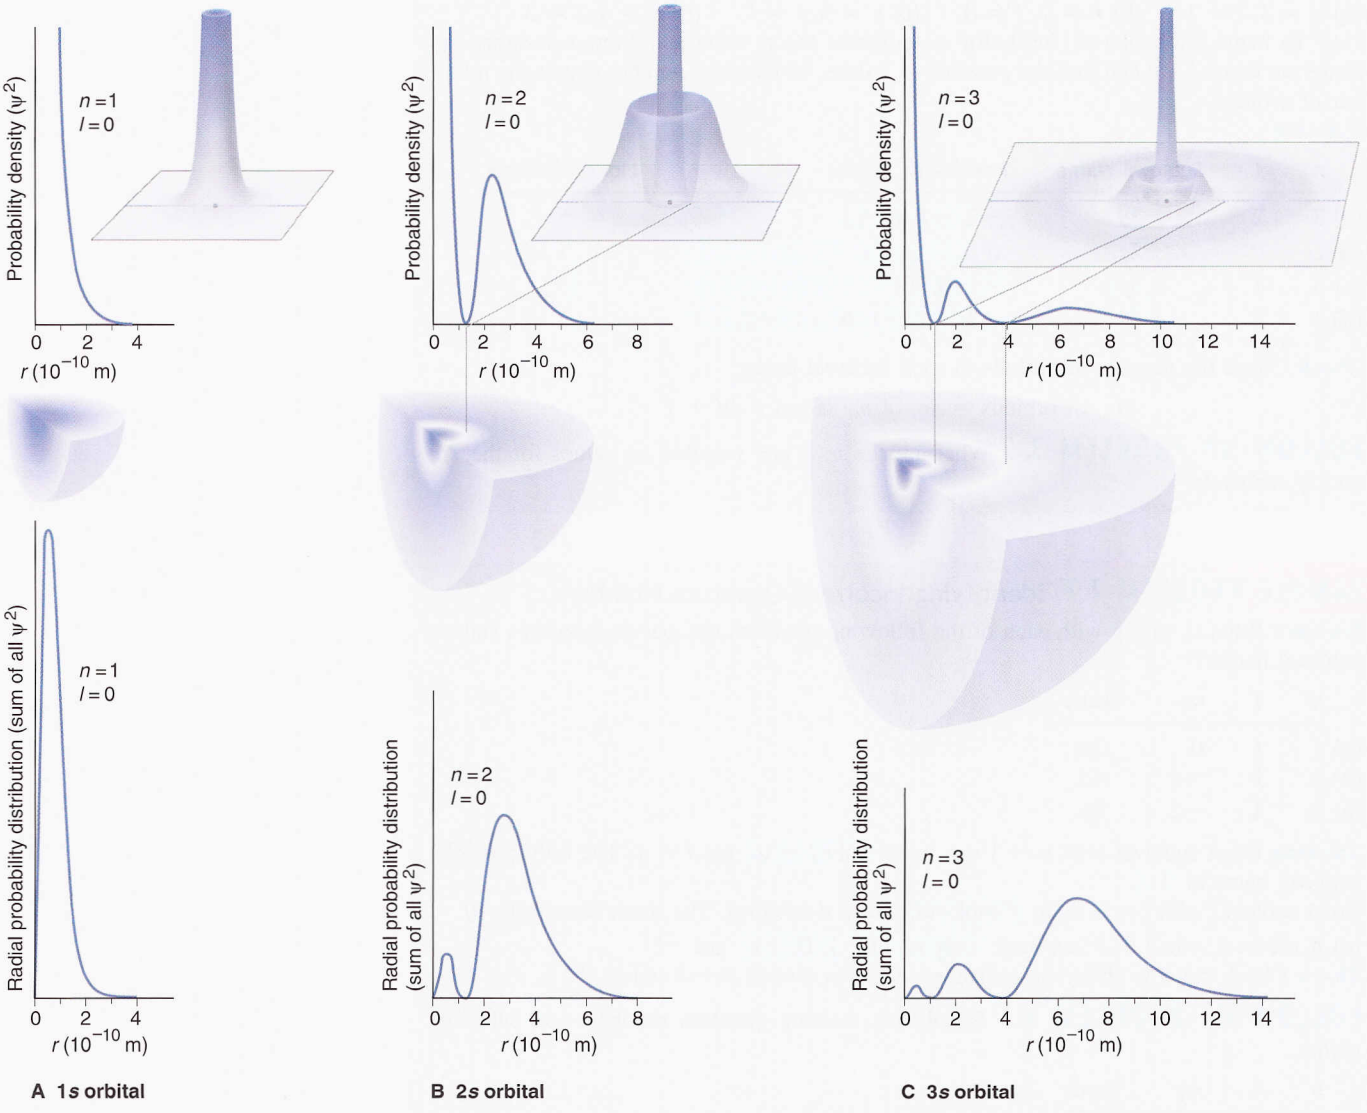


Figure 7.17 The 1*s*, 2*s*, and 3*s* orbitals. Information for each of the *s* orbitals is shown as a plot of probability density vs. distance *(top,* with the relief map, *inset,* showing the plot in three dimensions); as an electron cloud representation *(middle),* in which shading coincides with peaks in the plot above; and as a radial probability distribution *(bottom)* that shows where the electron spends its time. **A,** The 1*s* orbital. **B,** The 2*s* orbital. **C,** The 3*s* orbital. Nodes (regions of zero probability) appear in the 2*s* and 3*s* orbitals.

most of its time), is highest slightly out from the nucleus. Both plots fall off smoothly with distance.

The 2*s* orbital (Figure 7.17B) has two regions of higher electron density. The radial probability distribution (Figure 7.17B, *bottom*) of the more distant region is *higher* than that of the closer one because the sum of its ψ^2 is taken over a much larger volume. Between the two regions is a spherical **node,** a shell-like region where the probability drops to zero ($\psi^2 = 0$ at the node, analogous to zero amplitude of a wave). Because the 2*s* orbital is larger than the 1*s*, an electron in the 2*s* spends more time *farther* from the nucleus than when it occupies the 1*s*.

The 3*s* orbital, shown in Figure 7.17C, has three regions of high electron density and two nodes. Here again, the highest radial probability is at the greatest distance from the nucleus because the sum of all ψ^2 is taken over a larger volume. This pattern of more nodes and higher probability with distance continues for *s* orbitals of higher *n* value. An *s* orbital has a spherical shape, so it can have only one orientation and, thus, only one value for the magnetic quantum number: for any *s* orbital, $m_l = 0$.

The *p* Orbital An orbital with $l = 1$ has two regions (lobes) of high probability, one on *either side* of the nucleus, and is called a ***p* orbital.** Thus, as you can see in Figure 7.18, the *nucleus lies at the nodal plane* of this dumbbell-shaped orbital. The maximum value of l is $n - 1$, so only levels with $n = 2$ or higher can have a *p* orbital. Therefore, the lowest energy *p* orbital (the one closest to the nucleus) is the 2*p*. Keep in mind that *one p orbital consists of both lobes* and that the electron spends *equal* time in both. As we would expect from the pattern of *s* orbitals, a 3*p* orbital is larger than a 2*p* orbital, a 4*p* orbital is larger than a 3*p* orbital, and so forth.

Unlike an *s* orbital, each *p* orbital *does* have a specific orientation in space. The $l = 1$ value has three possible m_l values: -1, 0, and $+1$, which refer to three *mutually perpendicular p* orbitals. They are identical in size, shape, and energy, differing only in orientation. For convenience, we associate *p* orbitals with the *x*, *y*, and *z* axes (but there is no necessary relation between a spatial axis and a given m_l value): the p_x orbital lies along the *x* axis, the p_y along the *y* axis, and the p_z along the *z* axis.

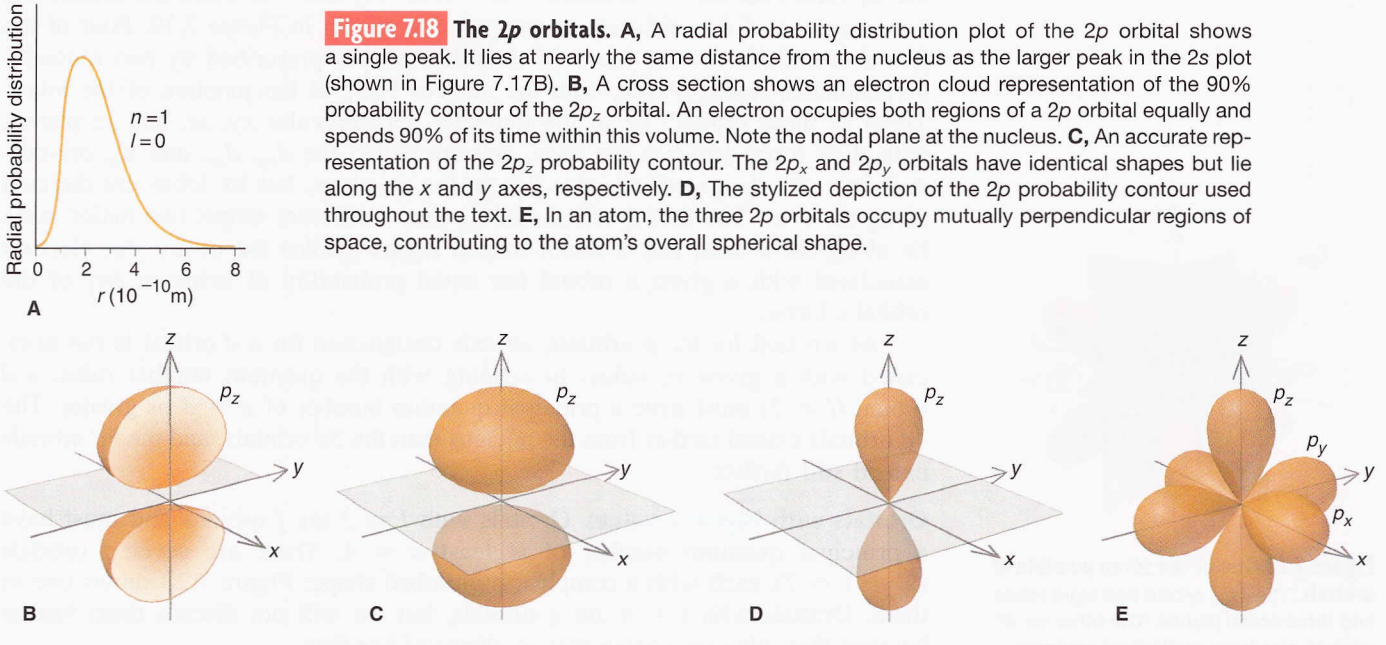

Figure 7.18 The 2*p* orbitals. A, A radial probability distribution plot of the 2*p* orbital shows a single peak. It lies at nearly the same distance from the nucleus as the larger peak in the 2*s* plot (shown in Figure 7.17B). **B,** A cross section shows an electron cloud representation of the 90% probability contour of the $2p_z$ orbital. An electron occupies both regions of a 2*p* orbital equally and spends 90% of its time within this volume. Note the nodal plane at the nucleus. **C,** An accurate representation of the $2p_z$ probability contour. The $2p_x$ and $2p_y$ orbitals have identical shapes but lie along the *x* and *y* axes, respectively. **D,** The stylized depiction of the 2*p* probability contour used throughout the text. **E,** In an atom, the three 2*p* orbitals occupy mutually perpendicular regions of space, contributing to the atom's overall spherical shape.

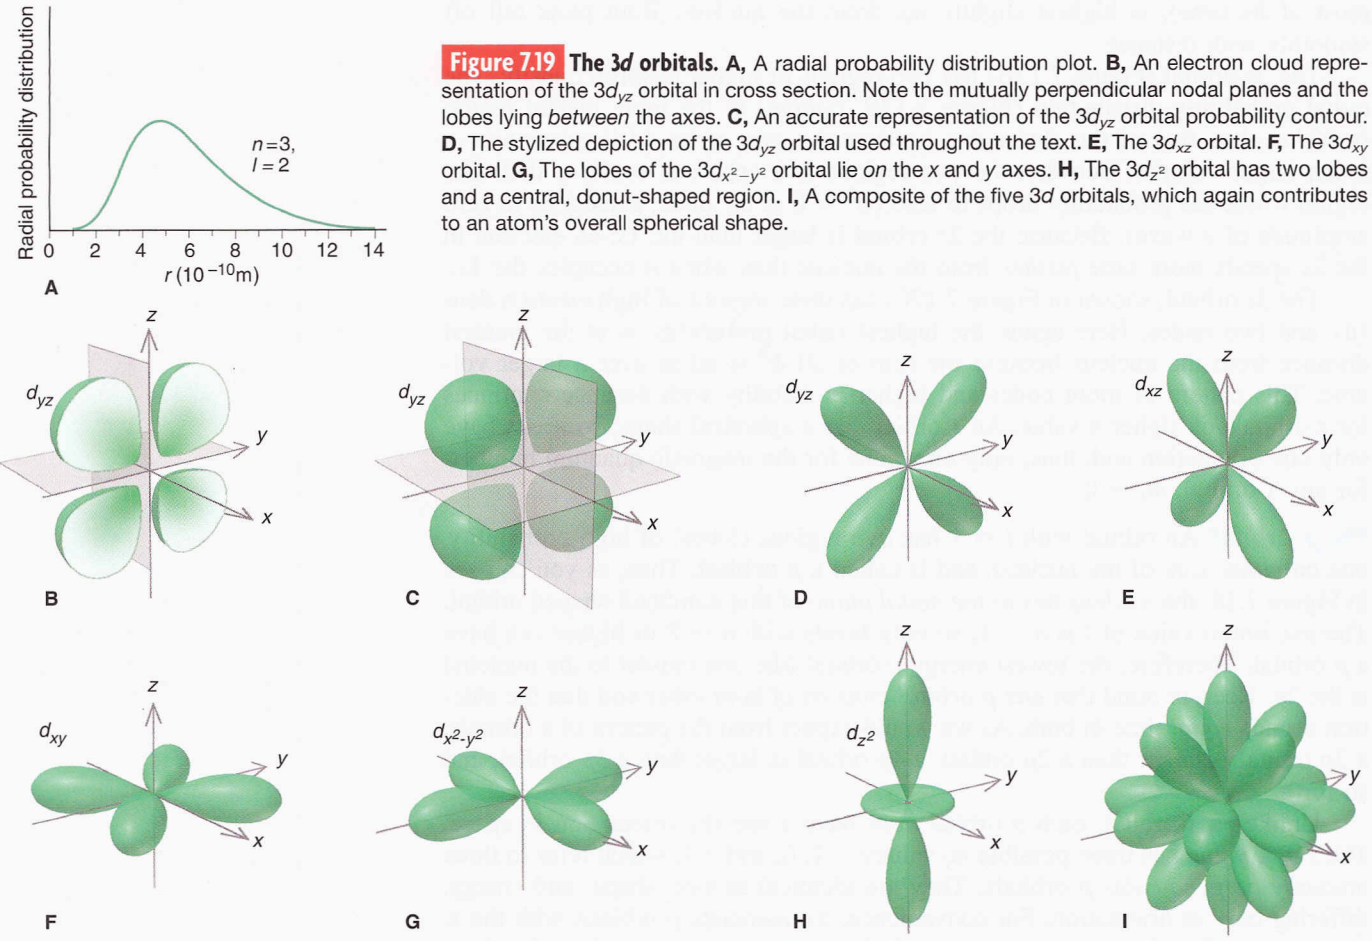

Figure 7.19 The 3*d* orbitals. **A,** A radial probability distribution plot. **B,** An electron cloud representation of the $3d_{yz}$ orbital in cross section. Note the mutually perpendicular nodal planes and the lobes lying *between* the axes. **C,** An accurate representation of the $3d_{yz}$ orbital probability contour. **D,** The stylized depiction of the $3d_{yz}$ orbital used throughout the text. **E,** The $3d_{xz}$ orbital. **F,** The $3d_{xy}$ orbital. **G,** The lobes of the $3d_{x^2-y^2}$ orbital lie *on* the *x* and *y* axes. **H,** The $3d_{z^2}$ orbital has two lobes and a central, donut-shaped region. **I,** A composite of the five 3*d* orbitals, which again contributes to an atom's overall spherical shape.

The *d* Orbital An orbital with $l = 2$ is called a ***d* orbital.** There are five possible m_l values for the $l = 2$ value: -2, -1, 0, $+1$, and $+2$. Thus, a *d* orbital can have any one of five different orientations, as shown in Figure 7.19. Four of the five *d* orbitals have four lobes (a cloverleaf shape) prescribed by two mutually perpendicular nodal planes, with the nucleus lying at the junction of the lobes. Three of these orbitals lie in the mutually perpendicular *xy*, *xz*, and *yz* planes, with their lobes *between* the axes, and are called the d_{xy}, d_{xz}, and d_{yz} orbitals. A fourth, the $d_{x^2-y^2}$ orbital, also lies in the *xy* plane, but its lobes are directed *along* the axes. The fifth *d* orbital, the d_{z^2}, has a different shape: two major lobes lie along the *z* axis, and a donut-shaped region girdles the center. An electron associated with a given *d* orbital has equal probability of being in any of the orbital's lobes.

As we said for the *p* orbitals, an axis designation for a *d* orbital is *not* associated with a given m_l value. In keeping with the quantum number rules, a *d* orbital ($l = 2$) must have a principal quantum number of $n = 3$ or greater. The 4*d* orbitals extend farther from the nucleus than the 3*d* orbitals, and the 5*d* orbitals extend still farther.

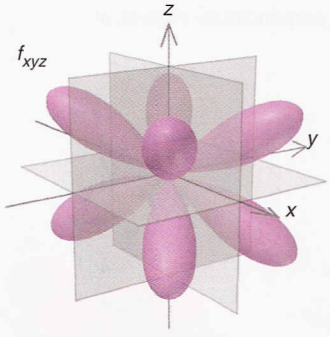

Figure 7.20 One of the seven possible 4*f* orbitals. The $4f_{xyz}$ orbital has eight lobes and three nodal planes. The other six 4*f* orbitals also have multilobed contours.

Orbitals with Higher *l* Values Orbitals with $l = 3$ are *f* orbitals and must have a principal quantum number of at least $n = 4$. There are seven *f* orbitals ($2l + 1 = 7$), each with a complex, multilobed shape; Figure 7.20 shows one of them. Orbitals with $l = 4$ are *g* orbitals, but we will not discuss them further because they play no known role in chemical bonding.

Energy Levels of the Hydrogen Atom

The energy state of the H atom depends on the principal quantum number ***n*** *only.* An electron in an orbital with a higher n value spends its time (on average) farther from the nucleus, so it is higher in energy. As you'll see in Chapter 8, the energy state of an atom of any other element depends on both the n *and* l values of the occupied sublevels. Thus, in the case of the H atom *only,* all four $n = 2$ sublevels (one $2s$ and three $2p$) have the same energy, and all nine $n = 3$ sublevels (one $3s$, three $3p$, and five $3d$) have the same energy (Figure 7.21).

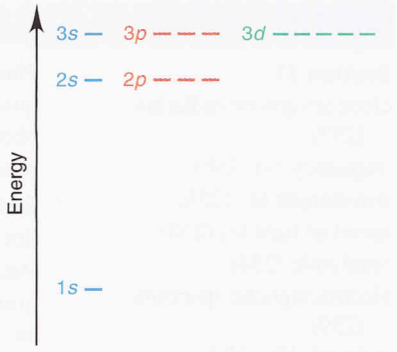

Figure 7.21 The energy levels in the H atom. In the H atom, the energy level depends only on the n value of the sublevels. For example, the $2s$ and the three $2p$ sublevels (shown as short lines) all have the same energy.

SECTION SUMMARY

The electron's wave function (ψ, atomic orbital) is a mathematical description of the electron's wavelike behavior in an atom. Each wave function is associated with one of the atom's allowed energy states. The probability density of finding the electron at a particular location is represented by ψ^2. An electron density diagram and a radial probability distribution plot show how the electron occupies the space near the nucleus for a particular energy level. Three features of an atomic orbital are described by quantum numbers: size (n), shape (l), and orientation (m_l). Orbitals with the same n and l values constitute a sublevel; sublevels with the same n value constitute an energy level. A sublevel with $l = 0$ has a spherical (s) orbital; a sublevel with $l = 1$ has three, two-lobed (p) orbitals; and a sublevel with $l = 2$ has five, four-lobed (d) orbitals. In the case of the H atom, the energy levels depend on the n value only.

Chapter Perspective

In this brief exploration of the origins of quantum physics, we see the everyday distinctions between matter and energy disappear and a new picture of the hydrogen atom gradually comes into focus. By the atom's very nature, however, this focus cannot be perfectly sharp. The sequel to these remarkable discoveries unfolds in Chapter 8, where we begin our discussion of how the periodic behavior of the elements emerges from the properties of the atom, which in turn arise from the electron occupancy of its orbitals.

For Review and Reference

(Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The wave characteristics of light (the interrelations of frequency, wavelength, and speed; the meaning of amplitude) and the general regions of the electromagnetic spectrum (7.1)
2. How particles and waves differ in terms of the phenomena of refraction, diffraction, and interference (7.1)
3. The quantization of energy and the fact that an atom changes its energy by emitting or absorbing quanta of radiation (7.1)
4. How the photon theory explains the photoelectric effect and the relation between photon absorbed and electron released (7.1)
5. How Bohr's theory explained the line spectra of the H atom; the importance of discrete atomic energy levels (7.2)
6. The wave-particle duality of matter and energy and the relevant theories and experiments that led to it (de Broglie wavelength, electron diffraction, photon momentum) (7.3)
7. The meaning of the uncertainty principle and how it limits our knowledge of electron properties (7.3)
8. The distinction between ψ (wave function, or atomic orbital) and ψ^2 (probability density) (7.4)
9. How electron density diagrams and radial probability distribution plots depict electron location within the atom (7.4)
10. The hierarchy of the quantum numbers that describe the size (n, energy), shape (l), and orientation (m_l) of an orbital (7.4)
11. The distinction between energy level (shell), sublevel (subshell), and orbital (7.4)
12. The shapes and nodes of s, p, and d orbitals (7.4)

Master These Skills

1. Interconverting wavelength and frequency (SP 7.1)
2. Calculating the energy of a photon from its frequency and/or wavelength (SP 7.2)
3. Applying de Broglie's equation to find the wavelength of a particle (SP 7.3)
4. Applying the uncertainty principle to see that the location and speed of a particle cannot be determined simultaneously (SP 7.4)
5. Determining quantum numbers and sublevel designations (SPs 7.5 to 7.7)

Key Equations and Relationships

7.1 Relating the speed of light to its frequency and wavelength (258):

$$c = \nu \times \lambda$$

7.2 Determining the smallest change in an atom's energy (262):

$$\Delta E = h\nu$$

7.3 Calculating the wavelength of any line in the H atom spectrum (Rydberg equation) (265):

$$\frac{1}{\lambda} = R\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right)$$

where n is a positive integer and $n_2 > n_1$

7.4 Finding the difference between two energy levels in the H atom (268):

$$\Delta E = E_{\text{final}} - E_{\text{initial}} = -2.18\times10^{-18}\ \text{J}\left(\frac{1}{n_{\text{final}}^2} - \frac{1}{n_{\text{initial}}^2}\right)$$

7.5 Calculating the wavelength of any moving particle (de Broglie wavelength) (272):

$$\lambda = \frac{h}{mu}$$

7.6 Finding the uncertainty in position or speed of a particle (Heisenberg uncertainty principle) (274):

$$\Delta x \cdot m\Delta u \geq \frac{h}{4\pi}$$

Brief Solutions to Follow-up Problems

7.1 $\lambda\ (\text{nm}) = \dfrac{3.00\times10^{8}\ \text{m/s}}{7.23\times10^{14}\ \text{s}^{-1}} \times \dfrac{10^{9}\ \text{nm}}{1\ \text{m}} = 415\ \text{nm}$

$$\lambda\ (\text{Å}) = 415\ \text{nm} \times \frac{10\ \text{Å}}{1\ \text{nm}} = 4150\ \text{Å}$$

7.2 UV: $E = hc/\lambda$

$$= \frac{(6.626\times10^{-34}\ \text{J·s})(3.00\times10^{8}\ \text{m/s})}{1\times10^{-8}\ \text{m}} = 2\times10^{-17}\ \text{J}$$

Visible: $E = 4\times10^{-19}$ J; IR: $E = 2\times10^{-21}$ J
As λ increases, E decreases.

7.3 $u = \dfrac{h}{m\lambda} = \dfrac{6.626\times10^{-34}\ \text{kg·m}^2/\text{s}}{(9.11\times10^{-31}\ \text{kg})\left(100\ \text{nm} \times \dfrac{1\ \text{m}}{10^{9}\ \text{nm}}\right)}$

$$= 7.27\times10^{3}\ \text{m/s}$$

7.4 $\Delta x \geq \dfrac{6.626\times10^{-34}\ \text{kg·m}^2/\text{s}}{4\pi(0.142\ \text{kg})(0.447\ \text{m/s})} \geq 8.31\times10^{-34}\ \text{m}$

7.5 $n = 4$, so $l = 0, 1, 2, 3$. In addition to the m_l values in Sample Problem 7.5, we have those for $l = 3$:

$$m_l = -3, -2, -1, 0, +1, +2, +3$$

7.6 For 2*p*: $n = 2$, $l = 1$, $m_l = -1, 0, +1$
For 5*f*: $n = 5$, $l = 3$, $m_l = -3, -2, -1, 0, +1, +2, +3$

7.7 (a) $n = 4$, $l = 1$; (b) name is 2*p*; (c) name is 3*d*;
(d) $n = 2$, $l = 0$, $m_l = 0$

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

The Nature of Light

(Sample Problems 7.1 and 7.2)

Concept Review Questions

7.1 In what ways are microwave and ultraviolet radiation the same? In what ways are they different?

7.2 Consider the following types of electromagnetic radiation:
(1) microwave (2) ultraviolet (3) radio waves
(4) infrared (5) x-ray (6) visible
(a) Arrange them in order of increasing wavelength.
(b) Arrange them in order of increasing frequency.
(c) Arrange them in order of increasing energy.

7.3 Define each of the following wave phenomena, and give an example of where each occurs: (a) refraction; (b) diffraction; (c) dispersion; (d) interference.

7.4 In the mid-17th century, Isaac Newton proposed that light existed as a stream of particles, and the wave-particle debate continued for over 250 years until Planck and Einstein presented their revolutionary ideas. Give two pieces of evidence for the wave model and two for the particle model.

7.5 What new idea about energy did Planck use to explain blackbody radiation?

7.6 What new idea about light did Einstein use to explain the photoelectric effect? Why does the photoelectric effect exhibit a threshold frequency? Why does it *not* exhibit a time lag?

Skill-Building Exercises *(grouped in similar pairs)*

7.7 An AM station broadcasts rock music at "960 on your radio dial." Units for AM frequencies are given in kilohertz (kHz). Find the wavelength of the station's radio waves in meters (m), nanometers (nm), and angstroms (Å).

7.8 An FM station broadcasts classical music at 93.5 MHz (megahertz, or 10^6 Hz). Find the wavelength (in m, nm, and Å) of these radio waves.

7.9 A radio wave has a frequency of 3.6×10^{10} Hz. What is the energy (in J) of one photon of this radiation?

7.10 An x-ray has a wavelength of 1.3 Å. Calculate the energy (in J) of one photon of this radiation.

7.11 Rank the following photons in terms of increasing energy: (a) blue (λ = 453 nm); (b) red (λ = 660 nm); (c) yellow (λ = 595 nm).

7.12 Rank the following photons in terms of decreasing energy: (a) IR ($\nu = 6.5\times10^{13}\ s^{-1}$); (b) microwave ($\nu = 9.8\times10^{11}\ s^{-1}$); (c) UV ($\nu = 8.0\times10^{15}\ s^{-1}$).

Problems in Context

7.13 Police often monitor traffic with "K-band" radar guns, which operate in the microwave region at 22.235 GHz (1 GHz = 10^9 Hz). Find the wavelength (in nm and Å) of this radiation.

7.14 Covalent bonds in a molecule absorb radiation in the IR region and vibrate at characteristic frequencies.
(a) The C—O bond in an organic compound absorbs radiation of wavelength 9.6 μm. What frequency (in s^{-1}) corresponds to that wavelength?
(b) The H—Cl bond has a frequency of vibration of 8.652×10^{13} Hz. What wavelength (in μm) corresponds to that frequency?

7.15 Cobalt-60 is a radioactive isotope used to treat cancers of the brain and other tissues. A gamma ray emitted by an atom of this isotope has an energy of 1.33 MeV (million electron volts; 1 eV = 1.602×10^{-19} J). What is the frequency (in Hz) and the wavelength (in m) of this gamma ray?

7.16 (a) The first step in the formation of ozone in the upper atmosphere occurs when oxygen molecules absorb UV radiation of wavelengths ≤ 242 nm. Calculate the frequency and energy of the least energetic of these photons.
(b) Ozone absorbs light having wavelengths of 2200 to 2900 Å, thus protecting organisms on Earth's surface from this high-energy UV radiation. What are the frequency and energy of the most energetic of these photons?

Atomic Spectra

Concept Review Questions

7.17 How is n_1 in the Rydberg equation (Equation 7.3) related to the quantum number n in the Bohr model?

7.18 How would a planetary (solar system) model of the atom differ from a key assumption in Bohr's model? What was the theoretical basis from which Bohr made this assumption?

7.19 Distinguish between an absorption spectrum and an emission spectrum. With which did Bohr work?

7.20 Which of these electron transitions correspond to absorption of energy and which to emission?
(a) $n = 2$ to $n = 4$ (b) $n = 3$ to $n = 1$
(c) $n = 5$ to $n = 2$ (d) $n = 3$ to $n = 4$

7.21 Why could the Bohr model not predict line spectra for atoms other than hydrogen?

7.22 The H atom and the Be^{3+} ion each have one electron. Does the Bohr model predict their spectra accurately? Would you expect their line spectra to be identical? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

7.23 Use the Rydberg equation (Equation 7.3) to calculate the wavelength (in nm) of the photon emitted when a hydrogen atom undergoes a transition from $n = 5$ to $n = 2$.

7.24 Use the Rydberg equation to calculate the wavelength (in Å) of the photon absorbed when a hydrogen atom undergoes a transition from $n = 1$ to $n = 3$.

7.25 What is the wavelength (in nm) of the least energetic spectral line in the infrared series of the H atom?

7.26 What is the wavelength (in nm) of the least energetic spectral line in the visible series of the H atom?

7.27 Calculate the energy difference (ΔE) for the transition in Problem 7.23 for 1 mol of H atoms.

7.28 Calculate the energy difference (ΔE) for the transition in Problem 7.24 for 1 mol of H atoms.

7.29 Arrange the following H atom electron transitions in order of *increasing* frequency of the photon absorbed or emitted:
(a) $n = 2$ to $n = 4$ (b) $n = 2$ to $n = 1$
(c) $n = 2$ to $n = 5$ (d) $n = 4$ to $n = 3$

7.30 Arrange the following H atom electron transitions in order of *decreasing* wavelength of the photon absorbed or emitted:
(a) $n = 2$ to $n = \infty$ (b) $n = 4$ to $n = 20$
(c) $n = 3$ to $n = 10$ (d) $n = 2$ to $n = 1$

7.31 The electron in a ground-state H atom absorbs a photon of wavelength 97.20 nm. To what energy level does the electron move?

7.32 An electron in the $n = 5$ level of an H atom emits a photon of wavelength 1281 nm. To what energy level does the electron move?

Problems in Context

7.33 In addition to continuous radiation, fluorescent lamps emit sharp lines in the visible region from a mercury discharge within the tube. Much of this light has a wavelength of 436 nm. What is the energy (in J) of one photon of this light?

7.34 The oxidizing agents that are used in most fireworks consist of potassium salts, such as $KClO_4$ or $KClO_3$, rather than the corresponding sodium salts. One of the problems with using sodium salts is their extremely intense yellow-orange emission at 589 nm, which obscures the other colors in the display. What is the energy (in J) of one photon of this light? What is the energy (in kJ) of 1 einstein of this light (1 einstein = 1 mol of photons)?

The Wave-Particle Duality of Matter and Energy

(Sample Problems 7.3 and 7.4)

Concept Review Questions

7.35 In what sense is the wave motion of a guitar string analogous to the motion of an electron in an atom?

7.36 What experimental support did de Broglie's concept receive?

7.37 If particles have wavelike motion, why don't we observe that motion in the macroscopic world?

7.38 Why can't we overcome the uncertainty predicted by Heisenberg's principle by building more precise devices to reduce the error in measurements below the $h/4\pi$ limit?

Skill-Building Exercises *(grouped in similar pairs)*

7.39 A 220-lb fullback runs the 40-yd dash at a speed of 19.6 ± 0.1 mi/h.
(a) What is his de Broglie wavelength (in meters)?
(b) What is the uncertainty in his position?

7.40 An alpha particle (mass = 6.6×10^{-24} g) emitted by radium travels at $3.4\times10^{7} \pm 0.1\times10^{7}$ mi/h.
(a) What is its de Broglie wavelength (in meters)?
(b) What is the uncertainty in its position?

7.41 How fast must a 56.5-g tennis ball travel in order to have a de Broglie wavelength that is equal to that of a photon of green light (5400 Å)?

7.42 How fast must a 142-g baseball travel in order to have a de Broglie wavelength that is equal to that of an x-ray photon with $\lambda = 100.$ pm?

7.43 A sodium flame has a characteristic yellow color due to emissions of wavelength 589 nm. What is the mass equivalence of one photon of this wavelength (1 J = 1 kg·m^2/s^2)?

7.44 A lithium flame has a characteristic red color due to emissions of wavelength 671 nm. What is the mass equivalence of 1 mol of photons of this wavelength (1 J = 1 kg·m^2/s^2)?

The Quantum-Mechanical Model of the Atom

(Sample Problems 7.5 to 7.7)

Concept Review Questions

7.45 What physical meaning is attributed to the square of the wave function, ψ^2?

7.46 Explain in your own words what the "electron density" in a particular tiny volume of space means.

7.47 Explain in your own words what it means for the peak in the radial probability distribution plot for the $n = 1$ level of a hydrogen atom to be at 0.529 Å. Is the probability of finding an electron at 0.529 Å from the nucleus greater for the 1*s* or the 2*s* orbital?

7.48 What feature of an orbital is related to each of the following quantum numbers?
(a) Principal quantum number (n)
(b) Angular momentum quantum number (l)
(c) Magnetic quantum number (m_l)

Skill-Building Exercises *(grouped in similar pairs)*

7.49 How many orbitals in an atom can have each of the following designations: (a) 1*s*; (b) 4*d*; (c) 3*p*; (d) $n = 3$?

7.50 How many orbitals in an atom can have each of the following designations: (a) 5*f*; (b) 4*p*; (c) 5*d*; (d) $n = 2$?

7.51 Give all possible m_l values for orbitals that have each of the following: (a) $l = 2$; (b) $n = 1$; (c) $n = 4$, $l = 3$.

7.52 Give all possible m_l values for orbitals that have each of the following: (a) $l = 3$; (b) $n = 2$; (c) $n = 6$, $l = 1$.

7.53 Draw 90% probability contours (with axes) for each of the following orbitals: (a) *s*; (b) p_x.

7.54 Draw 90% probability contours (with axes) for each of the following orbitals: (a) p_z; (b) d_{xy}.

7.55 For each of the following, give the sublevel designation, the allowable m_l values, and the number of orbitals:
(a) $n = 4$, $l = 2$ (b) $n = 5$, $l = 1$ (c) $n = 6$, $l = 3$

7.56 For each of the following, give the sublevel designation, the allowable m_l values, and the number of orbitals:
(a) $n = 2$, $l = 0$ (b) $n = 3$, $l = 2$ (c) $n = 5$, $l = 1$

7.57 For each of the following sublevels, give the n and l values and the number of orbitals: (a) 5*s*; (b) 3*p*; (c) 4*f*.

7.58 For each of the following sublevels, give the n and l values and the number of orbitals: (a) 6*g*; (b) 4*s*; (c) 3*d*.

7.59 Are the following quantum number combinations allowed? If not, show two ways to correct them:
(a) $n = 2$; $l = 0$; $m_l = -1$ (b) $n = 4$; $l = 3$; $m_l = -1$
(c) $n = 3$; $l = 1$; $m_l = 0$ (d) $n = 5$; $l = 2$; $m_l = +3$

7.60 Are the following quantum number combinations allowed? If not, show two ways to correct them:
(a) $n = 1$; $l = 0$; $m_l = 0$ (b) $n = 2$; $l = 2$; $m_l = +1$
(c) $n = 7$; $l = 1$; $m_l = +2$ (d) $n = 3$; $l = 1$; $m_l = -2$

Comprehensive Problems

7.61 The orange pigment in carrots and orange peel is mostly β-carotene, an organic compound that is insoluble in water but very soluble in benzene and chloroform. Describe an experimental method for determining the concentration of β-carotene in the oil expressed from orange peel.

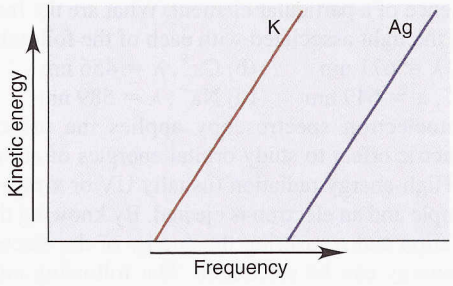
7.62 The quantum-mechanical treatment of the hydrogen atom gives the energy, E, of the electron as a function of the principal quantum number, n:

$$E = -\frac{h^2}{8\pi^2 m_e a_0^2 n^2} \qquad (n = 1, 2, 3, \ldots)$$

where h is Planck's constant, m_e is the electron mass, and a_0 is 52.92×10^{-12} m.

(a) Write the expression in the form $E = -(\text{constant})\frac{1}{n^2}$, evaluate the constant (in J), and compare it with the corresponding expression from Bohr's theory.
(b) Use the expression to find ΔE between $n = 2$ and $n = 3$.
(c) Calculate the wavelength of the photon that corresponds to this energy change. Is this photon seen in the hydrogen spectrum obtained from experiment (see Figure 7.8, p. 264)?

7.63 The photoelectric effect is illustrated in a plot of the kinetic energies of electrons ejected from the surface of potassium metal or silver metal at different frequencies of incident light.



(a) Why don't the lines begin at the origin?
(b) Why don't the lines begin at the same point?
(c) From which metal will light of a shorter wavelength eject an electron?
(d) Why are the slopes of the lines equal?

7.64 The human eye is a complex sensing device for visible light. The optic nerve needs a minimum of 2.0×10^{-17} J of energy to trigger a series of impulses that eventually reach the brain.
(a) How many photons of red light (700. nm) are needed?
(b) How many photons of blue light (475 nm)?

7.65 One reason carbon monoxide (CO) is toxic is that it binds to the blood protein hemoglobin more strongly than oxygen does. The bond between hemoglobin and CO absorbs radiation of 1953 cm^{-1}. (The units are the reciprocal of the wavelength in centimeters.) Calculate the wavelength (in nm and Å) and the frequency (in Hz) of the absorbed radiation.

7.66 A metal ion M^{n+} has a single electron. The highest energy line in its emission spectrum occurs at a frequency of 2.961×10^{16} Hz. Identify the ion.

7.67 TV and radio stations transmit in specific frequency bands of the radio region of the electromagnetic spectrum.
(a) TV channels 2 to 13 (VHF) broadcast signals between the frequencies of 59.5 and 215.8 MHz, whereas FM radio stations broadcast signals with wavelengths between 2.78 and 3.41 m. Do these bands of signals overlap?
(b) AM radio signals have frequencies between 550 and 1600 kHz. Which has a broader transmission band, AM or FM?

7.68 Compare the wavelengths of an electron (mass = 9.11×10^{-31} kg) and a proton (mass = 1.67×10^{-27} kg), each having (a) a speed of 3.0×10^{6} m/s; (b) a kinetic energy of 2.5×10^{-15} J.

7.69 Five lines in the H atom spectrum have wavelengths (in Å): (a) 1212.7; (b) 4340.5; (c) 4861.3; (d) 6562.8; (e) 10938. Three lines result from transitions to $n_{final} = 2$ (visible series). The other two result from transitions in different series, one with $n_{final} = 1$ and the other with $n_{final} = 3$. Identify $n_{initial}$ for each line.

7.70 In his explanation of the threshold frequency in the photoelectric effect, Einstein reasoned that the absorbed photon must have the minimum energy required to dislodge an electron from the metal surface. This energy is called the *work function* (ϕ) of that metal. What is the longest wavelength of radiation (in nm) that could cause the photoelectric effect in each of these metals?
(a) Calcium, $\phi = 4.60\times10^{-19}$ J
(b) Titanium, $\phi = 6.94\times10^{-19}$ J
(c) Sodium, $\phi = 4.41\times10^{-19}$ J

7.71 You have three metal samples—A, B, and C—that are tantalum (Ta), barium (Ba), and tungsten (W), but you don't know which is which. Metal A emits electrons in response to visible light; metals B and C require UV light. (a) Identify metal A, and find the longest wavelength that removes an electron. (b) What range of wavelengths would distinguish B and C? [The work functions are Ta (6.81×10^{-19} J), Ba (4.30×10^{-19} J), and W (7.16×10^{-19} J); work function is explained in Problem 7.70.]

7.72 Refractometry is an analytical method based on the difference between the speed of light as it travels through a substance (v) and its speed in a vacuum (c). In the procedure, light of known wavelength passes through a fixed thickness of the substance at a known temperature. The index of refraction equals c/v. Using yellow light ($\lambda = 589$ nm) at 20°C, for example, the index of refraction of water is 1.33 and that of diamond is 2.42. Calculate the speed of light in (a) water and (b) diamond.

7.73 A laser (*l*ight *a*mplification by *s*timulated *e*mission of *r*adiation) provides a coherent (in-phase) nearly monochromatic source of high-intensity light. Lasers are used in eye surgery, CD/DVD players, basic research, etc. Some modern dye lasers can be "tuned" to emit a desired wavelength. Fill in the blanks in the following table of the properties of some common lasers:

Type	λ (nm)	ν (s^{-1})	E (J)	Color
He-Ne	632.8	?	?	?
Ar	?	6.148×10^{14}	?	?
Ar-Kr	?	?	3.499×10^{-19}	?
Dye	663.7	?	?	?

7.74 As space exploration increases, means of communication with humans and probes on other planets are being developed. (a) How much time (in s) does it take for a radio wave of frequency 8.93×10^{7} s^{-1} to reach Mars, which is 8.1×10^{7} km from Earth? (b) If it takes this radiation 1.2 s to reach the Moon, how far (in m) is the Moon from Earth?

7.75 The following quantum number combinations are not allowed. Assuming the n and m_l values are correct, change the l value to create an allowable combination:
(a) $n = 3$; $l = 0$; $m_l = -1$ (b) $n = 3$; $l = 3$; $m_l = +1$
(c) $n = 7$; $l = 2$; $m_l = +3$ (d) $n = 4$; $l = 1$; $m_l = -2$

7.76 A ground-state H atom absorbs a photon of wavelength 94.91 nm, and its electron attains a higher energy level. The atom then emits two photons: one of wavelength 1281 nm to reach an intermediate level, and a second to reach the ground state.
(a) What higher level did the electron reach?
(b) What intermediate level did the electron reach?
(c) What was the wavelength of the second photon emitted?

7.77 Consider these ground-state ionization energies of one-electron species:

$$H = 1.31\times10^{3}\ \text{kJ/mol}$$
$$He^{+} = 5.24\times10^{3}\ \text{kJ/mol}$$
$$Li^{2+} = 1.18\times10^{4}\ \text{kJ/mol}$$

(a) Write a general expression for the ionization energy of any one-electron species. (b) Use your expression to calculate the ionization energy of B^{4+}. (c) What is the minimum wavelength required to remove the electron from the $n = 3$ level of He^{+}? (d) What is the minimum wavelength required to remove the electron from the $n = 2$ level of Be^{3+}?

7.78 Why do the spaces between spectral lines within a series decrease as the wavelength becomes shorter?

7.79 In the course of developing his model, Bohr arrived at the following formula for the radius of the electron's orbit: $r_n = n^2h^2\epsilon_0/\pi m_e e^2$, where m_e is the electron mass, e is its charge, and ϵ_0 is a constant related to charge attraction in a vacuum. Given that $m_e = 9.109\times10^{-31}$ kg, $e = 1.602\times10^{-19}$ C, and $\epsilon_0 = 8.854\times10^{-12}\ C^2/J\cdot m$, calculate the following:

(a) The radius of the 1st ($n = 1$) orbit in the H atom

(b) The radius of the 10th ($n = 10$) orbit in the H atom

7.80 (a) Calculate the Bohr radius of an electron in the $n = 3$ orbit of a hydrogen atom. (See Problem 7.79.)

(b) What is the energy (in J) of the atom in part (a)?

(c) What is the energy of an Li^{2+} ion when its electron is in the $n = 3$ orbit?

(d) Why are the answers to parts (b) and (c) different?

7.81 Enormous numbers of microwave photons are needed to warm macroscopic samples of matter. A portion of soup containing 252 g of water is heated in a microwave oven from 20.°C to 98°C, with radiation of wavelength 1.55×10^{-2} m. How many photons are absorbed by the water in the soup?

7.82 The quantum-mechanical treatment of the hydrogen atom gives an expression for the wave function, ψ, of the 1*s* orbital:

$$\psi = \frac{1}{\sqrt{\pi}}\left(\frac{1}{a_0}\right)^{3/2} e^{-r/a_0}$$

where r is the distance from the nucleus and a_0 is 52.92 pm. The electron probability density is the probability of finding the electron in a tiny volume at distance r from the nucleus and is proportional to ψ^2. The radial probability distribution is the total probability of finding the electron at all points at distance r from the nucleus and is proportional to $4\pi r^2\psi^2$. Calculate the values (to three significant figures) of ψ, ψ^2, and $4\pi r^2\psi^2$ to fill in the following table, and sketch plots of these quantities versus r. Compare the latter two plots with those in Figure 7.17A, p. 280:

r (pm)	ψ ($pm^{-3/2}$)	ψ^2 (pm^{-3})	$4\pi r^2\psi^2$ (pm^{-1})
0			
50			
100			
200			

7.83 Lines in one spectral series can overlap lines in another.

(a) Use the Rydberg equation to show whether the range of wavelengths in the $n_1 = 1$ series overlaps with the range in the $n_1 = 2$ series.

(b) Use the Rydberg equation to show whether the range of wavelengths in the $n_1 = 3$ series overlaps with the range in the $n_1 = 4$ series.

(c) How many lines in the $n_1 = 4$ series lie in the range of the $n_1 = 5$ series?

(d) What does this overlap imply about the hydrogen spectrum at longer wavelengths?

7.84 The following values are the only allowable energy levels of a hypothetical one-electron atom:

$$E_6 = -2\times10^{-19}\ J \qquad E_5 = -7\times10^{-19}\ J$$
$$E_4 = -11\times10^{-19}\ J \qquad E_3 = -15\times10^{-19}\ J$$
$$E_2 = -17\times10^{-19}\ J \qquad E_1 = -20\times10^{-19}\ J$$

(a) If the electron were in the $n = 3$ level, what would be the highest frequency (and minimum wavelength) of radiation that could be emitted?

(b) What is the ionization energy (in kJ/mol) of the atom in its ground state?

(c) If the electron were in the $n = 4$ level, what would be the shortest wavelength (in nm) of radiation that could be absorbed without causing ionization?

7.85 In fireworks displays, light of a given wavelength indicates the presence of a particular element. What are the frequency and color of the light associated with each of the following?

(a) Li^{+}, $\lambda = 671$ nm (b) Cs^{+}, $\lambda = 456$ nm

(c) Ca^{2+}, $\lambda = 649$ nm (d) Na^{+}, $\lambda = 589$ nm

7.86 Photoelectron spectroscopy applies the principle of the photoelectric effect to study orbital energies of atoms and molecules. High-energy radiation (usually UV or x-ray) is absorbed by a sample and an electron is ejected. By knowing the energy of the radiation and measuring the energy of the electron lost, the orbital energy can be calculated. The following energy differences were determined for several electron transitions:

$$\Delta E_{2\longrightarrow1} = 4.088\times10^{-17}\ J$$
$$\Delta E_{3\longrightarrow1} = 4.844\times10^{-17}\ J$$
$$\Delta E_{5\longrightarrow1} = 5.232\times10^{-17}\ J$$
$$\Delta E_{4\longrightarrow2} = 1.022\times10^{-17}\ J$$

Calculate the energy change and the wavelength of a photon emitted in the following transitions.

(a) Level 3 $\longrightarrow$ 2 (b) Level 4 $\longrightarrow$ 1 (c) Level 5 $\longrightarrow$ 4

7.87 Visible light provides green plants with the energy needed to drive photosynthesis. Horticulturists know that, for many plants, leaf color depends on how brightly lit the growing area is: dark green leaves are associated with low light levels, and pale green with high levels. (a) Use the photon theory of light to explain why a plant adapts this way. (b) What change in leaf composition might account for this behavior?

7.88 In compliance with conservation of energy, Einstein explained that in the photoelectric effect, the energy of a photon ($h\nu$) absorbed by a metal is the sum of the work function (ϕ), the minimum energy needed to dislodge an electron from the metal's surface, and the kinetic energy (E_k) of the electron: $h\nu = \phi + E_k$. When light of wavelength 358.1 nm falls on the surface of potassium metal, the speed (u) of the dislodged electron is 6.40×10^{5} m/s.

(a) What is E_k ($\frac{1}{2}mu^2$) of the dislodged electron?

(b) What is ϕ (in J) of potassium?

7.89 An electron microscope focuses electrons through magnetic lenses to observe objects at higher magnification than is possible with a light microscope. For any microscope, the smallest object that can be observed is one-half the wavelength of the light used. Thus, for example, the smallest object that can be observed with

light of 400 nm is 2×10^{-7} m. (a) What is the smallest object observable with an electron microscope using electrons moving at 5.5×10^{4} m/s? (b) At 3.0×10^{7} m/s?

7.90 In a typical fireworks device, the heat of the reaction between a strong oxidizing agent, such as $KClO_4$, and an organic compound excites certain salts, which emit specific colors. Strontium salts have an intense emission at 641 nm, and barium salts have one at 493 nm. (a) What colors do these emissions produce? (b) What is the energy (in kJ) of these emissions for 1.00 g each of the chloride salts of Sr and Ba? (Assume that all the heat released is converted to light emitted.)

7.91 Atomic hydrogen produces well-known series of spectral lines in several regions of the electromagnetic spectrum. Each series fits the Rydberg equation with its own particular n_1 value. Calculate the value of n_1 (by trial and error if necessary) that would produce a series of lines in which:
(a) The *highest* energy line has a wavelength of 3282 nm.
(b) The *lowest* energy line has a wavelength of 7460 nm.

7.92 Fish-liver oil is a good source of vitamin A, which is measured spectrophotometrically at a wavelength of 329 nm.
(a) Suggest a reason for using this wavelength.
(b) In what region of the spectrum does this wavelength lie?
(c) When 0.1232 g of fish-liver oil is dissolved in 500. mL of solvent, the absorbance is 0.724 units. When 1.67×10^{-3} g of vitamin A is dissolved in 250. mL of solvent, the absorbance is 1.018 units. Calculate the vitamin A concentration in the fish-liver oil.

7.93 Many calculators use photocells to provide their energy. Find the maximum wavelength needed to remove an electron from silver ($\phi = 7.59\times10^{-19}$ J). Is silver a good choice for a photocell that uses visible light?

7.94 As the uses of aluminum have become widespread, many methods have been developed to measure concentrations of its complexes in solution. In one method, the sodium salt of 2-quinizarinsulfonic acid forms a complex with Al^{3+} that absorbs strongly at 560 nm.
(a) Use the data below to draw a plot of absorbance vs. concentration of a complex in solution and find the slope and *y*-intercept:

Concentration (*M*)	Absorbance (560 nm)
1.0×10^{-5}	0.131
1.5×10^{-5}	0.201
2.0×10^{-5}	0.265
2.5×10^{-5}	0.329
3.0×10^{-5}	0.396

(b) When 20.0 mL of this complex solution is diluted with water to 150. mL, its absorbance is 0.236. Find the concentrations of the diluted solution and of the original solution.

7.95 In a game of "Clue," Ms. White is killed in the conservatory. You have a device in each room to help you find the murderer—a spectrometer that emits the entire visible spectrum to indicate who is in that room. For example, if someone wearing yellow is in a room, light at 580 nm is reflected. The suspects are Col. Mustard, Prof. Plum, Mr. Green, Ms. Peacock (blue), and Ms. Scarlet. At the time of the murder, the spectrometer in the dining room recorded a reflection at 520 nm, those in the lounge and study recorded reflections of lower frequencies, and the one in the library recorded a reflection of the shortest possible wavelength. Who killed Ms. White? Explain.

7.96 Technetium (Tc; $Z = 43$) is a synthetic element used as a radioactive tracer in medical studies. A Tc atom emits a beta particle (electron) with a kinetic energy (E_k) of 4.71×10^{-15} J. What is the de Broglie wavelength of this electron ($E_k = \frac{1}{2}mv^2$)?

7.97 Electric power is typically stated in units of watts (1 W = 1 J/s). About 95% of the power output of an incandescent bulb is converted to heat and 5% to light. If 10% of that light shines on your chemistry text, how many photons per second shine on the book from a 75-W bulb? (Assume the photons have a wavelength of 550 nm.)

7.98 The flame test for sodium is based on its intense emission at 589 nm, and the test for potassium is based on its emission at 404 nm. When both elements are present, the Na^+ emission is so strong that the K^+ emission can't be seen, except by looking through a cobalt-glass filter. (a) What are the colors of these Na^+ and K^+ emissions? (b) What does the cobalt-glass filter do?

7.99 The net change in the multistep biochemical process of photosynthesis is that CO_2 and H_2O form glucose ($C_6H_{12}O_6$) and O_2. Chlorophyll absorbs light in the 600 to 700 nm region. (a) Write a balanced thermochemical equation for formation of 1.00 mol of glucose. (b) What is the minimum number of photons with $\lambda = 680.$ nm needed to prepare 1.00 mol of glucose?

7.100 Only certain electron transitions are allowed from one energy level to another. In one-electron species, the change in the quantum number l of an allowed transition must be ±1. For example, a 3*p* electron can drop directly to a 2*s* orbital but not to a 2*p*. Thus, in the UV series, where $n_{final} = 1$, allowed electron transitions can start in a *p* orbital ($l = 1$) of $n = 2$ or higher, not in an *s* ($l = 0$) or *d* ($l = 2$) orbital of $n = 2$ or higher. From what orbital do each of the allowed electron transitions start for the first four emission lines in the visible series ($n_{final} = 2$)?

7.101 The discharge of phosphate compounds in detergents into the environment has led to serious imbalances in the natural life cycle of freshwater lakes. A chemist studying water pollution used a spectrophotometric method to measure total phosphate and obtained the following data for known standards:

Absorbance (400 nm)	Concentration (mol/L)
0	0.0
0.10	2.5×10^{-5}
0.16	3.2×10^{-5}
0.20	4.4×10^{-5}
0.25	5.6×10^{-5}
0.38	8.4×10^{-5}
0.48	10.5×10^{-5}
0.62	13.8×10^{-5}
0.76	17.0×10^{-5}
0.88	19.4×10^{-5}

(a) Draw a curve of absorbance vs. phosphate concentration.
(b) If a sample of lake water has an absorbance of 0.55, what is its phosphate concentration?

Remarkable Regularity In the regularity of an eclipse, a heartbeat, or the plumage of a peacock, nature exhibits predictably recurring patterns. The arrangement of electrons in atoms recurs periodically, too. As you'll see, this periodicity allows us to predict many properties of the elements, including much of their physical and chemical behavior.

- Trends in Electron Affinity

8.5 **Atomic Structure and Chemical Reactivity**
- Trends in Metallic Behavior
- Properties of Monatomic Ions

In Chapter 7, you saw how an outpouring of scientific creativity by early 20th-century physicists led to a new understanding of matter and energy, which in turn led to the quantum-mechanical model of the atom. But you can be sure that late 19th-century chemists were not sitting idly by, waiting for their colleagues in physics to develop that model. They were exploring the nature of electrolytes, establishing the kinetic-molecular theory, and developing chemical thermodynamics. The fields of organic chemistry and biochemistry were born, as were the fertilizer, explosives, glassmaking, soapmaking, bleaching, and dyestuff industries. And, for the first time, chemistry became a university subject in Europe and America. Superimposed on this activity was the accumulation of an enormous body of facts about the elements, which became organized into the periodic table.

The goal of this chapter is to show how the organization of the table, condensed from countless hours of laboratory work, was explained perfectly by the new quantum-mechanical atomic model. This model answers one of the central questions in chemistry: why do the elements behave as they do? Or, rephrasing the question to fit the main topic of this chapter: how does the **electron configuration** of an element—*the distribution of electrons within the orbitals of its atoms*—relate to its chemical and physical properties?

IN THIS CHAPTER . . . We first discuss the origin of the periodic table. Then we extend the quantum-mechanical model (Chapter 7) to many-electron atoms (those with more than one electron) to define a unique set of quantum numbers for each electron in the atoms of every element. Electrostatic effects lead to the order in which orbitals fill with electrons, and we'll see how that order correlates with the order of elements in the periodic table. We discuss how electron configuration and nuclear charge lead to periodic trends in atomic properties and how these trends account for the patterns of chemical reactivity. Finally, we apply these ideas to the properties of metals, nonmetals, and their ions.

Concepts & Skills to Review

before you study this chapter

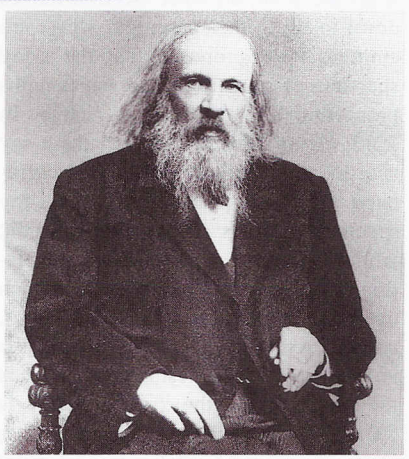
- format of the periodic table (Section 2.6)
- characteristics of metals and nonmetals (Section 2.6)
- application of Coulomb's law to electrostatic attraction (Section 2.7)
- characteristics of acids and bases (Section 4.4)
- rules for assigning quantum numbers (Section 7.4)

8.1 DEVELOPMENT OF THE PERIODIC TABLE

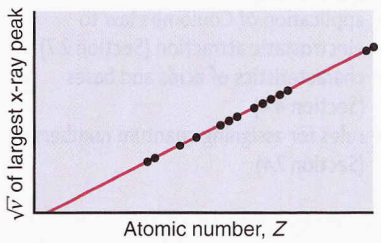
An essential requirement for the amazing growth in theoretical and practical chemistry in the second half of the 19th century was the ability to organize the facts known about element behavior. The earliest organizing attempt was made by Johann Döbereiner, who placed groups of three elements with similar properties, such as calcium, strontium, and barium, into "triads." Later, John Newlands noted similarities between every eighth element (arranged by atomic mass), like the similarity between every eighth note in the musical scale, and placed elements into "octaves." As more elements were discovered, however, these early numerical schemes lost much of their validity.

In Chapter 2, you saw that the most successful organizing scheme was made by the Russian chemist Dmitri Mendeleev. In 1870, he arranged the 65 elements then known into a *periodic table* and summarized their behavior in the **periodic law:** when arranged by atomic mass, the elements exhibit a periodic recurrence of similar properties. It is a curious quirk of history that Mendeleev and the German chemist Julius Lothar Meyer arrived at virtually the same organization simultaneously, yet independently. Mendeleev focused on chemical properties and Meyer on physical properties. The greater credit has gone to Mendeleev because he was able to *predict* the properties of several as-yet-undiscovered elements, for which he had left blank spaces in his table. Table 8.1 (on the next page) compares the actual properties of germanium, which Mendeleev gave the provisional name "eka silicon" ("first under silicon"), with his predictions for it.

Today's periodic table, which appears on the inside front cover of the text, resembles Mendeleev's in most details, although it includes 49 elements that were unknown in 1870. The only substantive change is that the elements are now arranged in order of *atomic number* (number of protons) rather than atomic mass.



Mendeleev's Great Contribution Born in a small Siberian town, Dmitri Ivanovich Mendeleev was the youngest of 17 children of the local schoolteacher. He showed early talent for mathematics and science, so his mother took him to St. Petersburg, where he remained to study and work for much of his life. Early research interests centered on the physical properties of gases and liquids, and later he was consulted frequently on the industrial processing of petroleum. In developing his periodic table, he prepared a note card on the properties of each element and arranged and rearranged them until he realized that properties repeated when the elements were placed in order of increasing atomic mass.



Moseley and Atomic Number When a metal is bombarded with high-energy electrons, an inner electron is knocked from the atom, an outer electron moves down to fill in the space, and x-rays are emitted. Bohr proposed that the x-ray spectrum of an element had wavelengths proportional to the nuclear charge. In 1913, Henry Moseley studied the x-ray spectra of a series of metals and correlated the largest peak in a metal's x-ray spectrum with its order in the periodic table (its *atomic number*). This correlation is known as *Moseley's law,* which may be expressed as $\nu^{1/2} = K(Z - \sigma)$, where Z represents the atomic number, σ is 1 for electrons nearest the nucleus, ν is the frequency of the x-rays, and K is $5.0\times10^7\ s^{-1}$. He showed that the nuclear charge increased by 1 for each element (see the graph). Among other results, the findings confirmed the placement of Co ($Z = 27$) *before* Ni ($Z = 28$), despite cobalt's higher atomic mass, and also confirmed that the gap between Cl ($Z = 17$) and K ($Z = 19$) is the place for Ar ($Z = 18$). Tragically, Moseley died in 1915 at the age of 26 while serving as a pilot in the British army during World War I.

Table 8.1 Mendeleev's Predicted Properties of Germanium ("eka Silicon") and Its Actual Properties

Property	Predicted Properties of eka Silicon (E)	Actual Properties of Germanium (Ge)
Atomic mass	72 amu	72.61 amu
Appearance	Gray metal	Gray metal
Density	5.5 g/cm^3	5.32 g/cm^3
Molar volume	13 cm^3/mol	13.65 cm^3/mol
Specific heat capacity	0.31 J/g·K	0.32 J/g·K
Oxide formula	EO_2	GeO_2
Oxide density	4.7 g/cm^3	4.23 g/cm^3
Sulfide formula and solubility	ES_2; insoluble in H_2O; soluble in aqueous $(NH_4)_2S$	GeS_2; insoluble in H_2O; soluble in aqueous $(NH_4)_2S$
Chloride formula (boiling point)	ECl_4 (<100°C)	$GeCl_4$ (84°C)
Chloride density	1.9 g/cm^3	1.844 g/cm^3
Element preparation	Reduction of K_2EF_6 with sodium	Reduction of K_2GeF_6 with sodium

This change was based on the work of the British physicist Henry G. J. Moseley, who found a direct dependence between an element's nuclear charge and its position in the periodic table.

8.2 CHARACTERISTICS OF MANY-ELECTRON ATOMS

Like the Bohr model, the Schrödinger equation does not give *exact* solutions for many-electron atoms. However, unlike the Bohr model, the Schrödinger equation gives very good *approximate* solutions. These solutions show that the atomic orbitals of many-electron atoms are *hydrogen-like;* that is, they resemble those of the H atom. This conclusion means we can use the same quantum numbers that we used for the H atom to describe the orbitals of other atoms.

Nevertheless, the existence of more than one electron in an atom requires us to consider three features that were not relevant in the case of hydrogen: (1) the need for a fourth quantum number, (2) a limit on the number of electrons allowed in a given orbital, and (3) a more complex set of orbital energy levels. Let's examine these new features and then go on to determine the electron configuration for each element.

The Electron-Spin Quantum Number

Recall from Chapter 7 that the three quantum numbers n, l, and m_l describe the size (energy), shape, and orientation, respectively, of an atomic orbital. However, an additional quantum number is needed to describe a property of the electron itself, called *spin,* which is not a property of the orbital. Electron spin becomes important when more than one electron is present.

When a beam of H atoms passes through a nonuniform magnetic field, as shown in Figure 8.1, it splits into two beams that bend away from each other. The explanation of the split beam is that the electron generates a tiny magnetic field, as though it were a spinning charge. The single electron in each H atom can have one of two possible values of *spin*, each of which generates a tiny magnetic field. These two fields have opposing directions, so half of the electrons are attracted into the large external magnetic field and the other half are repelled by it. As a result, the beam of H atoms splits.

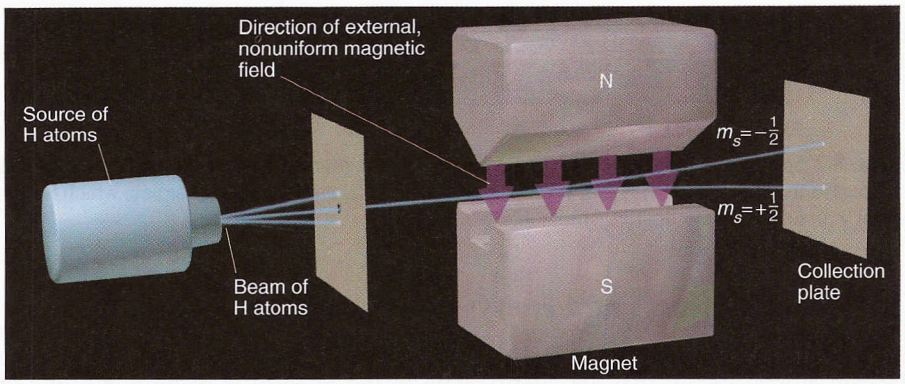


Figure 8.1 Observing the effect of electron spin. A nonuniform magnetic field, created by magnet faces with different shapes, splits a beam of hydrogen atoms in two. The split beam results from the two possible values of electron spin within each atom.

Like its charge, spin is an intrinsic property of the electron, and the **spin quantum number (m_s)** has values of either $+\frac{1}{2}$ or $-\frac{1}{2}$. Thus, *each electron in an atom is described completely by a set of **four** quantum numbers: the first three describe its orbital, and the fourth describes its spin.* The quantum numbers are summarized in Table 8.2.

Table 8.2 Summary of Quantum Numbers of Electrons in Atoms

Name	Symbol	Permitted Values	Property
Principal	n	Positive integers (1, 2, 3, ...)	Orbital energy (size)
Angular momentum	l	Integers from 0 to $n - 1$	Orbital shape (The l values 0, 1, 2, and 3 correspond to s, p, d, and f orbitals, respectively.)
Magnetic	m_l	Integers from $-l$ to 0 to $+l$	Orbital orientation
Spin	m_s	$+\frac{1}{2}$ or $-\frac{1}{2}$	Direction of e^- spin

Now we can write a set of four quantum numbers for any electron in the ground state of any atom. For example, the set of quantum numbers for the lone electron in hydrogen (H; $Z = 1$) is $n = 1$, $l = 0$, $m_l = 0$, and $m_s = +\frac{1}{2}$. (The spin quantum number for this electron could just as well have been $-\frac{1}{2}$, but by convention, we assign $+\frac{1}{2}$ for the first electron in an orbital.)

The Exclusion Principle

The element after hydrogen is helium (He; $Z = 2$), the first with atoms having more than one electron. The first electron in the He ground state has the same set of quantum numbers as the electron in the H atom, but the second He electron does not. Based on observations of the excited states of atoms, the Austrian physicist Wolfgang Pauli formulated the **exclusion principle:** *no two electrons in the same atom can have the same four quantum numbers.* That is, each electron must have a unique "identity" as expressed by its set of quantum numbers. Therefore, the second He electron occupies the same orbital as the first but has an opposite spin: $n = 1$, $l = 0$, $m_l = 0$, and $m_s = -\frac{1}{2}$.

Because the spin quantum number (m_s) can have only two values, the major consequence of the exclusion principle is that *an atomic orbital can hold a maximum of two electrons and they must have opposing spins.* We say that the 1*s* orbital in He is *filled* and that the electrons have *paired spins.* Thus, a beam of He atoms is not split in an experiment like that in Figure 8.1.

Baseball Quantum Numbers The unique set of quantum numbers that describes an electron is analogous to the unique location of a box seat at a baseball game. The stadium (atom) is divided into section (n, level), box (l, sublevel), row (m_l, orbital), and seat (m_s, spin). Only one person (electron) can have this particular set of stadium "quantum numbers."

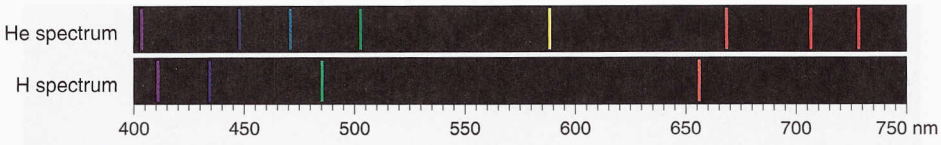

Figure 8.2 Spectral evidence of energy-level splitting in many-electron atoms. More spectral lines for He than for H indicates that an He atom has more available orbital energies, which is consistent with energy levels splitting into sublevels.

Electrostatic Effects and Energy-Level Splitting

Electrostatic effects play a major role in determining the energy states of many-electron atoms. Recall that the energy state of the H atom is determined *only* by the n value of the occupied orbital. In other words, in the H atom, all sublevels of a given level, such as the $2s$ and $2p$, have the same energy. The reason is that the only electrostatic interaction is the attraction between nucleus and electron. On the other hand, the energy states of many-electron atoms arise not only from nucleus-electron attractions, but also electron-electron repulsions. One major consequence of these additional interactions is *the splitting of energy levels into sublevels of differing energies: the energy of an orbital in a many-electron atom depends mostly on its n value (size) and to a lesser extent on its l value (shape).*

Thus, a more complex set of energy states exists for a many-electron atom than we saw in the H atom, and evidence for this appears in the more complex line spectra of many-electron atoms. Figure 8.2 shows that even though helium has only one more electron than hydrogen, it displays many more spectral lines, indicating more available orbital energies in its excited states.

Our first encounter with energy-level splitting in ground-state configurations occurs with lithium (Li; $Z = 3$). By definition, *the electrons of an atom in its ground state occupy the orbitals of lowest energy,* so the first two electrons in the ground state of Li fill its $1s$ orbital. Then, the third Li electron must go into the $n = 2$ level. But, this level has $2s$ *and* $2p$ sublevels: which has lower energy, that is, which does Li's third electron enter? As you'll see, the $2s$ is lower in energy than the $2p$. The reasons for this energy difference are based on three factors—*nuclear charge, electron repulsions,* and *orbital shape* (more specifically, radial probability distribution). Their interplay leads to the phenomena of *shielding* and *penetration*, which occur in all the atoms in the periodic table—except hydrogen.

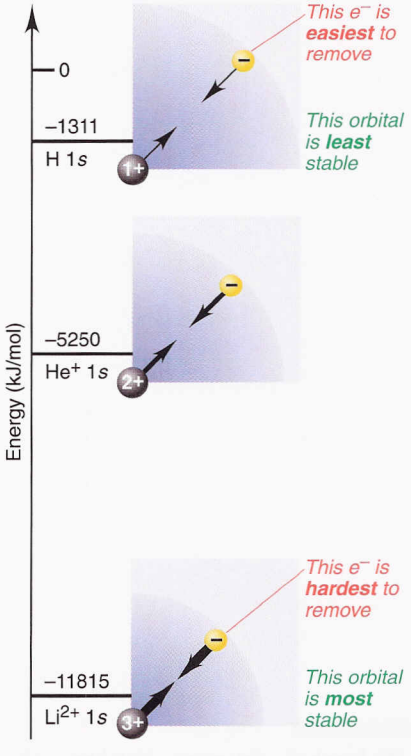

Figure 8.3 The effect of nuclear charge on orbital energy. Greater nuclear charge lowers orbital energy (more negative number), which makes the electron harder to remove. (Recall that an atom's energy is *defined* as negative.) In these one-electron species, the absolute value of the $1s$ orbital energy is related directly to Z^2: He^+ ($Z = 2$) is about 4 times H ($Z = 1$), and Li^{2+} ($Z = 3$) is about 9 times H.

The Effect of Nuclear Charge (Z) on Orbital Energy Nuclear protons create an ever-present pull on the electrons. You know that higher charges attract each other more strongly than lower charges (Coulomb's law, Section 2.7). Therefore, *higher nuclear charge lowers orbital energy (stabilizes the system) by increasing nucleus-electron attractions.* We can see this effect clearly by comparing the $1s$ orbital energies of the H atom ($Z = 1$), He^+ ion ($Z = 2$), and Li^{2+} ion ($Z = 3$). As Figure 8.3 shows, the H $1s$ orbital is the least stable (highest energy), so the least energy is needed to remove its electron; and the Li^{2+} $1s$ orbital is the most stable, so the most energy is needed to remove its electron.

Shielding: The Effect of Electron Repulsions on Orbital Energy In many-electron atoms, each electron "feels" not only the attraction to the nucleus but also the repulsion from other electrons. This repulsion counteracts the nuclear attraction somewhat, making each electron easier to remove by, in effect, helping to push it away. We speak of each electron "shielding" the other electrons somewhat from the nucleus. This **shielding** (also called *screening*) reduces the full nuclear charge to an **effective nuclear charge (Z_{eff}),** *the nuclear charge an electron actually experiences, thus making it easier to remove.* We see the effect of shielding by electrons in the *same* orbital when we compare the He atom and He^+ ion: both have a 2+ nuclear charge, but He has two electrons in the $1s$ orbital and He^+

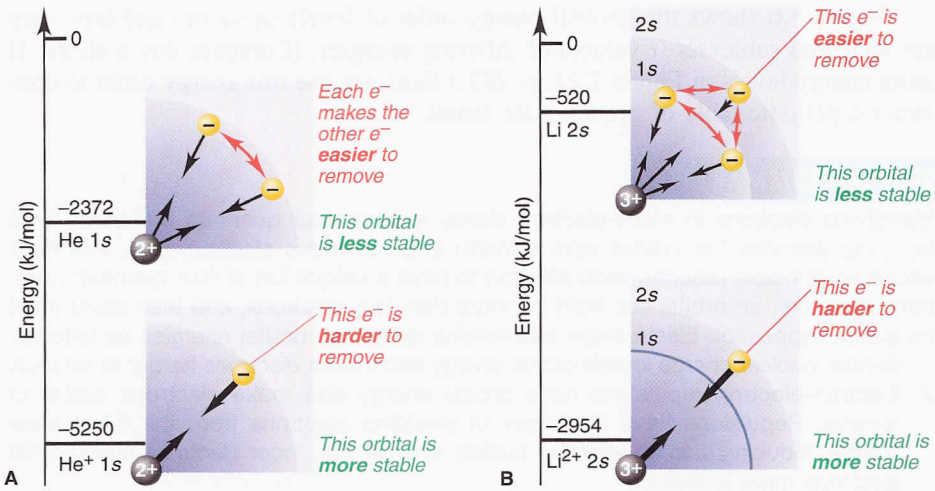

Figure 8.4 Shielding and orbital energy. **A,** Within an orbital each electron shields the other somewhat from the full nuclear charge. The lower Z_{eff} raises orbital energy, which makes the electron easier to remove. Thus, it takes less than half as much energy to remove an electron from He than from He^+. **B,** Inner electrons shield outer electrons much better than electrons in the same orbital shield one another. It takes only about one-sixth as much energy to remove an electron from Li as from Li^{2+}.

has only one (Figure 8.4A). It takes less than half as much energy to remove an electron from He (2372 kJ/mol) than from He^+ (5250 kJ/mol) because the second electron in He repels the first, in effect shielding the first electron from the full nuclear charge (lowering Z_{eff}).

Much greater shielding is provided by inner electrons. Because they spend nearly all their time *between* the outer electrons and the nucleus, inner electrons shield outer electrons very effectively, in fact, *much more effectively than do electrons in the same sublevel.* We can see this by comparing two atomic systems with the same nucleus, one *with* inner electrons and the other *without*. The ground-state Li atom has two inner (1*s*) electrons and one outer (2*s*) electron, while the Li^{2+} ion has only one electron, which occupies the 2*s* orbital in the first excited state (Figure 8.4B). It takes about 1/6th as much energy to remove the 2*s* electron from the Li atom (520 kJ/mol) as from the Li^{2+} ion (2954 kJ/mol), because the inner electrons shield very effectively. *Shielding by inner electrons greatly lowers the Z_{eff} felt by outer electrons.*

Penetration: The Effect of Orbital Shape on Orbital Energy To return to the question of why the 2*s* orbital is occupied (lower in energy) in the Li ground state, rather than the 2*p*, we have to consider orbital shapes, that is, radial probability distributions (Figure 8.5). At first, we might expect that the electron would enter the 2*p* orbital (*orange curve*) because it is slightly closer to the nucleus, on average, than the major portion of the 2*s* orbital (*blue curve*). But note that a minor portion of the 2*s* radial probability distribution appears within the 1*s* region. As a result, an electron in the 2*s* orbital spends part of its time "penetrating" very close to the nucleus. Charges attract more strongly if they are near each other than far apart (Coulomb's law, Section 2.7). Therefore, **penetration** by the 2*s* electron increases its overall attraction to the nucleus relative to that for a 2*p* electron. At the same time, penetration into the 1*s* region decreases the shielding of the 2*s* electron by the 1*s* electrons. Evidence shows that, indeed, the 2*s* orbital of Li *is* lower in energy than the 2*p* orbital, because it takes more energy to remove a 2*s* electron (520 kJ/mol) than a 2*p* (341 kJ/mol).

In general, *penetration and the resulting effects on shielding cause an energy level to split into sublevels of differing energy.* The lower the *l* value of an orbital, the more its electrons penetrate, and so the greater their attraction to the nucleus. Therefore, *for a given n value, the lower the l value, the lower the sublevel energy:*

$$\text{Order of sublevel energies: } s < p < d < f \qquad (8.1)$$

Thus, the 2*s* ($l = 0$) is lower in energy than the 2*p* ($l = 1$), the 3*p* ($l = 1$) is lower than the 3*d* ($l = 2$), and so forth.

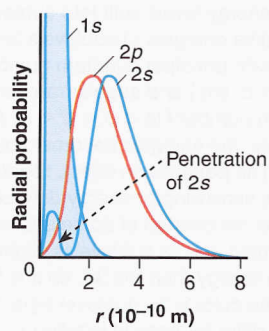

Figure 8.5 Penetration and orbital energy. Radial probability distributions show that a 2*s* electron spends most of its time slightly farther from the nucleus than does a 2*p* electron but penetrates near the nucleus for a small part of the time. Penetration by the 2*s* electron increases its attraction to the nucleus; thus the 2*s* orbital is more stable than the 2*p*.

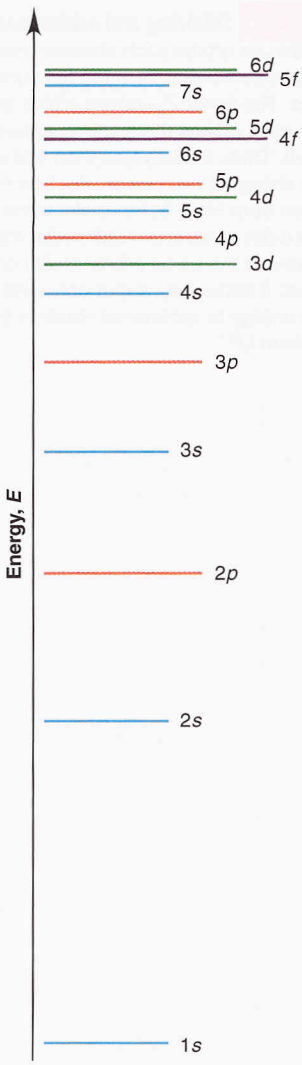

Figure 8.6 Order for filling energy sublevels with electrons. In many-electron atoms, energy levels split into sublevels. The relative energies of sublevels increase with principal quantum number n ($1 < 2 < 3$, etc.) and angular momentum quantum number l ($s < p < d < f$). As n increases, the energies become closer together. The penetration effect, together with this narrowing of energy differences, results in the overlap of some sublevels; for example, the 4*s* sublevel is slightly lower in energy than the 3*d*, so it is filled first. (Line color is by sublevel type; line lengths differ for ease in labeling.)

Figure 8.6 shows the general energy order of levels (n value) and how they are split into sublevels (l values) of differing energies. (Compare this with the H atom energy levels in Figure 7.21, p. 283.) Next, we use this energy order to construct a periodic table of ground-state atoms.

SECTION SUMMARY

Identifying electrons in many-electron atoms requires four quantum numbers: three (n, l, m_l) describe the orbital, and a fourth (m_s) describes electron spin. The Pauli exclusion principle requires each electron to have a unique set of four quantum numbers; therefore, an orbital can hold no more than two electrons, and their spins must be paired (opposite). Electrostatic interactions determine orbital energies as follows:

1. Greater nuclear charge lowers orbital energy and makes electrons harder to remove.
2. Electron-electron repulsions raise orbital energy and make electrons easier to remove. Repulsions have the effect of *shielding* electrons from the full nuclear charge, reducing it to an effective nuclear charge, Z_{eff}. Inner electrons shield outer electrons most effectively.
3. Greater radial probability distribution near the nucleus (greater *penetration*) makes an electron harder to remove because it is attracted more strongly and shielded less effectively. As a result, an energy level (shell) is split into sublevels (subshells) with the energy order $s < p < d < f$.

8.3 THE QUANTUM-MECHANICAL MODEL AND THE PERIODIC TABLE

Quantum mechanics provides the theoretical foundation for the experimentally based periodic table. In this section, we fill the table with elements and determine their electron configurations—the distributions of electrons within their atoms' orbitals. Note especially the *recurring pattern in electron configurations, which is the basis for the recurring pattern in chemical behavior.*

Building Up Periods 1 and 2

A useful way to determine the electron configurations of the elements is to start at the beginning of the periodic table and add one electron per element to the *lowest energy orbital available*. (Of course, one proton and one or more neutrons are also added to the nucleus.) This approach is based on the **aufbau principle** (German *aufbauen*, "to build up"), and it results in *ground-state* electron configurations. Let's assign sets of quantum numbers to the electrons in the ground state of the first 10 elements, those in the first two periods (horizontal rows).

For the electron in H, as you've seen, the set of quantum numbers is

$$\text{H } (Z = 1): \quad n = 1,\ l = 0,\ m_l = 0,\ m_s = +\tfrac{1}{2}$$

You also saw that the first electron in He has the same set as the electron in H, but the second He electron has opposing spin (exclusion principle):

$$\text{He } (Z = 2): \quad n = 1,\ l = 0,\ m_l = 0,\ m_s = -\tfrac{1}{2}$$

(As we go through each element in this discussion, the quantum numbers that follow refer to the element's *last added* electron.)

Here are two common ways to designate the orbital and its electrons:

1. *The electron configuration.* This shorthand notation consists of the principal energy level (n value), the letter designation of the sublevel (l value), and the number of electrons (#) in the sublevel, written as a superscript: $\boldsymbol{nl^{\#}}$. The electron configuration of H is $1s^1$ (spoken "one-ess-one"); that of He is $1s^2$ (spoken "one-ess-two," *not* "one-ess-squared"). This notation does *not* indicate electron spin but assumes you know that the two 1*s* electrons have paired (opposite) spins.

2. *The orbital diagram.* An **orbital diagram** consists of a box (or circle, or just a line) for each orbital in a given energy level, grouped by sublevel, with an

arrow indicating an electron *and* its spin. (Traditionally, ↑ is $+\frac{1}{2}$ and ↓ is $-\frac{1}{2}$, but these are arbitrary; it is necessary only to be consistent. Throughout the text, orbital occupancy is also indicated by color intensity: an orbital with no color is empty, pale color means half-filled, and full color means filled.) The electron configurations and orbital diagrams for the first two elements are

H ($Z = 1$) $1s^1$ ↑ (1s) He ($Z = 2$) $1s^2$ ↑↓ (1s)

The exclusion principle tells us that an orbital can hold only two electrons, so the 1*s* orbital in He is filled, and the $n = 1$ level is also filled. The $n = 2$ level is filled next, beginning with the 2*s* orbital, the next lowest in energy. As we said earlier, the first two electrons in Li fill the 1*s* orbital, and the last added Li electron has quantum numbers $n = 2$, $l = 0$, $m_l = 0$, $m_s = +\frac{1}{2}$. The electron configuration for Li is $1s^2 2s^1$. Note that the orbital diagram shows all the orbitals for $n = 2$, whether or not they are occupied:

Energy, *E* →

Li ($Z = 3$) $1s^2 2s^1$ ↑↓ (1s) ↑ (2s) | | | (2p)

To save space on a page, orbital diagrams are often written horizontally, but note that *the energy of the sublevels increases from left to right*. Figure 8.7 emphasizes this point by arranging the orbital diagram of lithium vertically.

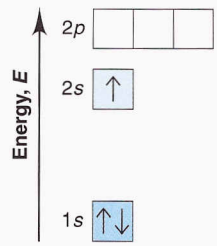

Figure 8.7 A vertical orbital diagram for the Li ground state. Although orbital diagrams are usually written horizontally, this vertical arrangement emphasizes that sublevel energy increases with increasing *n* and *l*.

With the 2*s* orbital only half-filled in Li, the fourth electron of beryllium fills it with the electron's spin paired: $n = 2$, $l = 0$, $m_l = 0$, $m_s = -\frac{1}{2}$.

Be ($Z = 4$) $1s^2 2s^2$ ↑↓ (1s) ↑↓ (2s) | | | (2p)

The next lowest energy sublevel is the 2*p*. A *p* sublevel has $l = 1$, so the m_l (orientation) values can be -1, 0, or $+1$. The three orbitals in the 2*p* sublevel have *equal energy* (same *n* and *l* values), which means that the fifth electron of boron can go into *any one of the 2p orbitals*. For convenience, let's label the boxes from left to right, -1, 0, $+1$. By convention, we place the electron in the $m_l = -1$ orbital: $n = 2$, $l = 1$, $m_l = -1$, $m_s = +\frac{1}{2}$.

-1 0 $+1$

B ($Z = 5$) $1s^2 2s^2 2p^1$ ↑↓ (1s) ↑↓ (2s) ↑ | | (2p)

To minimize electron-electron repulsions, the last added (sixth) electron of carbon enters one of the *unoccupied* 2*p* orbitals; by convention, we place it in the $m_l = 0$ orbital. Experiment shows that the spin of this electron is *parallel* to (the same as) the spin of the other 2*p* electron: $n = 2$, $l = 1$, $m_l = 0$, $m_s = +\frac{1}{2}$.

C ($Z = 6$) $1s^2 2s^2 2p^2$ ↑↓ (1s) ↑↓ (2s) ↑ ↑ | (2p)

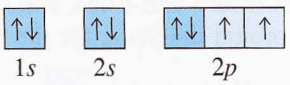
This placement of electrons for carbon exemplifies **Hund's rule:** *when orbitals of equal energy are available, the electron configuration of lowest energy has the maximum number of unpaired electrons with parallel spins.* Based on Hund's rule, nitrogen's seventh electron enters the last empty 2*p* orbital, with its spin parallel to the two other 2*p* electrons: $n = 2$, $l = 1$, $m_l = +1$, $m_s = +\frac{1}{2}$.

N ($Z = 7$) $1s^2 2s^2 2p^3$ ↑↓ (1s) ↑↓ (2s) ↑ ↑ ↑ (2p)

The eighth electron in oxygen must enter one of these three half-filled 2*p* orbitals and "pair up" with (have opposing spin to) the electron already present.

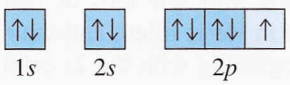
Since the $2p$ orbitals all have the same energy, we proceed as before and place the electron in the orbital previously designated $m_l = -1$. The quantum numbers are $n = 2$, $l = 1$, $m_l = -1$, $m_s = -\frac{1}{2}$.

O ($Z = 8$) $1s^2 2s^2 2p^4$



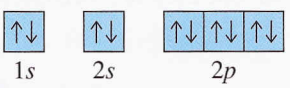
Fluorine's ninth electron enters either of the two remaining half-filled $2p$ orbitals: $n = 2$, $l = 1$, $m_l = 0$, $m_s = -\frac{1}{2}$.

F ($Z = 9$) $1s^2 2s^2 2p^5$



Only one unfilled orbital remains in the $2p$ sublevel, so the tenth electron of neon occupies it: $n = 2$, $l = 1$, $m_l = +1$, $m_s = -\frac{1}{2}$. With neon, the $n = 2$ level is filled.

Ne ($Z = 10$) $1s^2 2s^2 2p^6$



SAMPLE PROBLEM 8.1 Determining Quantum Numbers from Orbital Diagrams

Problem Write a set of quantum numbers for the third electron and a set for the eighth electron of the F atom.

Plan Referring to the orbital diagram, we count to the electron of interest and note its level (n), sublevel (l), orbital (m_l), and spin (m_s).

Solution The third electron is in the $2s$ orbital. The upward arrow indicates a spin of $+\frac{1}{2}$:

$$n = 2,\ l = 0,\ m_l = 0,\ m_s = +\tfrac{1}{2}$$

The eighth electron is in the first $2p$ orbital, which is designated $m_l = -1$, and has a downward arrow:

$$n = 2,\ l = 1,\ m_l = -1,\ m_s = -\tfrac{1}{2}$$

FOLLOW-UP PROBLEM 8.1 Use the periodic table to identify the element with the electron configuration $1s^2 2s^2 2p^4$. Write its orbital diagram, and give the quantum numbers of its sixth electron.

With so much attention paid to these notations, it's easy to forget that atoms are real spherical objects and that the electrons occupy volumes with specific shapes and orientations. Figure 8.8 shows ground-state electron configurations and orbital contours for the first 10 elements arranged in periodic table format.

Even at this early stage of filling the table, we can make an important correlation between chemical behavior and electron configuration: elements in the same group have similar outer electron configurations. As an example, helium (He) and neon (Ne) in Group 8A(18) both have filled outer sublevels—$1s^2$ for helium and $2p^6$ for neon—and neither element forms compounds. As we'll see often, *filled outer sublevels make elements unreactive.*

Building Up Period 3

The Period 3 elements, sodium through argon, lie directly under the Period 2 elements, lithium through neon. The sublevels of the $n = 3$ level are filled in the order $3s$, $3p$, $3d$. Table 8.3 presents *partial* orbital diagrams ($3s$ and $3p$ sublevels only) and electron configurations for the eight elements in Period 3 (with *filled inner levels* in brackets and the sublevel to which the last electron is added in colored type). Note the *group similarities in outer electron configuration* with the elements in Period 2 (refer to Figure 8.9, p. 300).

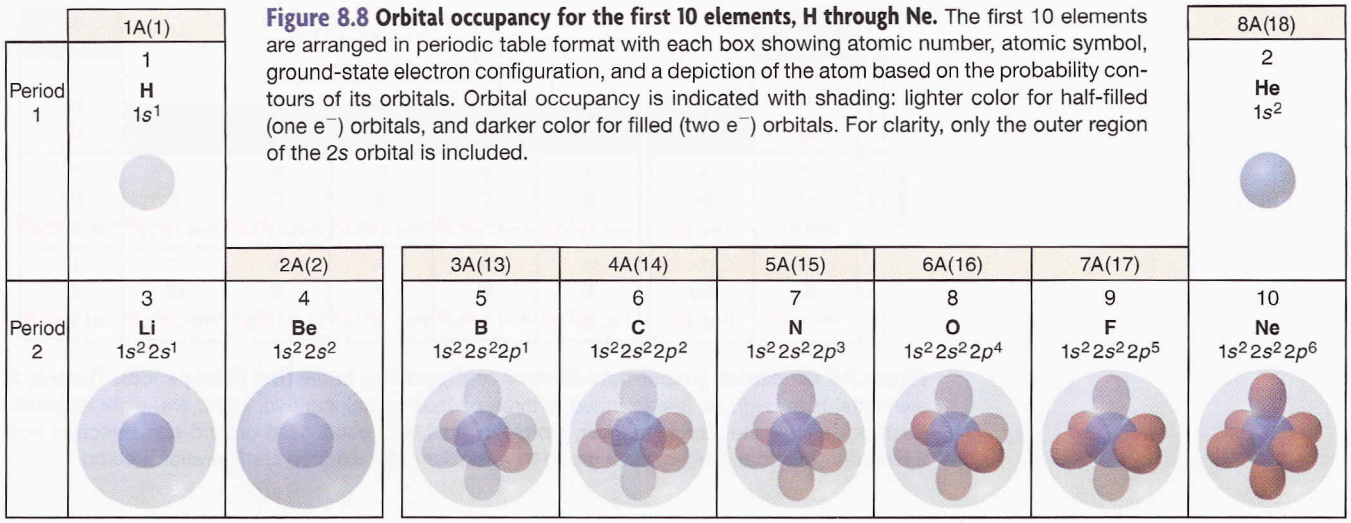


Figure 8.8 Orbital occupancy for the first 10 elements, H through Ne. The first 10 elements are arranged in periodic table format with each box showing atomic number, atomic symbol, ground-state electron configuration, and a depiction of the atom based on the probability contours of its orbitals. Orbital occupancy is indicated with shading: lighter color for half-filled (one e^-) orbitals, and darker color for filled (two e^-) orbitals. For clarity, only the outer region of the 2*s* orbital is included.

In sodium (the second alkali metal) and magnesium (the second alkaline earth metal), electrons are added to the 3*s* sublevel, which contains the 3*s* orbital only, just as they filled the 2*s* sublevel in lithium and beryllium in Period 2. Then, just as for boron, carbon, and nitrogen in Period 2, the last electrons added to aluminum, silicon, and phosphorus in Period 3 half-fill the three 3*p* orbitals with spins parallel (Hund's rule). The last electrons added to sulfur, chlorine, and argon then successively enter the three half-filled 3*p* orbitals, thereby filling the 3*p* sublevel. With argon, the next noble gas after helium and neon, we arrive at the end of Period 3. (As you'll see shortly, the 3*d* orbitals are filled in Period 4.)

The rightmost column of Table 8.3 shows the *condensed electron configuration*. In this simplified notation, the electron configuration of the previous noble gas is shown by its element symbol in brackets, and it is followed by the electron configuration of the energy level being filled. The condensed electron configuration of sulfur, for example, is [Ne] $3s^2 3p^4$, where [Ne] stands for $1s^2 2s^2 2p^6$.

Table 8.3 Partial Orbital Diagrams and Electron Configurations* for the Elements in Period 3

Atomic Number	Element	Partial Orbital Diagram (3*s* and 3*p* Sublevels Only)	Full Electron Configuration	Condensed Electron Configuration
		3*s* 3*p*		
11	Na	↑ | | |	$[1s^2 2s^2 2p^6]\ 3s^1$	[Ne] $3s^1$
12	Mg	↑↓ | | |	$[1s^2 2s^2 2p^6]\ 3s^2$	[Ne] $3s^2$

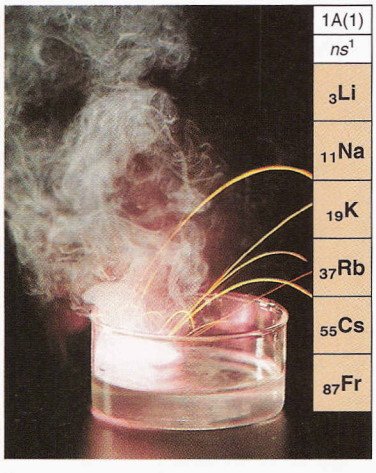
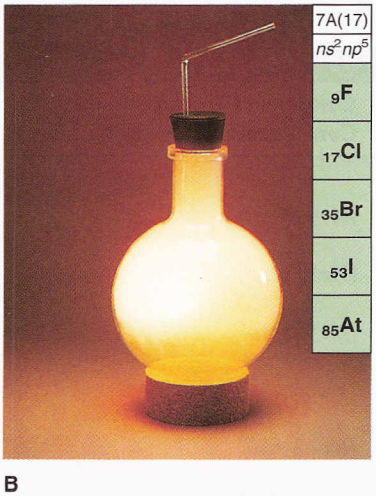
Figure 8.9 Condensed ground-state electron configurations in the first three periods. The first 18 elements, H through Ar, are arranged in three periods containing two, eight, and eight elements. Each box shows the atomic number, atomic symbol, and condensed ground-state electron configuration. Note that elements in a group have similar outer electron configurations *(color)*.



A



B

Figure 8.10 Similar reactivities within a group. A, Potassium metal and water reacting. All alkali metals [Group 1A(1)] react vigorously with water and displace H_2. **B,** Chlorine and potassium metal reacting. All halogens [Group 7A(17)] react with metals to form ionic halides.

Electron Configurations Within Groups

One of the central points in all chemistry is that *similar outer electron configurations correlate with similar chemical behavior.* Figure 8.9 shows the condensed electron configurations of the first 18 elements. Note the similarities within each group. Here are some examples from just two groups:

- In Group 1A(1), lithium and sodium have the condensed electron configuration [noble gas] ns^1 (where n is the quantum number of the outermost energy level), as do all the other alkali metals (K, Rb, Cs, Fr). All are highly reactive metals that form ionic compounds with nonmetals with formulas such as MCl, M_2O, and M_2S (where M represents the alkali metal), and all react vigorously with water to displace H_2 (Figure 8.10A).
- In Group 7A(17), fluorine and chlorine have the condensed electron configuration [noble gas] ns^2np^5, as do the other halogens (Br, I, At). Little is known about rare, radioactive astatine (At), but all the others are reactive nonmetals that occur as diatomic molecules, X_2 (where X represents the halogen). All form ionic compounds with metals (KX, MgX_2) (Figure 8.10B), covalent compounds with hydrogen (HX) that yield acidic solutions in water, and covalent compounds with carbon (CX_4).

To summarize, here is the major connection between quantum mechanics and chemical periodicity: *orbitals are filled in order of increasing energy, which leads to outer electron configurations that recur periodically, which leads to chemical properties that recur periodically.*

The First *d*-Orbital Transition Series: Building Up Period 4

The 3*d* orbitals are filled in Period 4. Note, however, that *the 4s orbital is filled before the 3d.* This switch in filling order is due to the shielding and penetration effects that we discussed in Section 8.2. The radial probability distribution of the 3*d* orbital is greater outside the filled, inner $n = 1$ and $n = 2$ levels, so a 3*d* electron is shielded very effectively from the nuclear charge. In contrast, penetration by the 4*s* electron means that it spends a significant part of its time near the nucleus and feels a greater nuclear attraction. Thus, the 4*s* orbital is slightly *lower* in energy than the 3*d*, and so fills first. Similarly, the 5*s* orbital fills before the 4*d*, and the 6*s* fills before the 5*d*. In general, *the ns sublevel fills before the* $(n - 1)d$ *sublevel.* As we proceed through the transition series, however, you'll see several exceptions to this pattern because the energies of the *ns* and $(n - 1)d$ sublevels become extremely close at higher values of n.

Table 8.4 shows the partial orbital diagrams and ground-state electron configurations for the 18 elements in Period 4 (again with filled inner levels in brackets and the sublevel to which the last electron has been added in colored type). The first two elements of the period, potassium and calcium, are the next alkali and alkaline earth metals, respectively, and their electrons fill the 4*s* sublevel. The third element, scandium ($Z = 21$), is the first of the **transition elements,** those in which *d* orbitals are being filled. The last electron in scandium occupies any one of the five 3*d* orbitals because they are equal in energy. Scandium has the electron configuration [Ar] $4s^2 3d^1$.

The filling of 3*d* orbitals proceeds one at a time, as with *p* orbitals, except in two cases: chromium ($Z = 24$) and copper ($Z = 29$). Vanadium ($Z = 23$), the element before chromium, has three half-filled *d* orbitals ([Ar] $4s^2 3d^3$). Rather than having its last electron enter a fourth empty *d* orbital to give [Ar] $4s^2 3d^4$, chromium has one electron in the 4*s* sublevel and five in the 3*d* sublevel. Thus, both the 4*s* and the 3*d* sublevels are *half-filled* (see margin).

The other anomalous filling pattern occurs with copper. Following nickel ([Ar] $4s^2 3d^8$), copper would be expected to have the [Ar] $4s^2 3d^9$ configuration.

Cr ($Z = 24$) [Ar] $4s^1 3d^5$

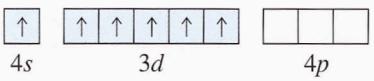


Table 8.4 Partial Orbital Diagrams and Electron Configurations* for the Elements in Period 4

Atomic Number	Element	Partial Orbital Diagram (4*s*, 3*d*, and 4*p* Sublevels Only)	Full Electron Configuration	Condensed Electron Configuration

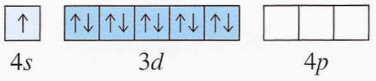
36	Kr	↑↓ ↑↓ ↑↓ ↑↓ ↑↓ ↑↓ ↑↓ ↑↓	$[1s^2 2s^2 2p^6 3s^2 3p^6]\ 4s^2 3d^{10} 4p^6$	[Ar] $4s^2 3d^{10} 4p^6$

*Colored type indicates sublevel(s) whose occupancy changes when the last electron is added.

Cu ($Z = 29$) [Ar] $4s^1 3d^{10}$



Instead, the 4*s* orbital of copper is half-filled (1 electron), and the 3*d* orbitals are *filled* with 10 electrons (see margin). The anomalous filling patterns in Cr and Cu lead us to conclude that *half-filled and filled sublevels are unexpectedly stable.* These are the first two cases of a pattern seen with many other elements.

In zinc, both the 4*s* and 3*d* sublevels are completely filled, and the first transition series ends. As Table 8.4 shows, the 4*p* sublevel is then filled by the next six elements. Period 4 ends with krypton, the next noble gas.

General Principles of Electron Configurations

There are 77 known elements beyond the 36 we have considered. Let's survey the ground-state electron configurations to highlight some key ideas.

Similar Outer Electron Configurations Within a Group To repeat one of chemistry's central themes and the key to the usefulness of the periodic table, *elements in a group have similar chemical properties because they have similar outer electron configurations* (Figure 8.11). Among the main-group elements (A groups)—the *s*-block and *p*-block elements—outer electron configurations within a group are essentially identical, as shown by the group headings in Figure 8.11. Some variations in the transition elements (B groups, *d* block) and inner transition elements (*f* block) occur, as you'll see.

Figure 8.11 A periodic table of partial ground-state electron configurations. These ground-state electron configurations show the electrons beyond the previous noble gas in the sublevel block being filled (excluding filled inner sublevels). For main-group elements, the group heading identifies the general outer configuration. Anomalous electron configurations occur often among the *d*-block and *f*-block elements, with the first two appearing for Cr ($Z = 24$) and Cu ($Z = 29$). Helium is colored as an *s*-block element but placed with the other members of Group 8A(18). Configurations for elements 110 to 112, 114, and 116 have not yet been confirmed.

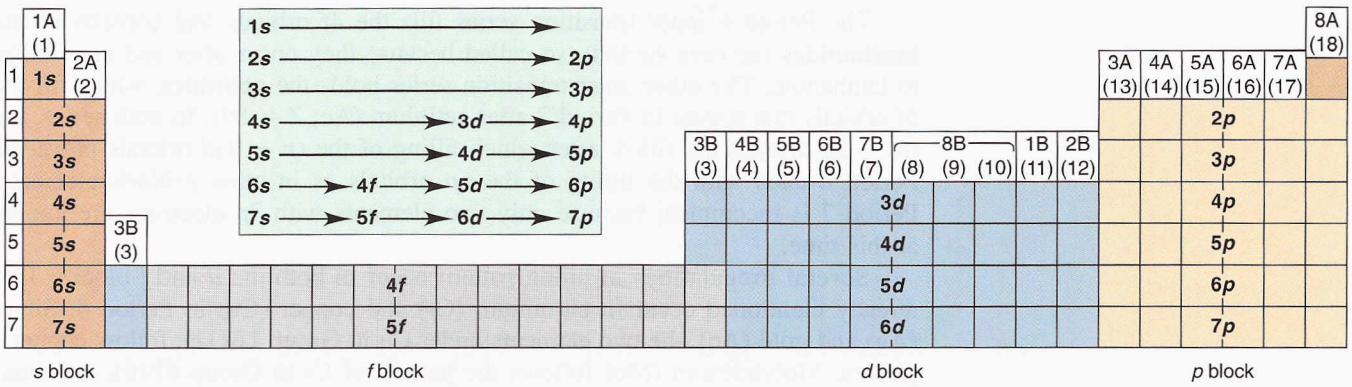

Figure 8.12 The relation between orbital filling and the periodic table. If we "read" the periods like the words on a page, the elements are arranged into sublevel blocks that occur in the order of increasing energy. This form of the periodic table shows the sublevel blocks. (The *f* blocks fit between the first and second elements of the *d* blocks in Periods 6 and 7.) *Inset:* A simple version of sublevel order.

Orbital Filling Order When the elements are "built up" by filling their levels and sublevels in order of increasing energy, we obtain the actual sequence of elements in the periodic table. Thus, reading the table from left to right, as you read words on a page, gives the energy order of levels and sublevels, which is shown in Figure 8.12. The arrangement of the periodic table is the best way to learn the orbital filling order of the elements, but a useful memory aid is shown in Figure 8.13.

Categories of Electrons The elements have three categories of electrons:

1. **Inner (core) electrons** are those seen in the previous noble gas and any completed transition series. They fill all the *lower energy levels* of an atom.
2. **Outer electrons** are those in the *highest energy level* (highest n value). They spend most of their time farthest from the nucleus.
3. **Valence electrons** are those involved in forming compounds. *Among the main-group elements, the valence electrons* ***are*** *the outer electrons.* Among the transition elements, the $(n - 1)d$ electrons are counted among the valence electrons because some or all of them are often involved in bonding.

Group and Period Numbers Key information is embedded in the periodic table:

1. Among the main-group elements (A groups), *the group number equals the number of outer electrons* (those with the highest n): chlorine (Cl; Group **7**A) has 7 outer electrons, tellurium (Te; Group **6**A) has 6, and so forth.
2. *The period number is the n value of the highest energy level.* Thus, in Period 2, the $n = 2$ level has the highest energy; in Period 5, it is the $n = 5$ level.
3. The n value squared (n^2) gives the total number of *orbitals* in that energy level. Because an orbital can hold no more than two electrons (exclusion principle), $2n^2$ gives the maximum number of *electrons* (or elements) in the energy level. For example, for the $n = 3$ level, the number of orbitals is $n^2 = 9$: one $3s$, three $3p$, and five $3d$. The number of electrons is $2n^2$, or 18: two $3s$ and six $3p$ electrons occur in the eight elements of Period 3, and ten $3d$ electrons are added in the ten transition elements of Period 4.

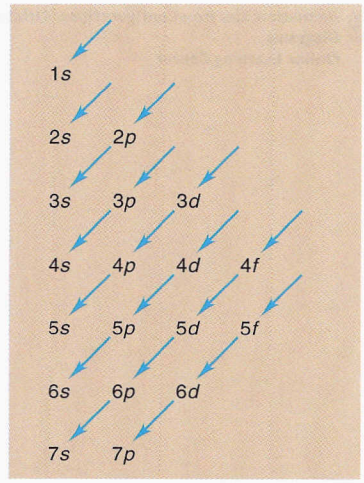

Figure 8.13 Aid to memorizing sublevel filling order. List the sublevels as shown, and read from 1s, following the direction of the arrows. Note that the
- n value is constant horizontally
- l value is constant vertically
- $n + l$ sum is constant diagonally.

Unusual Configurations: Transition and Inner Transition Elements

Periods 4, 5, 6, and 7 incorporate the *d*-block transition elements. The general pattern, as you've seen, is that the $(n - 1)d$ orbitals are filled between the ns and np orbitals. Thus, Period 5 follows the same general pattern as Period 4. In Period 6, the $6s$ sublevel is filled in cesium (Cs) and barium (Ba), and then lanthanum (La; $Z = 57$), the first member of the $5d$ transition series, occurs. At this point, the first series of **inner transition elements,** those in which *f* orbitals are being filled, intervenes (Figure 8.12). The *f* orbitals have $l = 3$, so the possible m_l values are -3, -2, -1, 0, $+1$, $+2$, and $+3$; that is, there are seven *f* orbitals, for a total of 14 elements in *each* of the two inner transition series.

The Period 6 inner transition series fills the 4*f* orbitals and consists of the **lanthanides** (or **rare earths**), so called because they occur after and are similar to lanthanum. The other inner transition series holds the **actinides,** which fill the 5*f* orbitals that appear in Period 7 after actinium (Ac; $Z = 89$). In both series, the $(n - 2)f$ orbitals are filled, after which filling of the $(n - 1)d$ orbitals proceeds. Period 6 ends with the filling of the 6*p* orbitals as in other *p*-block elements. Period 7 is incomplete because only two elements with 7*p* electrons are known at this time.

Several irregularities in filling pattern occur in both the *d* and *f* blocks. Two already mentioned occur in chromium (Cr) and copper (Cu) in Period 4. Silver (Ag) and gold (Au), the two elements under Cu in Group 1B(11), follow copper's pattern. Molybdenum (Mo) follows the pattern of Cr in Group 6B(6), but tungsten (W) does not. Other anomalous configurations appear among the transition elements in Periods 5 and 6. Note, however, that even though minor variations from the expected configurations occur, the sum of *ns* electrons and $(n - 1)d$ electrons always equals the *new* group number. For instance, despite variations in the electron configurations in Group 6B(**6**)—Cr, Mo, W, and Sg—the sum of *ns* and $(n - 1)d$ electrons is 6; in Group 8B(**10**)—Ni, Pd, and Pt—the sum is 10.

Whenever our observations differ from our expectations, remember that the fact always takes precedence over the model; in other words, the electrons don't "care" what orbitals *we* think they should occupy. As the atomic orbitals in larger atoms fill with electrons, sublevel energies differ very little, which results in these variations from the expected pattern.

SAMPLE PROBLEM 8.2 Determining Electron Configurations

Problem Using the periodic table on the inside cover of the text (not Figure 8.11 or Table 8.4), give the full and condensed electron configurations, partial orbital diagrams showing valence electrons, and number of inner electrons for the following elements:

(a) Potassium (K; $Z = 19$) **(b)** Molybdenum (Mo; $Z = 42$) **(c)** Lead (Pb; $Z = 82$)

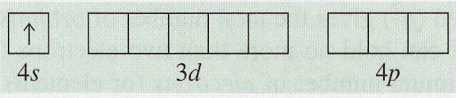
Plan The atomic number tells us the number of electrons, and the periodic table shows the order for filling sublevels. In the partial orbital diagrams, we include all electrons after those of the previous noble gas *except* those in *filled* inner sublevels. The number of inner electrons is the sum of those in the previous noble gas and in filled *d* and *f* sublevels.

Animation: Electron Configurations/Orbital Diagrams
Online Learning Center

Solution **(a)** For K ($Z = 19$), the full electron configuration is $1s^2 2s^2 2p^6 3s^2 3p^6 4s^1$.

The condensed configuration is [Ar] $4s^1$.

The partial orbital diagram for valence electrons is



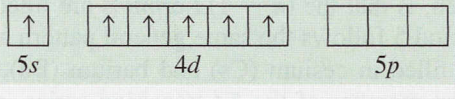
K is a main-group element in Group 1A(1) of Period 4, so there are 18 inner electrons.

(b) For Mo ($Z = 42$), we would expect the full electron configuration to be $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^{10} 4p^6 5s^2 4d^4$. However, Mo lies under Cr in Group 6B(6) and exhibits the same variation in filling pattern in the *ns* and $(n - 1)d$ sublevels:

$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^{10} 4p^6 5s^1 4d^5$.

The condensed electron configuration is [Kr] $5s^1 4d^5$.

The partial orbital diagram for valence electrons is



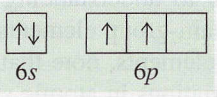
Mo is a transition element in Group 6B(6) of Period 5, so there are 36 inner electrons.

(c) For Pb ($Z = 82$), the full electron configuration is

$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^{10} 4p^6 5s^2 4d^{10} 5p^6 6s^2 4f^{14} 5d^{10} 6p^2$.

The condensed electron configuration is [Xe] $6s^2 4f^{14} 5d^{10} 6p^2$.

The partial orbital diagram for valence electrons (no filled inner sublevels) is



Pb is a main-group element in Group 4A(14) of Period 6, so there are 54 (in Xe) + 14 (in 4*f* series) + 10 (in 5*d* series) = 78 inner electrons.

Check Be sure the sum of the superscripts (electrons) in the full electron configuration equals the atomic number, and that the number of *valence* electrons in the condensed configuration equals the number of electrons in the partial orbital diagram.

FOLLOW-UP PROBLEM 8.2 Without referring to Table 8.4 or Figure 8.11, give full and condensed electron configurations, partial orbital diagrams showing valence electrons, and the number of inner electrons for the following elements:

(a) Ni ($Z = 28$) **(b)** Sr ($Z = 38$) **(c)** Po ($Z = 84$)

SECTION SUMMARY

In the aufbau method, one electron is added to an atom of each successive element in accord with Pauli's exclusion principle (no two electrons can have the same set of quantum numbers) and Hund's rule (orbitals of equal energy become half-filled, with electron spins parallel, before any pairing occurs). The elements of a group have similar outer electron configurations and similar chemical behavior. For the main-group elements, valence electrons (those involved in reactions) are in the outer (highest energy) level only. For transition elements, $(n - 1)d$ electrons are also involved in reactions. In general, $(n - 1)d$ orbitals fill after *ns* and before *np* orbitals. In Periods 6 and 7, $(n - 2)f$ orbitals fill between the first and second $(n - 1)d$ orbitals.

8.4 TRENDS IN THREE KEY ATOMIC PROPERTIES

All physical and chemical behavior of the elements is based ultimately on the electron configurations of their atoms. In this section, we focus on three properties of atoms that are directly influenced by electron configuration and, thus, effective nuclear charge: atomic size, ionization energy (the energy required to remove an electron from a gaseous atom), and electron affinity (the energy change involved in adding an electron to a gaseous atom). These properties are *periodic:* they generally increase and decrease in a recurring manner throughout the periodic table. As a result, their relative magnitudes can often be predicted, and they often exhibit consistent changes, or *trends,* within a group or period that correlate with element behavior.

Trends in Atomic Size

In Chapter 7, we noted that an electron in an atom can lie relatively far from the nucleus, so we commonly represent atoms as spheres in which the electrons spend 90% of their time. However, we often *define* atomic size in terms of how closely one atom lies next to another. In practice, we measure the distance between identical, adjacent atomic nuclei in a sample of an element and divide that distance in half. (The technique is discussed in Chapter 12.) Because atoms do not have hard surfaces, the size of an atom in a compound depends somewhat on the atoms near it. In other words, *atomic size varies slightly from substance to substance.*

Figure 8.14 shows two common definitions of atomic size. The **metallic radius** is one-half the distance between nuclei of adjacent atoms in a crystal of the element; we typically use this definition for metals. For elements commonly occurring as molecules, mostly nonmetals, we define atomic size by the **covalent radius,** one-half the distance between nuclei of identical covalently bonded atoms.

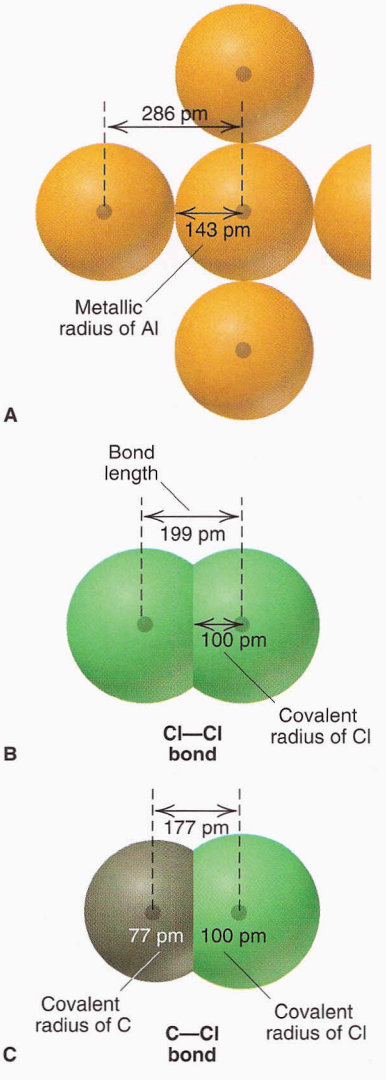


Figure 8.14 Defining metallic and covalent radii. A, The metallic radius is one-half the distance between nuclei of adjacent atoms in a crystal of the element, as shown here for aluminum. **B,** The covalent radius is one-half the distance between bonded nuclei in a molecule of the element, as shown here for chlorine. In effect, it is one-half the bond length. **C,** In a covalent compound, the bond length and known covalent radii are used to determine other radii. Here the C—Cl bond length (177 pm) and the covalent radius of Cl (100 pm) are used to find a value for the covalent radius of C (177 pm − 100 pm = 77 pm).

Trends Among the Main-Group Elements Atomic size greatly influences other atomic properties and is critical to understanding element behavior. Figure 8.15 shows the atomic radii of the main-group elements and most of the transition elements. Among the main-group elements, note that atomic size varies within both a group and a period. These variations in atomic size are the result of two opposing influences:

1. *Changes in n.* As the principal quantum number (n) increases, the probability that the outer electrons will spend more time farther from the nucleus increases as well; thus, the atoms are larger.
2. *Changes in Z_{eff}.* As the effective nuclear charge (Z_{eff})—the positive charge "felt" by an electron—increases, outer electrons are pulled closer to the nucleus; thus, the atoms are smaller.

The net effect of these influences depends on shielding of the increasing nuclear charge by inner electrons:

1. *Down a group, n dominates.* As we move down a main group, each member has one more level of *inner* electrons that shield the *outer* electrons very effectively. Even though calculations show Z_{eff} on the outer electrons rising moderately for each element in the group, the atoms get larger as a result of the increasing n value. *Atomic radius generally* ***increases*** *in a group from top to bottom.*
2. *Across a period, Z_{eff} dominates.* As we move across a period of main-group elements, electrons are added to the same outer level, so the shielding by inner electrons does not change. Because outer electrons shield each other poorly, Z_{eff} on the outer electrons rises significantly, and so they are pulled closer to the nucleus. *Atomic radius generally* ***decreases*** *in a period from left to right.*

Trends Among the Transition Elements As Figure 8.15 shows, these trends hold well for the main-group elements but *not* as consistently for the transition elements. As we move from left to right, size shrinks through the first two or three transition elements because of the increasing nuclear charge. But, from then on, *the size remains relatively constant* because shielding by the inner d electrons counteracts the usual increase in Z_{eff}. For instance, vanadium (V; $Z = 23$), the third Period 4 transition metal, has the same radius as zinc (Zn; $Z = 30$), the last Period 4 transition metal. This pattern of atomic size shrinking also appears in Periods 5 and 6 in the d-block transition series and in both series of inner transition elements.

This shielding by d electrons causes a major size decrease from Group 2A(2) to Group 3A(13), the two main groups that flank the transition series. The size decrease in Periods 4, 5, and 6 (*with* a transition series) is much greater than in Period 3 (*without* a transition series). Because electrons in the np orbitals penetrate more than those in the $(n - 1)d$ orbitals, the first np electron [Group 3A(13)] "feels" a Z_{eff} that has been increased by the protons added to all the intervening transition elements. The greatest change in size occurs in Period 4, in which calcium (Ca; $Z = 20$) is nearly 50% larger than gallium (Ga; $Z = 31$). In fact, filling the d orbitals in the transition series causes such a major size contraction that gallium is slightly *smaller* than aluminum (Al; $Z = 13$), even though Ga is below Al in the same group!

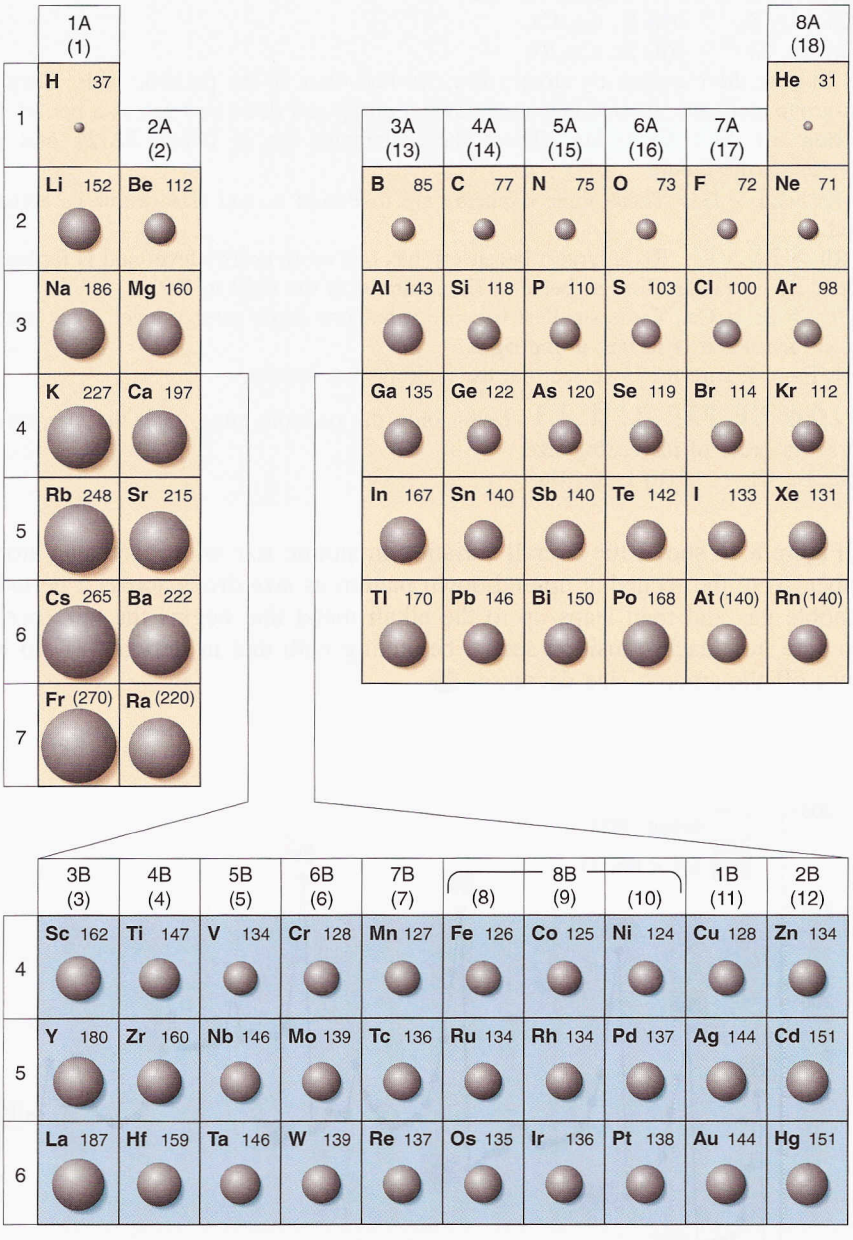

Figure 8.15 Atomic radii of the main-group and transition elements. Atomic radii (in picometers) are shown as half-spheres of proportional size for the main-group elements (*tan*) and the transition elements (*blue*). Among the main-group elements, atomic radius generally increases from top to bottom and decreases from left to right. The transition elements do not exhibit this consistent decrease in size. (Values in parentheses have only two significant figures; values for the noble gases are based on quantum-mechanical calculations.)

SAMPLE PROBLEM 8.3 Ranking Elements by Atomic Size

Problem Using only the periodic table (not Figure 8.15), rank each set of main-group elements in order of *decreasing* atomic size:

(a) Ca, Mg, Sr **(b)** K, Ga, Ca

(c) Br, Rb, Kr **(d)** Sr, Ca, Rb

Plan To rank the elements by atomic size, we find them in the periodic table. They are main-group elements, so size increases down a group and decreases across a period.

Solution **(a)** Sr > Ca > Mg. These three elements are in Group 2A(2), and size decreases up the group.

(b) K > Ca > Ga. These three elements are in Period 4, and size decreases across a period.

(c) Rb > Br > Kr. Rb is largest because it has one more energy level and is farthest to the left. Kr is smaller than Br because Kr is farther to the right in Period 4.

(d) Rb > Sr > Ca. Ca is smallest because it has one fewer energy level. Sr is smaller than Rb because it is farther to the right.

Check From Figure 8.15, we see that the rankings are correct.

FOLLOW-UP PROBLEM 8.3 Using only the periodic table, rank the elements in each set in order of *increasing* size:

(a) Se, Br, Cl **(b)** I, Xe, Ba

Packing 'Em In The increasing nuclear charge shrinks the space in which each electron can move. For example, in Group 1A(1), the atomic radius of cesium (Cs; $Z = 55$) is only 1.7 times that of lithium (Li; $Z = 3$); so the volume of Cs is about five times that of Li, even though Cs has 18 times as many electrons. At the opposite ends of Period 2, neon (Ne; $Z = 10$) has about one-tenth the volume of Li ($Z = 3$), but Ne has three times as many electrons. Thus, whether size increases down a group or decreases across a period, the attraction caused by the larger number of protons in the nucleus greatly crowds the electrons.

Figure 8.16 shows the overall variation in atomic size with increasing atomic number. Note the recurring up-and-down pattern as size drops across a period to the noble gas and then leaps up to the alkali metal that begins the next period. Also note how each transition series, beginning with that in Period 4 (K to Kr), throws off the smooth size decrease.

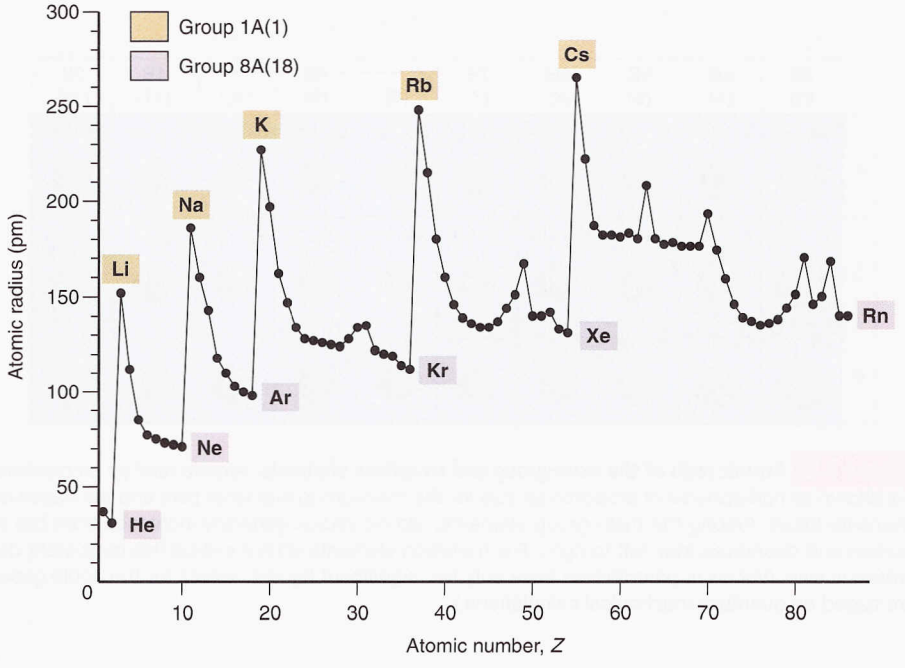

Figure 8.16 Periodicity of atomic radius. A plot of atomic radius vs. atomic number for the elements in Periods 1 through 6 shows a periodic change: the radius generally decreases through a period to the noble gas [Group 8A(18); *purple*] and then increases suddenly to the next alkali metal [Group 1A(1); *brown*]. Deviation from the general decrease occurs among the transition elements.

Trends in Ionization Energy

The **ionization energy (IE)** is the energy (in kJ) required for the *complete removal* of 1 mol of electrons from 1 mol of gaseous atoms or ions. Pulling an electron away from a nucleus *requires* energy to overcome the attraction. Because energy flows *into* the system, the ionization energy is always positive (like ΔH of an endothermic reaction).

In Chapter 7, you saw that the ionization energy of the H atom is the energy difference between $n = 1$ and $n = \infty$, the point at which the electron is completely removed. Many-electron atoms can lose more than one electron. The first ionization energy (IE_1) removes an outermost electron (highest energy sublevel) from the gaseous atom:

$$\text{Atom}(g) \longrightarrow \text{ion}^+(g) + e^- \qquad \Delta E = IE_1 > 0 \tag{8.2}$$

The second ionization energy (IE_2) removes a second electron. This electron is pulled away from a positively charged ion, so IE_2 is always larger than IE_1:

$$\text{Ion}^+(g) \longrightarrow \text{ion}^{2+}(g) + e^- \qquad \Delta E = IE_2 \text{ (always} > IE_1)$$

The first ionization energy is a key factor in an element's chemical reactivity because, as you'll see, *atoms with a low IE_1 tend to form cations during reactions, whereas those with a high IE_1 (except the noble gases) often form anions.*

Variations in First Ionization Energy The elements exhibit a periodic pattern in first ionization energy, as shown in Figure 8.17. By comparing this figure with Figure 8.16, you can see a roughly *inverse* relationship between IE_1 and atomic size: *as size decreases, it takes more energy to remove an electron.* This inverse relationship appears throughout the groups and periods of the table.

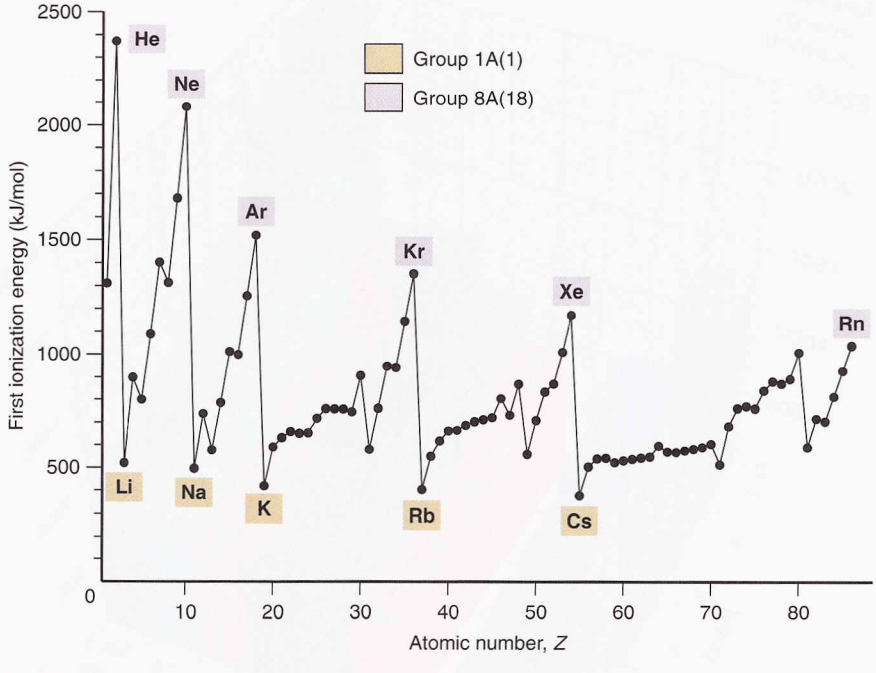

Figure 8.17 Periodicity of first ionization energy (IE_1). A plot of IE_1 vs. atomic number for the elements in Periods 1 through 6 shows a periodic pattern: the lowest values occur for the alkali metals (*brown*) and the highest for the noble gases (*purple*). This is the *inverse* of the trend in atomic size (see Figure 8.16).

Let's examine the two trends and their exceptions.

1. *Down a group.* As we move *down* a main group, the orbital's n value increases and so does atomic size. As the distance from nucleus to outermost electron increases, the attraction between them lessens, which makes the electron easier to remove. Figure 8.18 shows that *ionization energy generally* ***decreases down*** *a group:* it is easier to remove an outer electron from an element in Period 6 than Period 2.

The only significant exception to this pattern occurs in Group 3A(13), right after the transition series, and is due to the effect of the series on atomic size: IE_1 decreases from boron (B) to aluminum (Al), but not for the rest of the group. Filling the d sublevels in Periods 4, 5, and 6 causes a greater-than-expected Z_{eff}, which holds the outer electrons more tightly in the larger Group 3A members.

2. *Across a period.* As we move left to right across a period, the orbital's n value stays the same, so Z_{eff} increases and atomic size decreases. As a result, the attraction between nucleus and outer electrons increases, which makes an electron harder to remove. *Ionization energy generally* ***increases across*** *a period:* it is easier to remove an outer electron from an alkali metal than from a noble gas.

There are several small "dips" in the otherwise smooth increase in ionization energy. These occur in Group 3A(13) for B and Al and in Group 6A(16) for O and S. The dips in Group 3A occur because these electrons are the first in the np sublevel. This sublevel is higher in energy than the ns, so the electron in it is pulled off more easily, leaving a stable, filled ns sublevel. The dips in Group 6A occur because the np^4 electron is the first to pair up with another np electron, and electron-electron repulsions raise the orbital energy. Removing the np^4 electron relieves the repulsions and leaves a stable, half-filled np sublevel; so the fourth p electron comes off more easily than the third one does.

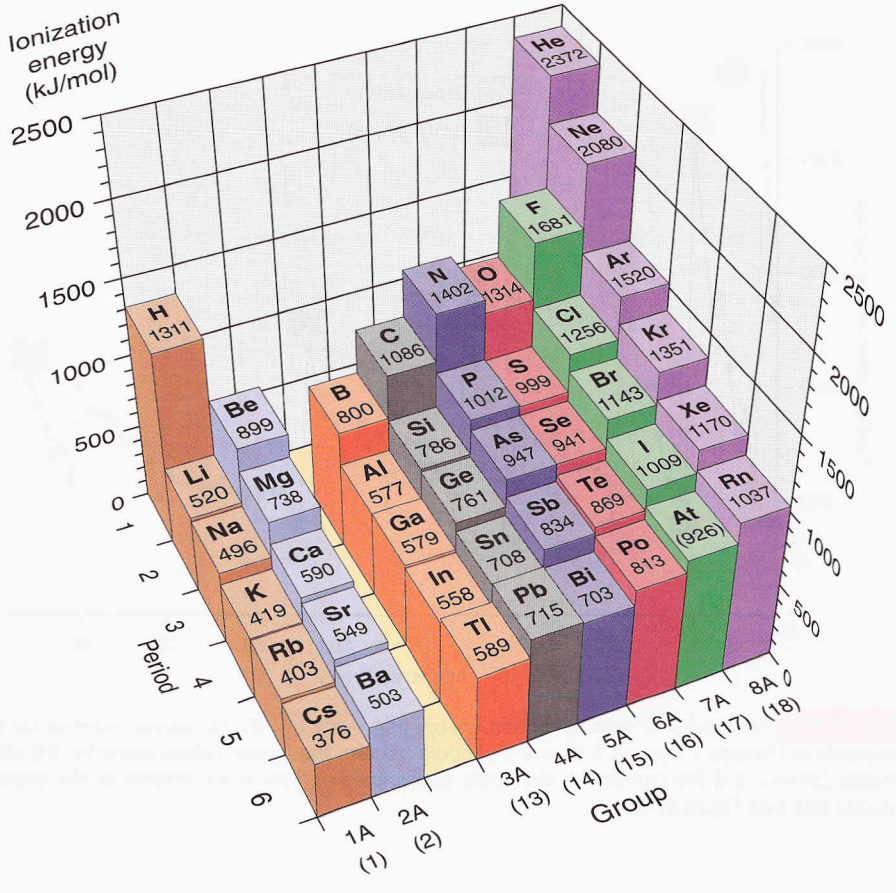

Figure 8.18 First ionization energies of the main-group elements. Values for IE_1 (in kJ/mol) of the main-group elements are shown as posts of varying height. Note the general increase within a period and decrease within a group. Thus, the lowest value is at the bottom of Group 1A(1), and the highest is at the top of Group 8A(18).

SAMPLE PROBLEM 8.4 Ranking Elements by First Ionization Energy

Problem Using the periodic table only, rank the elements in each of the following sets in order of *decreasing* IE_1:

(a) Kr, He, Ar **(b)** Sb, Te, Sn

(c) K, Ca, Rb **(d)** I, Xe, Cs

Plan As in Sample Problem 8.3, we first find the elements in the periodic table and then apply the general trends of decreasing IE_1 down a group and increasing IE_1 across a period.

Solution **(a)** He > Ar > Kr. These three are all in Group 8A(18), and IE_1 decreases down a group.

(b) Te > Sb > Sn. These three are all in Period 5, and IE_1 increases across a period.

(c) Ca > K > Rb. IE_1 of K is larger than IE_1 of Rb because K is higher in Group 1A(1). IE_1 of Ca is larger than IE_1 of K because Ca is farther to the right in Period 4.

(d) Xe > I > Cs. IE_1 of I is smaller than IE_1 of Xe because I is farther to the left. IE_1 of I is larger than IE_1 of Cs because I is farther to the right and in the previous period.

Check Since trends in IE_1 are generally the opposite of the trends in size, you can rank the elements by size and check that you obtain the reverse order.

FOLLOW-UP PROBLEM 8.4 Rank the elements in each of the following sets in order of increasing IE_1:

(a) Sb, Sn, I **(b)** Sr, Ca, Ba

Variations in Successive Ionization Energies Successive ionization energies (IE_1, IE_2, and so on) of a given element increase because each electron is pulled away from an ion with a progressively higher positive charge. Note from Figure 8.19, however, that this increase is not smooth, but includes an enormous jump.

A more complete picture is presented in Table 8.5, which shows successive ionization energies for the elements in Period 2 and the first element in Period 3. Move horizontally through the values for a given element, and you reach a point that separates relatively low from relatively high IE values (shaded area to right of line). This jump appears *after* the outer (valence) electrons have been removed and, thus, reflects the much greater energy needed to remove an inner (core) electron. For example, follow the values for boron (B): IE_1 is lower than IE_2, which is lower than IE_3, which is *much* lower than IE_4. Thus, boron has three electrons in the highest energy level ($1s^2 2s^2 2p^1$). Because of the significantly greater energy needed to remove core electrons, they are *not* involved in chemical reactions.

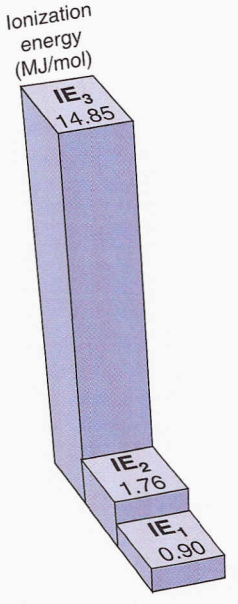

Figure 8.19 The first three ionization energies of beryllium (in MJ/mol). Successive ionization energies always increase, but an exceptionally large increase occurs when the first core electron is removed. For Be, this occurs with the third electron (IE_3). (Also see Table 8.5.)

Table 8.5 Successive Ionization Energies of the Elements Lithium Through Sodium

Z	Element	Number of Valence Electrons	Ionization Energy (MJ/mol)*									
			IE_1	IE_2	IE_3	IE_4	IE_5	IE_6	IE_7	IE_8	IE_9	IE_{10}
3	Li	1	0.52	7.30	11.81							
4	Be	2	0.90	1.76	14.85	21.01			CORE ELECTRONS			
5	B	3	0.80	2.43	3.66	25.02	32.82					
6	C	4	1.09	2.35	4.62	6.22	37.83	47.28				
7	N	5	1.40	2.86	4.58	7.48	9.44	53.27	64.36			
8	O	6	1.31	3.39	5.30	7.47	10.98	13.33	71.33	84.08

SAMPLE PROBLEM 8.5 Identifying an Element from Successive Ionization Energies

Problem Name the Period 3 element with the following ionization energies (in kJ/mol), and write its electron configuration:

IE_1	IE_2	IE_3	IE_4	IE_5	IE_6
1012	1903	2910	4956	6278	22,230

Plan We look for a large jump in the IE values, which occurs after all valence electrons have been removed. Then we refer to the periodic table to find the Period 3 element with this number of valence electrons and write its electron configuration.

Solution The exceptionally large jump occurs after IE_5, indicating that the element has five valence electrons and, thus, is in Group 5A(15). This Period 3 element is phosphorus (P; $Z = 15$). Its electron configuration is $1s^2 2s^2 2p^6 3s^2 3p^3$.

FOLLOW-UP PROBLEM 8.5 Element Q is in Period 3 and has the following ionization energies (in kJ/mol):

IE_1	IE_2	IE_3	IE_4	IE_5	IE_6
577	1816	2744	11,576	14,829	18,375

Name element Q and write its electron configuration.

Trends in Electron Affinity

The **electron affinity (EA)** is the energy change (in kJ) accompanying the *addition* of 1 mol of electrons to 1 mol of gaseous atoms or ions. As with ionization energy, there is a first electron affinity, a second, and so forth. The *first electron affinity* (EA_1) refers to the formation of 1 mol of monovalent (1−) gaseous anions:

$$\text{Atom}(g) + e^- \longrightarrow \text{ion}^-(g) \quad \Delta E = EA_1$$

In most cases, *energy is released when the first electron is added* because it is attracted to the atom's nuclear charge. Thus, EA_1 is usually negative (just as ΔH for an exothermic reaction is negative).* The second electron affinity (EA_2), on the other hand, is always positive because energy must be *absorbed* in order to overcome electrostatic repulsions and add another electron to a negative ion.

Factors other than Z_{eff} and atomic size affect electron affinities, so trends are not as regular as those for the previous two properties. For instance, we might expect electron affinities to decrease smoothly down a group (smaller negative number) because the nucleus is farther away from an electron being added. But, as Figure 8.20 shows, only Group 1A(1) exhibits this behavior. We might also expect a regular increase in electron affinities across a period (larger negative number) because size decreases and the increasing Z_{eff} should attract the electron being added more strongly. An overall left-to-right increase in magnitude is there, but we certainly cannot say that it is a regular increase. These exceptions arise from changes in sublevel energy and in electron-electron repulsion.

1A (1)	2A (2)	3A (13)	4A (14)	5A (15)	6A (16)	7A (17)	8A (18)
H −72.8							He (0.0)
Li −59.6	Be ≤0	B −26.7	C −122	N +7	O −141	F −328	Ne (+29)
Na −52.9	Mg ≤0	Al −42.5	Si −134	P −72.0	S −200	Cl −349	Ar (+35)
K −48.4	Ca −2.37	Ga −28.9	Ge −119	As −78.2	Se −195	Br −325	Kr (+39)
Rb −46.9	Sr −5.03	In −28.9	Sn −107	Sb −103	Te −190	I −295	Xe (+41)
Cs −45.5	Ba −13.95	Tl −19.3	Pb −35.1	Bi −91.3	Po −183	At −270	Rn (+41)

Figure 8.20 Electron affinities of the main-group elements. The electron affinities (in kJ/mol) of the main-group elements are shown. Negative values indicate that energy is released when the anion forms. Positive values, which occur in Group 8A(18), indicate that energy is absorbed to form the anion; in fact, these anions are unstable and the values are estimated.

*Tables of first electron affinity often list them as positive if energy is *absorbed* to remove an electron from the anion. Keep this convention in mind when researching these values in reference texts. Electron affinities are difficult to measure, so values are frequently updated with more accurate data. Values for Group 2A(2) reflect recent changes.

Despite the irregularities, three key points emerge when we examine the relative values of ionization energy and electron affinity:

1. *Reactive nonmetals.* The elements in Groups 6A(16) and especially those in Group 7A(17) (halogens) have high ionization energies and highly negative (exothermic) electron affinities. These elements lose electrons with difficulty but attract them strongly. Therefore, *in their ionic compounds, they form negative ions.*
2. *Reactive metals.* The elements in Groups 1A(1) and 2A(2) have low ionization energies and slightly negative (exothermic) electron affinities. Both groups lose electrons readily but attract them only weakly, if at all. Therefore, *in their ionic compounds, they form positive ions.*
3. *Noble gases.* The elements in Group 8A(18) have very high ionization energies and slightly positive (endothermic) electron affinities. Therefore, *these elements tend* ***not*** *to lose or gain electrons.* In fact, only the larger members of the group (Kr, Xe, Rn) form any compounds at all.

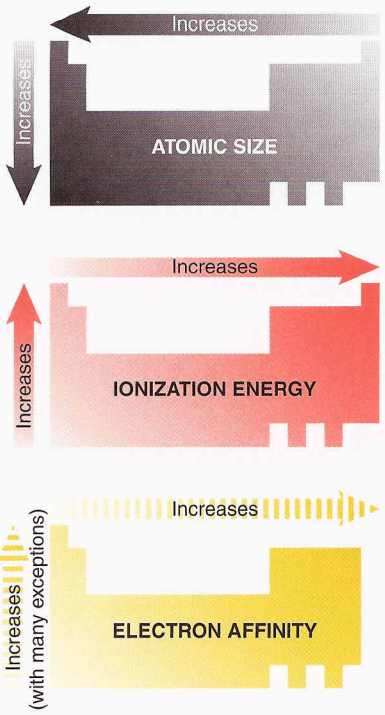

Figure 8.21 Trends in three atomic properties. Periodic trends are depicted as gradations in shading on miniature periodic tables, with arrows indicating the direction of general *increase* in a group or period. For electron affinity, Group 8A(18) is not shown, and the dashed arrows indicate the numerous exceptions to expected trends.

SECTION SUMMARY

Trends in three atomic properties are summarized in Figure 8.21. Atomic size increases down a main group and decreases across a period. Across a transition series, size remains relatively constant. First ionization energy (the energy required to remove the outermost electron from a mole of gaseous atoms) is inversely related to atomic size: IE_1 decreases down a main group and increases across a period. An element's successive ionization energies show a very large increase when the first inner (core) electron is removed. Electron affinity (the energy involved in adding an electron to a mole of gaseous atoms) shows many variations from expected trends. Based on the relative sizes of IEs and EAs, in their ionic compounds, the Group 1A(1) and 2A(2) elements tend to form cations, and the Group 6A(16) and 7A(17) elements tend to form anions.

8.5 ATOMIC STRUCTURE AND CHEMICAL REACTIVITY

Our main purpose for discussing atomic properties is, of course, to see how they affect element behavior. In this section, you'll see how the properties we just examined influence metallic behavior and determine the type of ion an element can form, as well as how electron configuration relates to magnetic properties.

Trends in Metallic Behavior

Metals are located in the left and lower three-quarters of the periodic table. They are typically shiny solids with moderate to high melting points, are good thermal and electrical conductors, can be drawn into wires and rolled into sheets, and tend to lose electrons to nonmetals. *Nonmetals* are located in the upper right quarter of the table. They are typically not shiny, have relatively low melting points, are poor thermal and electrical conductors, are crumbly or gaseous, and tend to gain electrons from metals. *Metalloids* are located in the region between the other two classes and have properties between them as well. Thus, *metallic behavior decreases left to right and increases top to bottom* in the periodic table (Figure 8.22).

It's important to realize, however, that an element's properties may not fall neatly into our categories. For instance, the nonmetal carbon in the form of graphite is a good electrical conductor. Iodine, another nonmetal, is a shiny solid. Gallium and cesium are metals that melt at temperatures below body temperature, and mercury is a liquid at room temperature. And iron is quite brittle. Despite such exceptions, we can make several generalizations about metallic behavior.

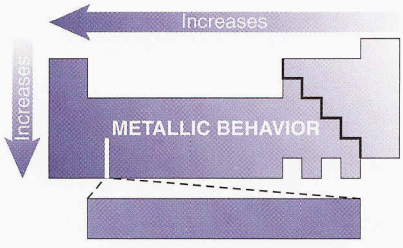

Figure 8.22 Trends in metallic behavior. The gradation in metallic behavior among the elements is depicted as a gradation in shading from bottom left to top right, with arrows showing the direction of increase. Elements that *behave* as metals appear in the left and lower three-quarters of the table. (Hydrogen appears next to helium in this periodic table.)

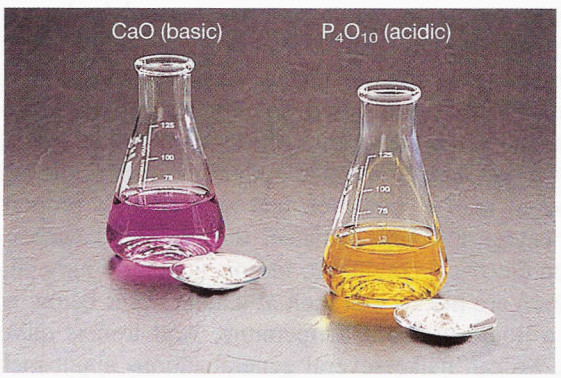
Relative Tendency to Lose Electrons Metals tend to lose electrons during chemical reactions because they have low ionization energies compared to nonmetals. The increase in metallic behavior down a group is most obvious in the physical and chemical behavior of the elements in Groups 3A(13) through 6A(16), which contain more than one class of element. For example, consider the elements in Group 5A(15), which appear vertically in Figure 8.23. Here, the change is so great that, with regard to monatomic ions, *elements at the top tend to form anions and those at the bottom tend to form cations*. Nitrogen (N) is a gaseous nonmetal, and phosphorus (P) is a solid nonmetal. Both occur occasionally as 3− anions in their compounds. Arsenic (As) and antimony (Sb) are metalloids, with Sb the more metallic of the two; neither forms ions readily. Bismuth (Bi), the largest member, is a typical metal, forming mostly ionic compounds in which it appears as a 3+ cation. Even in Group 2A(2), which consists entirely of metals, the tendency to form cations increases down the group. Beryllium (Be), for example, forms covalent compounds with nonmetals, whereas the compounds of barium (Ba) are ionic.

As we move across a period, it becomes more difficult to lose an electron (IE increases) and easier to gain one (EA becomes more negative). Therefore, with regard to monatomic ions, *elements at the left tend to form cations and those at the right tend to form anions*. The typical decrease in metallic behavior across a period is clear among the elements in Period 3, which appear horizontally in Figure 8.23. Sodium and magnesium are metals. Sodium is shiny when freshly cut under mineral oil, but it loses an electron so readily to O_2 that, if cut in air, its surface is coated immediately with a dull oxide. These metals exist naturally as Na^+ and Mg^{2+} ions in oceans, minerals, and organisms. Aluminum is metallic in its physical properties and forms the Al^{3+} ion in some compounds, but it bonds covalently in most others. Silicon (Si) is a shiny metalloid that does not occur as a monatomic ion. The most common form of phosphorus is a white, waxy nonmetal that, as noted above, forms the P^{3-} ion in a few compounds. Sulfur is a crumbly yellow nonmetal that forms the sulfide ion (S^{2-}) in many compounds. Diatomic chlorine (Cl_2) is a yellow-green, gaseous nonmetal that attracts electrons avidly and exists in nature as the Cl^- ion.

Acid-Base Behavior of the Element Oxides Metals are also distinguished from nonmetals by the acid-base behavior of their oxides in water:

- Most main-group metals *transfer* electrons to oxygen, so their *oxides are ionic. In water, these oxides act as bases,* producing OH^- ions and reacting with acids. Calcium oxide is an example (turns indicator pink; see photo below, *left*).
- Nonmetals *share* electrons with oxygen, so *nonmetal oxides are covalent. In water, they act as acids,* producing H^+ ions and reacting with bases. Tetraphosphorus decaoxide is an example (turns indicator yellow; see photo below, *right*).



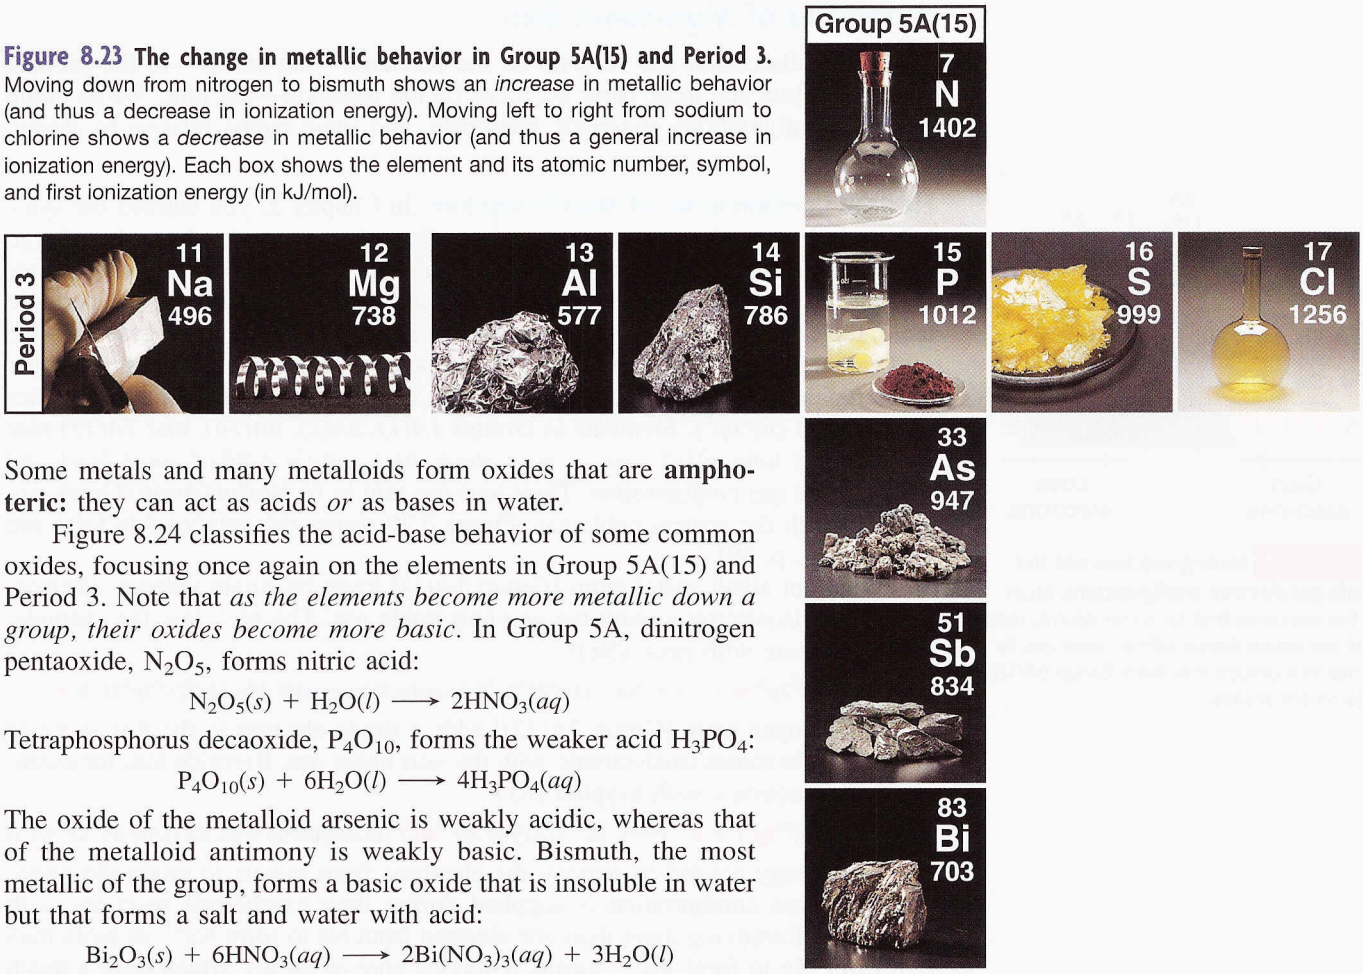


Figure 8.23 The change in metallic behavior in Group 5A(15) and Period 3. Moving down from nitrogen to bismuth shows an *increase* in metallic behavior (and thus a decrease in ionization energy). Moving left to right from sodium to chlorine shows a *decrease* in metallic behavior (and thus a general increase in ionization energy). Each box shows the element and its atomic number, symbol, and first ionization energy (in kJ/mol).

Some metals and many metalloids form oxides that are **amphoteric:** they can act as acids *or* as bases in water.

Figure 8.24 classifies the acid-base behavior of some common oxides, focusing once again on the elements in Group 5A(15) and Period 3. Note that *as the elements become more metallic down a group, their oxides become more basic.* In Group 5A, dinitrogen pentaoxide, N_2O_5, forms nitric acid:

$$N_2O_5(s) + H_2O(l) \longrightarrow 2HNO_3(aq)$$

Tetraphosphorus decaoxide, P_4O_{10}, forms the weaker acid H_3PO_4:

$$P_4O_{10}(s) + 6H_2O(l) \longrightarrow 4H_3PO_4(aq)$$

The oxide of the metalloid arsenic is weakly acidic, whereas that of the metalloid antimony is weakly basic. Bismuth, the most metallic of the group, forms a basic oxide that is insoluble in water but that forms a salt and water with acid:

$$Bi_2O_3(s) + 6HNO_3(aq) \longrightarrow 2Bi(NO_3)_3(aq) + 3H_2O(l)$$

Note that *as the elements become less metallic across a period, their oxides become more acidic.* In Period 3, sodium and magnesium form the strongly basic oxides Na_2O and MgO. Metallic aluminum forms amphoteric aluminum oxide (Al_2O_3), which reacts with acid or with base:

$$Al_2O_3(s) + 6HCl(aq) \longrightarrow 2AlCl_3(aq) + 3H_2O(l)$$

$$Al_2O_3(s) + 2NaOH(aq) + 3H_2O(l) \longrightarrow 2NaAl(OH)_4(aq)$$

Silicon dioxide is weakly acidic, forming a salt and water with base:

$$SiO_2(s) + 2NaOH(aq) \longrightarrow Na_2SiO_3(aq) + H_2O(l)$$

The common oxides of phosphorus, sulfur, and chlorine form acids of increasing strength: H_3PO_4, H_2SO_4, and $HClO_4$.

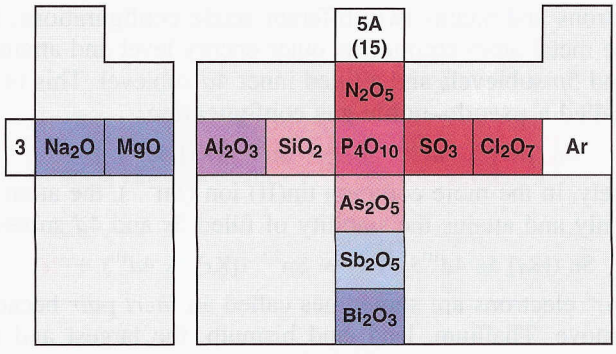

Figure 8.24 The trend in acid-base behavior of element oxides. The trend in acid-base behavior for some common oxides of Group 5A(15) and Period 3 elements is shown as a gradation in color (*red* = acidic; *blue* = basic). Note that the metals form basic oxides and the nonmetals form acidic oxides. Aluminum forms an oxide (*purple*) that can act as an acid or as a base. Thus, as atomic size increases, ionization energy decreases, and oxide basicity increases.

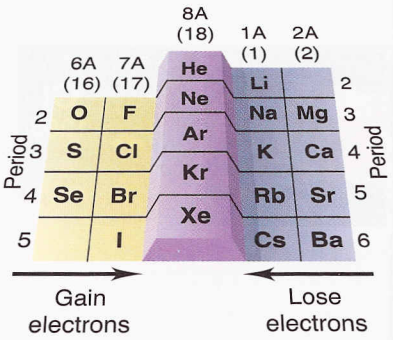

Figure 8.25 Main-group ions and the noble gas electron configurations. Most of the elements that form monatomic ions that are isoelectronic with a noble gas lie in the four groups that flank Group 8A(18), two on either side.

Properties of Monatomic Ions

So far our discussion has focused on the reactants—the atoms—in the process of electron loss and gain. Now we focus on the products—the ions. We examine electron configurations, magnetic properties, and ionic radius relative to atomic radius.

Electron Configurations of Main-Group Ions In Chapter 2, you learned the symbols and charges of many monatomic ions. But *why* does an ion have that charge in its compounds? Why is a sodium ion Na^+ and not Na^{2+}, and why is a fluoride ion F^- and not F^{2-}? For elements at the left and right ends of the periodic table, the explanation concerns the very low reactivity of the noble gases. As we said earlier, because they have high IEs and positive (endothermic) EAs, the noble gases typically do not form ions and remain chemically stable with a *filled* outer energy level (ns^2np^6). *Elements in Groups 1A(1), 2A(2), 6A(16), and 7A(17) that readily form ions either lose or gain electrons to attain a filled outer level and thus a noble gas configuration.* Their ions are said to be **isoelectronic** (Greek *iso,* "same") with the nearest noble gas. Figure 8.25 shows this relationship (also see Figure 2.14, p. 59).

When an alkali metal atom [Group 1A(1)] loses its single valence electron, it becomes isoelectronic with the *previous* noble gas. The Na^+ ion, for example, is isoelectronic with neon (Ne):

$$Na\ (1s^2 2s^2 2p^6 3s^1) \longrightarrow Na^+\ (1s^2 2s^2 2p^6)\ [\text{isoelectronic with Ne } (1s^2 2s^2 2p^6)] + e^-$$

When a halogen atom [Group 7A(17)] adds a single electron to the five in its *np* sublevel, it becomes isoelectronic with the *next* noble gas. Bromide ion, for example, is isoelectronic with krypton (Kr):

$$Br\ ([Ar]\ 4s^2 3d^{10} 4p^5) + e^- \longrightarrow Br^-\ ([Ar]\ 4s^2 3d^{10} 4p^6)\ [\text{isoelectronic with Kr } ([Ar]\ 4s^2 3d^{10} 4p^6)]$$

The energy needed to remove the electrons from metals to attain the previous noble gas configuration is supplied during their exothermic reactions with nonmetals. Removing more than one electron from Na to form Na^{2+} or more than two from Mg to form Mg^{3+} means removing core electrons, which have a much higher Z_{eff}, and overcoming the nucleus-electron attractions requires more energy than is available in a reaction. This is the reason that $NaCl_2$ and MgF_3 do *not* exist. Similarly, adding two electrons to F to form F^{2-} or three to O to form O^{3-} means placing the extra electron into the next energy level. With 18 electrons acting as inner electrons and shielding the nuclear charge very effectively, adding an electron to the negative ion, F^- or O^{2-}, requires too much energy. Thus, we never see Na_2F or Mg_3O_2.

The larger metals of Groups 3A(13), 4A(14), and 5A(15) form cations through a different process, because it would be energetically impossible for them to lose enough electrons to attain a noble gas configuration. For example, tin (Sn; $Z = 50$) would have to lose 14 electrons—two $5p$, ten $4d$, and two $5s$—to be isoelectronic with krypton (Kr; $Z = 36$), the previous noble gas. Instead, tin loses far fewer electrons and attains two different stable configurations. In the tin(IV) ion (Sn^{4+}), the metal atom empties its outer energy level and attains the stability of empty $5s$ and $5p$ sublevels and a filled inner $4d$ sublevel. This $(n-1)d^{10}$ configuration is called a **pseudo–noble gas configuration:**

$$Sn\ ([Kr]\ 5s^2 4d^{10} 5p^2) \longrightarrow Sn^{4+}\ ([Kr]\ 4d^{10}) + 4e^-$$

Alternatively, in the more common tin(II) ion (Sn^{2+}), the atom loses the two $5p$ electrons only and attains the stability of filled $5s$ and $4d$ sublevels:

$$Sn\ ([Kr]\ 5s^2 4d^{10} 5p^2) \longrightarrow Sn^{2+}\ ([Kr]\ 5s^2 4d^{10}) + 2e^-$$

The retained ns^2 electrons are sometimes called an *inert pair* because they seem difficult to remove. Thallium, lead, and bismuth, the largest and most metallic

members of Groups 3A(13) to 5A(15), commonly form ions that retain the ns^2 pair of electrons: Tl^+, Pb^{2+}, and Bi^{3+}.

Excessively high energy cost is also the reason that some elements do not form monatomic ions in any of their reactions. For instance, carbon would have to lose four electrons to form C^{4+} and attain the He configuration, or gain four to form C^{4-} and attain the Ne configuration, but neither ion forms. (Such multivalent ions *are* observed in the spectra of stars, however, where temperatures exceed 10^6 K.) As you'll see in Chapter 9, carbon and other atoms that do not form ions attain a filled shell by *sharing* electrons through covalent bonding.

SAMPLE PROBLEM 8.6 Writing Electron Configurations of Main-Group Ions

Problem Using condensed electron configurations, write reactions for the formation of the common ions of the following elements:

(a) Iodine ($Z = 53$) **(b)** Potassium ($Z = 19$) **(c)** Indium ($Z = 49$)

Plan We identify the element's position in the periodic table and recall two general points:

- Ions of elements in Groups 1A(1), 2A(2), 6A(16), and 7A(17) are typically isoelectronic with the nearest noble gas.
- Metals in Groups 3A(13) to 5A(15) can lose the *ns* and *np* electrons or just the *np* electrons.

Solution **(a)** Iodine is in Group 7A(17), so it gains one electron and is isoelectronic with xenon:

$$I\ ([Kr]\ 5s^2 4d^{10} 5p^5) + e^- \longrightarrow I^-\ ([Kr]\ 5s^2 4d^{10} 5p^6) \quad \text{(same as Xe)}$$

(b) Potassium is in Group 1A(1), so it loses one electron and is isoelectronic with argon:

$$K\ ([Ar]\ 4s^1) \longrightarrow K^+\ ([Ar]) + e^-$$

(c) Indium is in Group 3A(13), so it loses either three electrons to form In^{3+} (pseudo–noble gas configuration) or one to form In^+ (inert pair):

$$In\ ([Kr]\ 5s^2 4d^{10} 5p^1) \longrightarrow In^{3+}\ ([Kr]\ 4d^{10}) + 3e^-$$

$$In\ ([Kr]\ 5s^2 4d^{10} 5p^1) \longrightarrow In^+\ ([Kr]\ 5s^2 4d^{10}) + e^-$$

Check Be sure that the number of electrons in the ion's electron configuration, plus those gained or lost to form the ion, equals *Z*.

FOLLOW-UP PROBLEM 8.6 Using condensed electron configurations, write reactions showing the formation of the common ions of the following elements:

(a) Ba ($Z = 56$) **(b)** O ($Z = 8$) **(c)** Pb ($Z = 82$)

Electron Configurations of Transition Metal Ions In contrast to most main-group ions, *transition metal ions rarely attain a noble gas configuration,* and the reason, once again, is that energy costs are too high. The exceptions in Period 4 are scandium, which forms Sc^{3+}, and titanium, which occasionally forms Ti^{4+} in some compounds. The typical behavior of a transition element is to *form more than one cation by losing all of its ns and some of its (n − 1)d electrons.* (We focus here on the Period 4 series, but these points hold for Periods 5 and 6 also.)

In the aufbau process of building up the ground-state atoms, Period 3 ends with the noble gas argon. At the beginning of Period 4, the radial probability distribution of the 4*s* orbital near the nucleus makes it more stable than the empty 3*d*. Therefore, the first and second electrons added in the period enter the 4*s* in K and Ca. But, as soon as we reach the transition elements and the 3*d* orbitals begin to fill, the increasing nuclear charge attracts their electrons more and more strongly. Moreover, the added 3*d* electrons fill inner orbitals, so they are not very well shielded from the increasing nuclear charge by the 4*s* electrons. As a result,

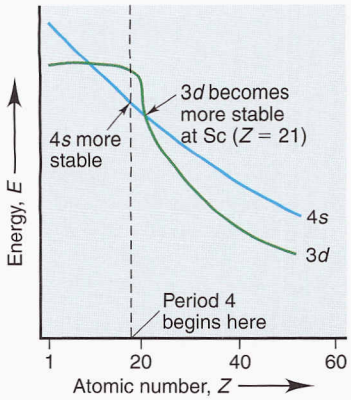

Figure 8.26 The Period 4 crossover in sublevel energies. The 3*d* orbitals are empty in elements at the beginning of Period 4. Because the 4*s* electron penetrates closer to the nucleus, the energy of the 4*s* orbital is lower in K and Ca; thus, the 4*s* fills before the 3*d*. But as the 3*d* orbitals fill, beginning with $Z = 21$, these inner electrons are attracted by the increasing nuclear charge, and they also shield the 4*s* electrons. As a result, there is an energy crossover, with the 3*d* sublevel becoming lower in energy than the 4*s*. For this reason, the 4*s* electrons are removed first when the transition metal ion forms. In other words,

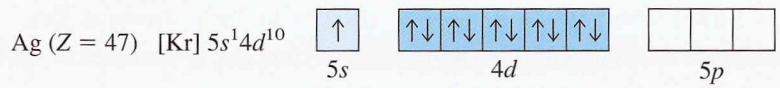
- For a main-group metal ion, the highest *n* level of electrons is "last-in, first-out."
- For a transition metal ion, the highest *n* level of electrons is "first-in, first out."

the 3*d* orbital becomes *more stable* than the 4*s*. In effect, a *crossover in orbital energy* occurs as we enter the transition series (Figure 8.26). The effect on ion formation is critical: because the 3*d* orbitals are more stable, *the 4s electrons are lost before the 3d electrons to form the Period 4 transition metal ions*. Thus, the 4*s* electrons are added before the 3*d* to form the atom but lost before the 3*d* to form the ion: "first-in, first-out."

To summarize, *electrons with the highest n value are removed first*. Here are a few simple rules for forming the ion of any main-group or transition element:

- For main-group, *s*-block metals, remove all electrons with the highest *n* value.
- For main-group, *p*-block metals, remove *np* electrons before *ns* electrons.
- For transition (*d*-block) metals, remove *ns* electrons before $(n - 1)d$ electrons.
- For nonmetals, add electrons to the *p* orbitals of highest *n* value.

Magnetic Properties of Transition Metal Ions If we can't see electrons in orbitals, how do we know that a particular electron configuration is correct? Although analysis of atomic spectra is the most important method for determining configuration, the magnetic properties of an element and its compounds can support or refute conclusions from spectra. Recall that electron spin generates a tiny magnetic field, which causes a beam of H atoms to split in an external magnetic field (see Figure 8.1). Only chemical species (atoms, ions, or molecules) with one or more *unpaired* electrons are affected by the external field. The species used in the original 1921 split-beam experiment was the silver atom:



Note the unpaired 5*s* electron. A beam of cadmium atoms, the element after silver, is not split because their 5*s* electrons are *paired* (Cd: [Kr] $5s^2 4d^{10}$).

A species with unpaired electrons exhibits **paramagnetism:** it is attracted by an external magnetic field. A species with all electrons paired exhibits **diamagnetism:** it is not attracted (and, in fact, is slightly repelled) by a magnetic field. Figure 8.27 shows how this magnetic behavior is studied. Many transition metals and their compounds are paramagnetic because their atoms and ions have unpaired electrons.

Let's see how studies of paramagnetism might be used to provide additional evidence for a proposed electron configuration. Spectral analysis of the titanium atom yields the configuration [Ar] $4s^2 3d^2$. Experiment shows that Ti metal is paramagnetic, which is consistent with the presence of unpaired electrons in its atoms. Spectral analysis of the Ti^{2+} ion yields the configuration [Ar] $3d^2$, indicating loss of the two 4*s* electrons. Once again, experiment supports these findings by show-

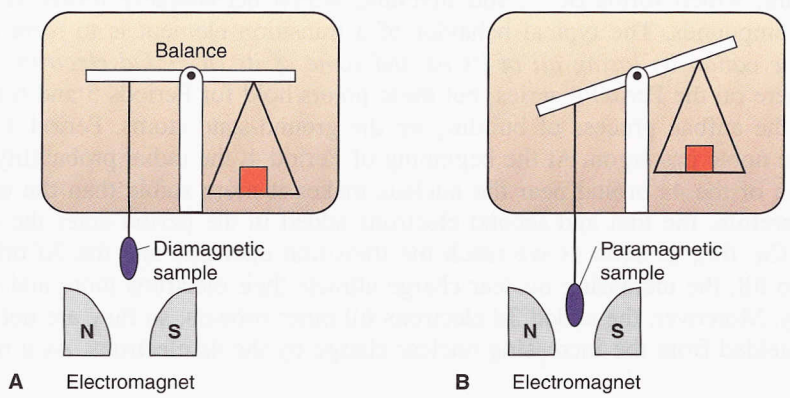


Figure 8.27 Apparatus for measuring the magnetic behavior of a sample. The substance is weighed on a very sensitive balance in the absence of an external magnetic field. **A,** If the substance is diamagnetic (has all *paired* electrons), its apparent mass is unaffected (or slightly reduced) when the magnetic field is "on." **B,** If the substance is paramagnetic (has *unpaired* electrons), its apparent mass increases when the field is "on" because the balance arm feels an additional force. This method is used to estimate the number of unpaired electrons in transition metal compounds.

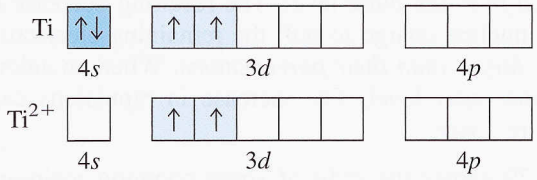
ing that Ti^{2+} compounds are paramagnetic. If Ti had lost its two $3d$ electrons during ion formation, its compounds would be diamagnetic because the $4s$ electrons are paired. Thus, the [Ar] $3d^2$ configuration supports the conclusion that electrons of highest n value are lost first:

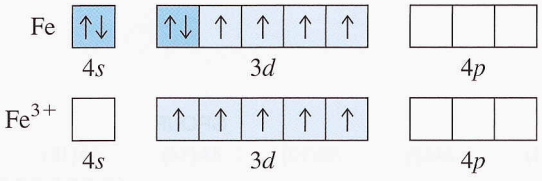
$$Ti\ ([Ar]\ 4s^2 3d^2) \longrightarrow Ti^{2+}\ ([Ar]\ 3d^2) + 2e^-$$

The partial orbital diagrams are



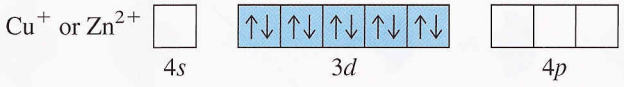
An increase in paramagnetism occurs when iron metal (Fe) forms Fe^{3+} compounds. This fact is consistent with Fe losing its $4s$ electrons and one of its paired $3d$ electrons:

$$Fe\ ([Ar]\ 4s^2 3d^6) \longrightarrow Fe^{3+}\ ([Ar]\ 3d^5) + 3e^-$$



Copper (Cu) is paramagnetic, but zinc (Zn) is diamagnetic, as are the Cu^+ and Zn^{2+} ions. These observations support the electron configurations proposed by spectral analysis. The two ions are isoelectronic:

$$Cu\ ([Ar]\ 4s^1 3d^{10}) \longrightarrow Cu^+\ ([Ar]\ 3d^{10}) + e^-$$
$$Zn\ ([Ar]\ 4s^2 3d^{10}) \longrightarrow Zn^{2+}\ ([Ar]\ 3d^{10}) + 2e^-$$



SAMPLE PROBLEM 8.7 Writing Electron Configurations and Predicting Magnetic Behavior of Transition Metal Ions

Problem Use condensed electron configurations to write the reaction for the formation of each transition metal ion, and predict whether the ion is paramagnetic:
(a) Mn^{2+} ($Z = 25$) **(b)** Cr^{3+} ($Z = 24$) **(c)** Hg^{2+} ($Z = 80$)

Plan We first write the condensed electron configuration of the atom, noting the irregularity for Cr in **(b)**. Then we remove electrons, beginning with ns electrons, to attain the ion charge. If unpaired electrons are present, the ion is paramagnetic.

Solution **(a)** $Mn\ ([Ar]\ 4s^2 3d^5) \longrightarrow Mn^{2+}\ ([Ar]\ 3d^5) + 2e^-$

There are five unpaired e^-, so Mn^{2+} is paramagnetic.

(b) $Cr\ ([Ar]\ 4s^1 3d^5) \longrightarrow Cr^{3+}\ ([Ar]\ 3d^3) + 3e^-$

There are three unpaired e^-, so Cr^{3+} is paramagnetic.

(c) $Hg\ ([Xe]\ 6s^2 4f^{14} 5d^{10}) \longrightarrow Hg^{2+}\ ([Xe]\ 4f^{14} 5d^{10}) + 2e^-$

There are no unpaired e^-, so Hg^{2+} is *not* paramagnetic (is diamagnetic).

Check We removed the ns electrons first, and the sum of the lost electrons and those in the electron configuration of the ion equals Z.

FOLLOW-UP PROBLEM 8.7 Write the condensed electron configuration of each transition metal ion, and predict whether it is paramagnetic:
(a) V^{3+} ($Z = 23$) **(b)** Ni^{2+} ($Z = 28$) **(c)** La^{3+} ($Z = 57$)

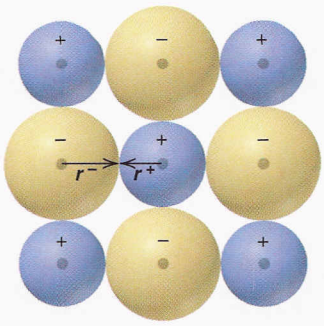


Figure 8.28 Depicting ionic radius. The cation radius (r^+) and the anion radius (r^-) each make up a portion of the total distance between the nuclei of adjacent ions in a crystalline ionic compound.

Ionic Size vs. Atomic Size The **ionic radius** is an estimate of the size of an ion in a crystalline ionic compound. You can picture it as one ion's portion of the distance between the nuclei of neighboring ions in the solid (Figure 8.28). From the relation between effective nuclear charge and atomic size, we can predict the size of an ion relative to its parent atom:

- *Cations are smaller than their parent atoms.* When a cation forms, electrons are *removed from* the outer level. The resulting decrease in electron repulsions allows the nuclear charge to pull the remaining electrons closer.
- *Anions are larger than their parent atoms.* When an anion forms, electrons are *added to* the outer level. The increase in repulsions causes the electrons to occupy more space.

Figure 8.29 shows the radii of some common main-group monatomic ions relative to their parent atoms. As you can see, *ionic size increases down a group* because the number of energy levels increases. Across a period, however, the pattern is more complex. Size decreases among the cations, then increases tremendously with the first of the anions, and finally decreases again among the anions.

Animation: Isoelectronic Series
Online Learning Center

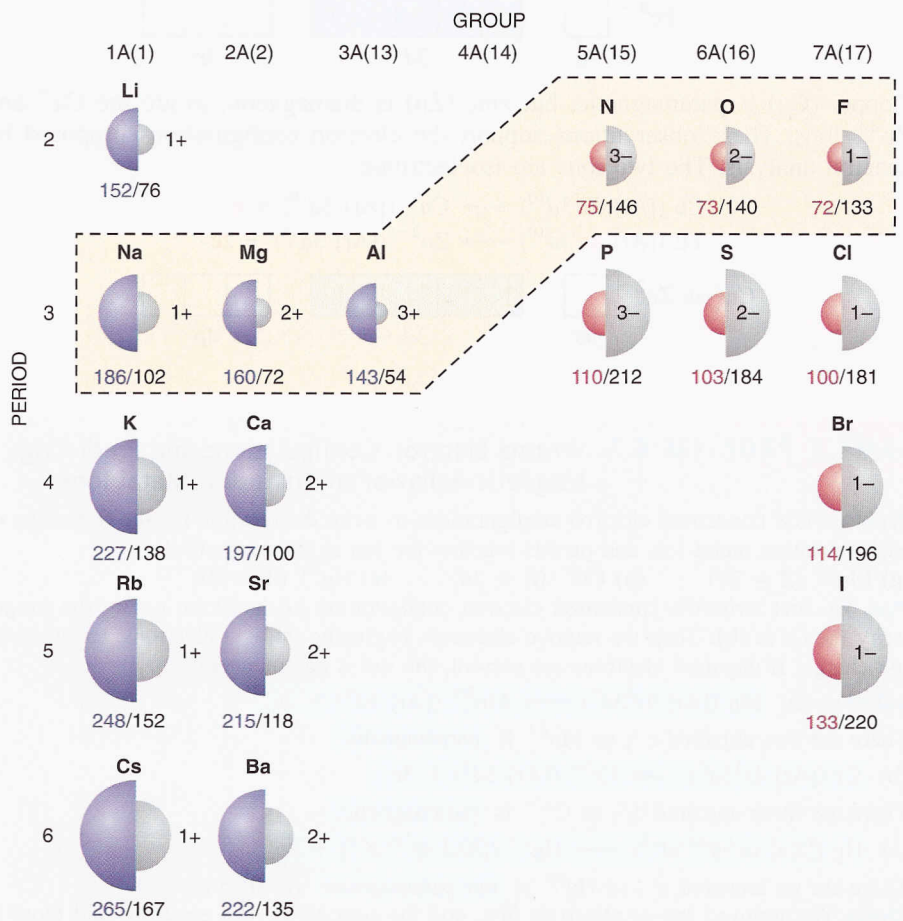

Figure 8.29 Ionic vs. atomic radii. The atomic radii (*colored half-spheres*) and ionic radii (*gray half-spheres*) of some main-group elements are arranged in periodic table format (with all radii values in picometers). Note that metal atoms (*blue*) form *smaller* positive ions, whereas nonmetal atoms (*red*) form *larger* negative ions. The dashed outline sets off ions of Period 2 nonmetals and Period 3 metals that are *isoelectronic* with neon. Note the size decrease from anions to cations.

This pattern results from changes in effective nuclear charge and electron-electron repulsions. In Period 3 (Na through Cl), for example, increasing Z_{eff} from left to right makes Na^+ larger than Mg^{2+}, which in turn is larger than Al^{3+}. The great jump in size from cations to anions occurs because we are *adding* electrons rather than removing them, so repulsions increase sharply. For instance, P^{3-} has eight more electrons than Al^{3+}. Then, the ongoing rise in Z_{eff} makes P^{3-} larger than S^{2-}, which is larger than Cl^-. These factors lead to some striking effects even among ions with the same number of electrons. Look at the ions within the dashed outline in Figure 8.29, which are all isoelectronic with neon. Even though the cations form from elements in the next period, the anions are still much larger. The pattern is

$$3- > 2- > 1- > 1+ > 2+ > 3+$$

When an element forms more than one cation, *the greater the ionic charge, the smaller the ionic radius*. Consider Fe^{2+} and Fe^{3+}. The number of protons is the same, but Fe^{3+} has one fewer electron, so electron repulsions are reduced somewhat. As a result, Z_{eff} increases, which pulls all the electrons closer, so Fe^{3+} is smaller than Fe^{2+}.

To summarize the main points,

- Ionic size increases down a group.
- Ionic size decreases across a period but increases from cations to anions.
- Ionic size decreases with increasing positive (or decreasing negative) charge in an isoelectronic series.
- Ionic size decreases as charge increases for different cations of a given element.

SAMPLE PROBLEM 8.8 Ranking Ions by Size

Problem Rank each set of ions in order of *decreasing* size, and explain your ranking:
(a) Ca^{2+}, Sr^{2+}, Mg^{2+} **(b)** K^+, S^{2-}, Cl^- **(c)** Au^+, Au^{3+}

Plan We find the position of each element in the periodic table and apply the ideas presented in the text.

Solution **(a)** Since Mg^{2+}, Ca^{2+}, and Sr^{2+} are all from Group 2A(2), they decrease in size up the group: $Sr^{2+} > Ca^{2+} > Mg^{2+}$.

(b) The ions K^+, S^{2-}, and Cl^- are isoelectronic. S^{2-} has a lower Z_{eff} than Cl^-, so it is larger. K^+ is a cation, and has the highest Z_{eff}, so it is smallest: $S^{2-} > Cl^- > K^+$.

(c) Au^+ has a lower charge than Au^{3+}, so it is larger: $Au^+ > Au^{3+}$.

FOLLOW-UP PROBLEM 8.8 Rank the ions in each set in order of *increasing* size:
(a) Cl^-, Br^-, F^- **(b)** Na^+, Mg^{2+}, F^- **(c)** Cr^{2+}, Cr^{3+}

SECTION SUMMARY

Highly metallic behavior correlates with large atomic size and low ionization energy. Thus, metallic behavior increases down a group and decreases across a period. Within the main groups, metal oxides are basic and nonmetal oxides acidic. Thus, oxides become more acidic across a period and more basic down a group. Many main-group elements form ions that are isoelectronic with the nearest noble gas. Removing (or adding) more electrons than needed to attain the previous noble gas configuration requires a prohibitive amount of energy. Metals in Groups 3A(13) to 5A(15) lose either their *np* electrons or both their *ns* and *np* electrons. Transition metals lose *ns* electrons before $(n - 1)d$ electrons and commonly form more than one ion. Many transition metals and their compounds are paramagnetic because their atoms (or ions) have unpaired electrons. Cations are smaller and anions larger than their parent atoms. Ionic radius increases down a group. Across a period, cationic and anionic radii decrease, but a large increase occurs from cations to anions.

Chapter Perspective

This chapter is our springboard to understanding the chemistry of the elements. We have begun to see that recurring electron configurations lead to trends in atomic properties, which in turn lead to trends in chemical behavior. With this insight, we can go on to investigate how atoms bond (Chapter 9), how molecular shapes arise (Chapter 10), how molecular shapes and other properties can be explained using certain models (Chapter 11), how the physical properties of liquids and solids emerge from atomic properties (Chapter 12), and how those properties influence the solution process (Chapter 13). We will briefly review these ideas and gain a perspective on where they lead (Interchapter) before we can survey elemental behavior in greater detail (Chapter 14) and see how it applies to the remarkable diversity of organic compounds (Chapter 15). Within this group of chapters, you will see chemical models come alive in chemical facts.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The meaning of the periodic law and the arrangement of elements by atomic number (8.1)
2. The reason for the spin quantum number and its two possible values (8.2)
3. How the exclusion principle applies to orbital filling (8.2)
4. The effects of nuclear charge, shielding, and penetration on the splitting of orbital energies; the meaning of effective nuclear charge (8.2)
5. How the order in the periodic table is based on the order of orbital energies (8.3)
6. How orbitals are filled in main-group and transition elements; the importance of Hund's rule (8.3)
7. How outer electron configuration within a group is related to chemical behavior (8.3)
8. The distinction among inner, outer, and valence electrons (8.3)
9. The meaning of atomic radius, ionization energy, and electron affinity (8.4)
10. How n value and effective nuclear charge give rise to the periodic trends of atomic size and ionization energy (8.4)
11. The importance of core electrons to the pattern of successive ionization energies (8.4)
12. How atomic properties are related to the tendency to form ions (8.4)
13. The general properties of metals and nonmetals (8.5)
14. How the vertical and horizontal trends in metallic behavior are related to ion formation and oxide acidity (8.5)
15. Why main-group ions are either isoelectronic with the nearest noble gas or have a pseudo–noble gas electron configuration (8.5)
16. Why transition elements lose ns electrons first (8.5)
17. The origin of paramagnetic and diamagnetic behavior (8.5)
18. The relation between ionic and atomic size and the trends in ionic size (8.5)

Master These Skills

1. Using orbital diagrams to determine the set of quantum numbers for any electron in an atom (SP 8.1)
2. Writing full and condensed electron configurations of an element (SP 8.2)
3. Using periodic trends to rank elements by atomic size and first ionization energy (SPs 8.3 and 8.4)
4. Identifying an element from its successive ionization energies (SP 8.5)
5. Writing electron configurations of main-group and transition metal ions (SPs 8.6 and 8.7)
6. Using periodic trends to rank ions by relative size (SP 8.8)

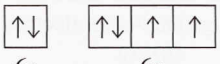
Brief Solutions to Follow-up Problems

8.1 The element has eight electrons, so $Z = 8$: oxygen.
Sixth electron: $n = 2, l = 1, m_l = 0, m_s = +\frac{1}{2}$

8.2 (a) For Ni, $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^8$; [Ar] $4s^2 3d^8$

Ni has 18 inner electrons.
(b) For Sr, $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^{10} 4p^6 5s^2$; [Kr] $5s^2$

Sr has 36 inner electrons.
(c) For Po, $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^{10} 4p^6 5s^2 4d^{10} 5p^6 6s^2 4f^{14} 5d^{10} 6p^4$; [Xe] $6s^2 4f^{14} 5d^{10} 6p^4$



Po has 78 inner electrons.

8.3 (a) Cl < Br < Se; (b) Xe < I < Ba
8.4 (a) Sn < Sb < I; (b) Ba < Sr < Ca
8.5 Q is aluminum: $1s^2 2s^2 2p^6 3s^2 3p^1$
8.6 (a) Ba ([Xe] $6s^2$) $\longrightarrow$ Ba^{2+} ([Xe]) + $2e^-$
(b) O ([He] $2s^2 2p^4$) + $2e^-$ $\longrightarrow$ O^{2-} ([He] $2s^2 2p^6$) (same as Ne)
(c) Pb ([Xe] $6s^2 4f^{14} 5d^{10} 6p^2$) $\longrightarrow$ Pb^{2+} ([Xe] $6s^2 4f^{14} 5d^{10}$) + $2e^-$
Pb ([Xe] $6s^2 4f^{14} 5d^{10} 6p^2$) $\longrightarrow$ Pb^{4+} ([Xe] $4f^{14} 5d^{10}$) + $4e^-$
8.7 (a) V^{3+}: [Ar] $3d^2$; paramagnetic
(b) Ni^{2+}: [Ar] $3d^8$; paramagnetic
(c) La^{3+}: [Xe]; not paramagnetic (diamagnetic)
8.8 (a) $F^- < Cl^- < Br^-$; (b) $Mg^{2+} < Na^+ < F^-$;
(c) $Cr^{3+} < Cr^{2+}$

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Development of the Periodic Table

Concept Review Questions

8.1 What would be your reaction to a claim that a new element had been discovered and it fit between tin (Sn) and antimony (Sb) in the periodic table?

8.2 Based on results of his study of atomic x-ray spectra, Moseley discovered a relationship that replaced atomic mass as the criterion for ordering the elements. By what criterion are the elements now ordered in the periodic table? Give an example of a sequence of element order that was confirmed by Moseley's findings.

Skill-Building Exercises *(grouped in similar pairs)*

8.3 Before Mendeleev published his periodic table, Döbereiner grouped similar elements into triads, in which the unknown properties of one member could be predicted by averaging known values of the properties of the others. To test this idea, predict the values of the following quantities:
(a) The atomic mass of K from the atomic masses of Na and Rb
(b) The melting point of Br_2 from the melting points of Cl_2 (−101.0°C) and I_2 (113.6°C) (actual value = −7.2°C)

8.4 To test Döbereiner's idea (Problem 8.3), predict:
(a) The boiling point of HBr from the boiling points of HCl (−84.9°C) and HI (−35.4°C) (actual value = −67.0°C)
(b) The boiling point of AsH_3 from the boiling points of PH_3 (−87.4°C) and SbH_3 (−17.1°C) (actual value = −55°C)

Characteristics of Many-Electron Atoms

Concept Review Questions

8.5 Summarize the rules for the allowable values of the four quantum numbers of an electron in an atom.

8.6 Which of the quantum numbers relate(s) to the electron only? Which relate(s) to the orbital?

8.7 State the exclusion principle. What does it imply about the number and spin of electrons in an atomic orbital?

8.8 What is the key distinction between sublevel energies in one-electron species, such as the H atom, and those in many-electron species, such as the C atom? What factors lead to this distinction? Would you expect the pattern of sublevel energies in Be^{3+} to be more like that in H or that in C? Explain.

8.9 Define *shielding* and *effective nuclear charge*. What is the connection between the two?

8.10 What is the penetration effect? How is it related to shielding? Use the penetration effect to explain the difference in relative orbital energies of a 3*p* and a 3*d* electron in the same atom.

Skill-Building Exercises *(grouped in similar pairs)*

8.11 How many electrons in an atom can have each of the following quantum number or sublevel designations?
(a) $n = 2, l = 1$ (b) 3*d* (c) 4*s*

8.12 How many electrons in an atom can have each of the following quantum number or sublevel designations?
(a) $n = 2, l = 1, m_l = 0$ (b) 5*p* (c) $n = 4, l = 3$

8.13 How many electrons in an atom can have each of the following quantum number or sublevel designations?
(a) 4*p* (b) $n = 3, l = 1, m_l = +1$ (c) $n = 5, l = 3$

8.14 How many electrons in an atom can have each of the following quantum number or sublevel designations?
(a) 2*s* (b) $n = 3, l = 2$ (c) 6*d*

The Quantum-Mechanical Model and the Periodic Table

(Sample Problems 8.1 and 8.2)

Concept Review Questions

8.15 State the periodic law, and explain its relation to electron configuration. (Use Na and K in your explanation.)

8.16 State Hund's rule in your own words, and show its application in the orbital diagram of the nitrogen atom.

8.17 How does the aufbau principle, in connection with the periodic law, lead to the format of the periodic table?

8.18 For main-group elements, are outer electron configurations similar or different within a group? Within a period? Explain.

8.19 For which blocks of elements are outer electrons the same as valence electrons? For which are *d* electrons often included among valence electrons?

8.20 What is the electron capacity of the *n*th energy level? What is the capacity of the fourth energy level?

Skill-Building Exercises *(grouped in similar pairs)*

8.21 Write a full set of quantum numbers for the following:
(a) The outermost electron in an Rb atom
(b) The electron gained when an S^- ion becomes an S^{2-} ion
(c) The electron lost when an Ag atom ionizes
(d) The electron gained when an F^- ion forms from an F atom

8.22 Write a full set of quantum numbers for the following:
(a) The outermost electron in an Li atom
(b) The electron gained when a Br atom becomes a Br^- ion
(c) The electron lost when a Cs atom ionizes
(d) The highest energy electron in the ground-state B atom

8.23 Write the full ground-state electron configuration for each:
(a) Rb (b) Ge (c) Ar

8.24 Write the full ground-state electron configuration for each:
(a) Br (b) Mg (c) Se

8.25 Write the full ground-state electron configuration for each:
(a) Cl (b) Si (c) Sr

8.26 Write the full ground-state electron configuration for each:
(a) S (b) Kr (c) Cs

8.27 Draw an orbital diagram showing valence electrons, and write the condensed ground-state electron configuration for each:
(a) Ti (b) Cl (c) V

8.28 Draw an orbital diagram showing valence electrons, and write the condensed ground-state electron configuration for each:
(a) Ba (b) Co (c) Ag

8.29 Draw an orbital diagram showing valence electrons, and write the condensed ground-state electron configuration for each:
(a) Mn (b) P (c) Fe

8.30 Draw an orbital diagram showing valence electrons, and write the condensed ground-state electron configuration for each:
(a) Ga (b) Zn (c) Sc

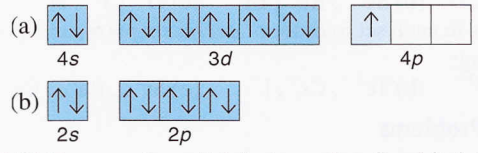
8.31 Draw the partial (valence-level) orbital diagram, and write the symbol, group number, and period number of the element:
(a) [He] $2s^2 2p^4$ (b) [Ne] $3s^2 3p^3$

8.32 Draw the partial (valence-level) orbital diagram, and write the symbol, group number, and period number of the element:
(a) [Kr] $5s^2 4d^{10}$ (b) [Ar] $4s^2 3d^8$

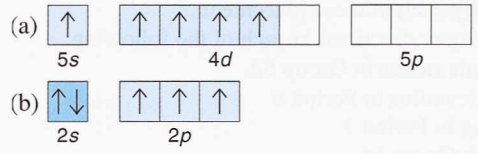
8.33 Draw the partial (valence-level) orbital diagram, and write the symbol, group number, and period number of the element:
(a) [Ne] $3s^2 3p^5$ (b) [Ar] $4s^2 3d^{10} 4p^3$

8.34 Draw the partial (valence-level) orbital diagram, and write the symbol, group number, and period number of the element:
(a) [Ar] $4s^2 3d^5$ (b) [Kr] $5s^2 4d^2$

8.35 From each partial (valence-level) orbital diagram, write the ground-state electron configuration and group number:



8.36 From each partial (valence-level) orbital diagram, write the ground-state electron configuration and group number:



8.37 How many inner, outer, and valence electrons are present in an atom of each of the following elements?
(a) O (b) Sn (c) Ca (d) Fe (e) Se

8.38 How many inner, outer, and valence electrons are present in an atom of each of the following elements?
(a) Br (b) Cs (c) Cr (d) Sr (e) F

8.39 Identify each element below, and give the symbols of the other elements in its group:
(a) [He] $2s^2 2p^1$ (b) [Ne] $3s^2 3p^4$ (c) [Xe] $6s^2 5d^1$

8.40 Identify each element below, and give the symbols of the other elements in its group:
(a) [Ar] $4s^2 3d^{10} 4p^4$ (b) [Xe] $6s^2 4f^{14} 5d^2$ (c) [Ar] $4s^2 3d^5$

8.41 Identify each element below, and give the symbols of the other elements in its group:
(a) [He] $2s^2 2p^2$ (b) [Ar] $4s^2 3d^3$ (c) [Ne] $3s^2 3p^3$

8.42 Identify each element below, and give the symbols of the other elements in its group:
(a) [Ar] $4s^2 3d^{10} 4p^2$ (b) [Ar] $4s^2 3d^7$ (c) [Kr] $5s^2 4d^5$

Problems in Context

8.43 After an atom in its ground state absorbs energy, it exists in an excited state. Spectral lines are produced when the atom returns to its ground state. The yellow-orange line in the sodium spectrum, for example, is produced by the emission of energy when excited sodium atoms return to their ground state. Write the electron configuration and the orbital diagram of the first excited state of sodium. (*Hint:* The outermost electron is excited.)

8.44 One reason spectroscopists study excited states is to gain information about the energies of orbitals that are unoccupied in an atom's ground state. Each of the following electron configurations represents an atom in an excited state. Identify the element, and write its condensed ground-state configuration:
(a) $1s^2 2s^2 2p^6 3s^1 3p^1$ (b) $1s^2 2s^2 2p^6 3s^2 3p^4 4s^1$
(c) $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^4 4p^1$ (d) $1s^2 2s^2 2p^5 3s^1$

Trends in Three Key Atomic Properties

(Sample Problems 8.3 to 8.5)

Concept Review Questions

8.45 If the exact outer limit of an isolated atom cannot be measured, what criterion can we use to determine atomic radii? What is the difference between a covalent radius and a metallic radius?

8.46 Explain the relationship between the trends in atomic size and in ionization energy within the main groups.

8.47 In what region of the periodic table will you find elements with relatively high IEs? With relatively low IEs?

8.48 Why do successive IEs of a given element always increase? When the difference between successive IEs of a given element is exceptionally large (for example, between IE_1 and IE_2 of K), what do we learn about its electron configuration?

8.49 In a plot of IE_1 for the Period 3 elements (see Figure 8.17, p. 309), why do the values for elements in Groups 3A(13) and 6A(16) drop slightly below the generally increasing trend?

8.50 Which group in the periodic table has elements with high (endothermic) IE_1 and very negative (exothermic) first electron affinities (EA_1)? Give the charge on the ions these atoms form.

8.51 The EA_2 of an oxygen atom is positive, even though its EA_1 is negative. Why does this change of sign occur? Which other elements exhibit a positive EA_2? Explain.

8.52 How does *d*-electron shielding influence atomic size among the Period 4 transition elements?

Skill-Building Exercises *(grouped in similar pairs)*

8.53 Arrange each set in order of *increasing* atomic size:
(a) Rb, K, Cs (b) C, O, Be (c) Cl, K, S (d) Mg, K, Ca

8.54 Arrange each set in order of *decreasing* atomic size:
(a) Ge, Pb, Sn (b) Sn, Te, Sr (c) F, Ne, Na (d) Be, Mg, Na

8.55 Arrange each set of atoms in order of *increasing* IE_1:
(a) Sr, Ca, Ba (b) N, B, Ne (c) Br, Rb, Se (d) As, Sb, Sn

8.56 Arrange each set of atoms in order of *decreasing* IE_1:
(a) Na, Li, K (b) Be, F, C (c) Cl, Ar, Na (d) Cl, Br, Se

8.57 Write the full electron configuration of the Period 2 element with the following successive IEs (in kJ/mol):
$IE_1 = 801$ $IE_2 = 2427$ $IE_3 = 3659$
$IE_4 = 25{,}022$ $IE_5 = 32{,}822$

8.58 Write the full electron configuration of the Period 3 element with the following successive IEs (in kJ/mol):
$IE_1 = 738$ $IE_2 = 1450$ $IE_3 = 7732$
$IE_4 = 10{,}539$ $IE_5 = 13{,}628$

8.59 Which element in each of the following sets would you expect to have the *highest* IE_2?
(a) Na, Mg, Al (b) Na, K, Fe (c) Sc, Be, Mg

8.60 Which element in each of the following sets would you expect to have the *lowest* IE_3?
(a) Na, Mg, Al (b) K, Ca, Sc (c) Li, Al, B

Atomic Structure and Chemical Reactivity

(Sample Problems 8.6 to 8.8)

Concept Review Questions

8.61 List three ways in which metals and nonmetals differ.

8.62 Summarize the trend in metallic character as a function of position in the periodic table. Is it the same as the trend in atomic size? Ionization energy?

8.63 Summarize the acid-base behavior of the main-group metal and nonmetal oxides in water. How does oxide acidity in water change down a group and across a period?

8.64 What ions are possible for the two largest elements in Group 4A(14)? How does each arise?

8.65 What is a pseudo–noble gas configuration? Give an example of one ion from Group 3A(13) that has it.

8.66 How are measurements of paramagnetism used to support electron configurations derived spectroscopically? Use Cu(I) and Cu(II) chlorides as examples.

8.67 The charges of a set of isoelectronic ions vary from 3+ to 3−. Place the ions in order of increasing size.

Skill-Building Exercises *(grouped in similar pairs)*

8.68 Which element would you expect to be *more* metallic?
(a) Ca or Rb (b) Mg or Ra (c) Br or I

8.69 Which element would you expect to be *more* metallic?
(a) S or Cl (b) In or Al (c) As or Br

8.70 Which element would you expect to be *less* metallic?
(a) Sb or As (b) Si or P (c) Be or Na

8.71 Which element would you expect to be *less* metallic?
(a) Cs or Rn (b) Sn or Te (c) Se or Ge

8.72 Does the reaction of a main-group nonmetal oxide in water produce an acidic or a basic solution? Write a balanced equation for the reaction of a Group 6A(16) nonmetal oxide with water.

8.73 Does the reaction of a main-group metal oxide in water produce an acidic solution or a basic solution? Write a balanced equation for the reaction of a Group 2A(2) oxide with water.

8.74 Write the charge and full ground-state electron configuration of the monatomic ion most likely to be formed by each:
(a) Cl (b) Na (c) Ca

8.75 Write the charge and full ground-state electron configuration of the monatomic ion most likely to be formed by each:
(a) Rb (b) N (c) Br

8.76 Write the charge and full ground-state electron configuration of the monatomic ion most likely to be formed by each:
(a) Al (b) S (c) Sr

8.77 Write the charge and full ground-state electron configuration of the monatomic ion most likely to be formed by each:
(a) P (b) Mg (c) Se

8.78 How many unpaired electrons are present in the ground state of an atom from each of the following groups?
(a) 2A(2) (b) 5A(15) (c) 8A(18) (d) 3A(13)

8.79 How many unpaired electrons are present in the ground state of an atom from each of the following groups?
(a) 4A(14) (b) 7A(17) (c) 1A(1) (d) 6A(16)

8.80 Which of these are paramagnetic in their ground state?
(a) Ga (b) Si (c) Be (d) Te

8.81 Are compounds of these ground-state ions paramagnetic?
(a) Ti^{2+} (b) Zn^{2+} (c) Ca^{2+} (d) Sn^{2+}

8.82 Write the condensed ground-state electron configurations of these transition metal ions, and state which are paramagnetic:
(a) V^{3+} (b) Cd^{2+} (c) Co^{3+} (d) Ag^{+}

8.83 Write the condensed ground-state electron configurations of these transition metal ions, and state which are paramagnetic:
(a) Mo^{3+} (b) Au^{+} (c) Mn^{2+} (d) Hf^{2+}

8.84 Palladium (Pd; $Z = 46$) is diamagnetic. Draw partial orbital diagrams to show which of the following electron configurations is consistent with this fact:
(a) [Kr] $5s^2 4d^8$ (b) [Kr] $4d^{10}$ (c) [Kr] $5s^1 4d^9$

8.85 Niobium (Nb; $Z = 41$) has an anomalous ground-state electron configuration for a Group 5B(5) element: [Kr] $5s^1 4d^4$. What is the expected electron configuration for elements in this group? Draw partial orbital diagrams to show how paramagnetic measurements could support niobium's actual configuration.

8.86 Rank the ions in each set in order of *increasing* size, and explain your ranking:
(a) Li^+, K^+, Na^+ (b) Se^{2-}, Rb^+, Br^- (c) O^{2-}, F^-, N^{3-}

8.87 Rank the ions in each set in order of *decreasing* size, and explain your ranking:
(a) Se^{2-}, S^{2-}, O^{2-} (b) Te^{2-}, Cs^+, I^- (c) Sr^{2+}, Ba^{2+}, Cs^+

Comprehensive Problems

8.88 Some versions of the periodic table show hydrogen at the top of Group 1A(1) *and* at the top of Group 7A(17). What properties of hydrogen justify each of these placements?

8.89 Name the element described in each of the following:
(a) Smallest atomic radius in Group 6A
(b) Largest atomic radius in Period 6
(c) Smallest metal in Period 3
(d) Highest IE_1 in Group 14
(e) Lowest IE_1 in Period 5
(f) Most metallic in Group 15
(g) Group 3A element that forms the most basic oxide
(h) Period 4 element with filled outer level
(i) Condensed ground-state electron configuration is [Ne] $3s^2 3p^2$
(j) Condensed ground-state electron configuration is [Kr] $5s^2 4d^6$
(k) Forms 2+ ion with electron configuration [Ar] $3d^3$
(l) Period 5 element that forms 3+ ion with pseudo–noble gas configuration
(m) Period 4 transition element that forms 3+ diamagnetic ion
(n) Period 4 transition element that forms 2+ ion with a half-filled *d* sublevel
(o) Heaviest lanthanide
(p) Period 3 element whose 2− ion is isoelectronic with Ar
(q) Alkaline earth metal whose cation is isoelectronic with Kr
(r) Group 5A(15) metalloid with the most acidic oxide

8.90 Use electron configurations to account for the stability of the lanthanide ions Ce^{4+} and Eu^{2+}.

8.91 The NaCl crystal structure consists of alternating Na^+ and Cl^- ions lying next to each other in three dimensions. If the Na^+ radius is 56.4% of the Cl^- radius and the distance between Na^+ nuclei is 566 pm, what are the radii of the two ions?

8.92 When a nonmetal oxide reacts with water, it forms an oxoacid with the same nonmetal oxidation state. Give the name and formula of the oxide used to prepare each of these oxoacids: (a) hypochlorous acid; (b) chlorous acid; (c) chloric acid; (d) perchloric acid; (e) sulfuric acid; (f) sulfurous acid; (g) nitric acid; (h) nitrous acid; (i) carbonic acid; (j) phosphoric acid.

8.93 A fundamental relationship of electrostatics states that the energy required to separate opposite charges of magnitudes Q_1 and Q_2 that are the distance d apart is proportional to $\frac{Q_1 \times Q_2}{d}$. Use this relationship and any other factors to explain these observations: (a) the IE_2 of He ($Z = 2$) is *more* than twice the IE_1 of H ($Z = 1$); (b) the IE_1 of He is *less* than twice the IE_1 of H.

8.94 The energy difference between the 5*d* and 6*s* sublevels in gold accounts for its color. Assuming this energy difference is about 2.7 eV (electron volt; 1 eV = 1.602×10^{-19} J), explain why gold has a warm yellow color.

8.95 Write the formula and name of the compound formed from the following ionic interactions: (a) The 2+ ion and the 1− ion are both isoelectronic with the atoms of a chemically unreactive Period 4 element. (b) The 2+ ion and the 2− ion are both isoelectronic with the Period 3 noble gas. (c) The 2+ ion is the smallest with a filled *d* subshell; the anion forms from the smallest halogen. (d) The ions form from the largest and smallest ionizable atoms in Period 2.

8.96 For over a century, chemists have noted several "diagonal relationships" in the periodic table: exceptional similarities between an element in Period 2 and another in Period 3 in the next higher group. Suggest a reason based on atomic and ionic properties for each of the following: (a) the chemical behavior of Li is very similar to that of Mg; (b) the acidity of $Be(OH)_2$ is very similar to that of $Al(OH)_3$.

8.97 The energy changes for many unusual reactions can be determined using Hess's law (Section 6.5).
(a) Calculate ΔE for the conversion of $F^-(g)$ into $F^+(g)$.
(b) Calculate ΔE for the conversion of $Na^+(g)$ into $Na^-(g)$.

8.98 Use Table 8.5, p. 311, to explain the major differences in the relative values of IE_1 through IE_5 for carbon and oxygen.

8.99 The hot glowing gases around the Sun, the *corona*, can reach millions of degrees Celsius, high enough to remove many electrons from gaseous atoms. Iron ions with charges as high as 14+ have been observed in the corona. Which ions from Fe^+ to Fe^{14+} are paramagnetic? Which would be most attracted to a magnetic field?

8.100 There are some exceptions to the trends of first and successive ionization energies. For each of the following pairs, explain which ionization energy would be higher:
(a) IE_1 of Ga or IE_1 of Ge
(b) IE_2 of Ga or IE_2 of Ge
(c) IE_3 of Ga or IE_3 of Ge
(d) IE_4 of Ga or IE_4 of Ge

8.101 The photoelectric effect is based on the ability of light to ionize metal atoms. Use Figure 8.18, p. 310, to answer: (a) Calculate the longest wavelength of electromagnetic (EM) radiation that can ionize any alkali metal. (b) Calculate the longest wavelength of EM radiation that can ionize any alkaline earth metal. (c) Which elements, other than the alkali and alkaline earth metals, could also be ionized by the radiation from part (b)? (d) In which region of the EM spectrum are these photons found?

8.102 Half of the first 18 elements have an odd number of electrons, and half have an even number. Show why these elements aren't half paramagnetic and half diamagnetic.

8.103 Scientists have speculated that as yet unknown superheavy elements might be moderately stable. In fact, in 1976, it was mistakenly believed that Element 126 had been discovered in a sample of mica. Predict the n and l quantum numbers for the outermost electron in an atom of this element. What is the sublevel designation of the outermost orbital? How many orbitals would be in this sublevel?

8.104 Two members of the boron family owe their names to bright lines in their emission spectra. Indium has a bright indigo-blue line (451.1 nm), and thallium has a bright green line (535.0 nm) (*thallus* means "green stalk"). What are the energies of these two spectral lines?

8.105 Like main-group metal oxides, transition metal oxides are basic, but this is not obvious in water because of their low solubility. They do, however, react with acids. Complete and write balanced molecular equations for the following reactions:
(a) Iron(II) oxide and hydrochloric acid
(b) Chromium(III) oxide and nitric acid
(c) Cobalt(III) oxide and sulfuric acid
(d) Copper(I) oxide and hydrobromic acid
(e) Manganese(II) oxide and phosphoric acid

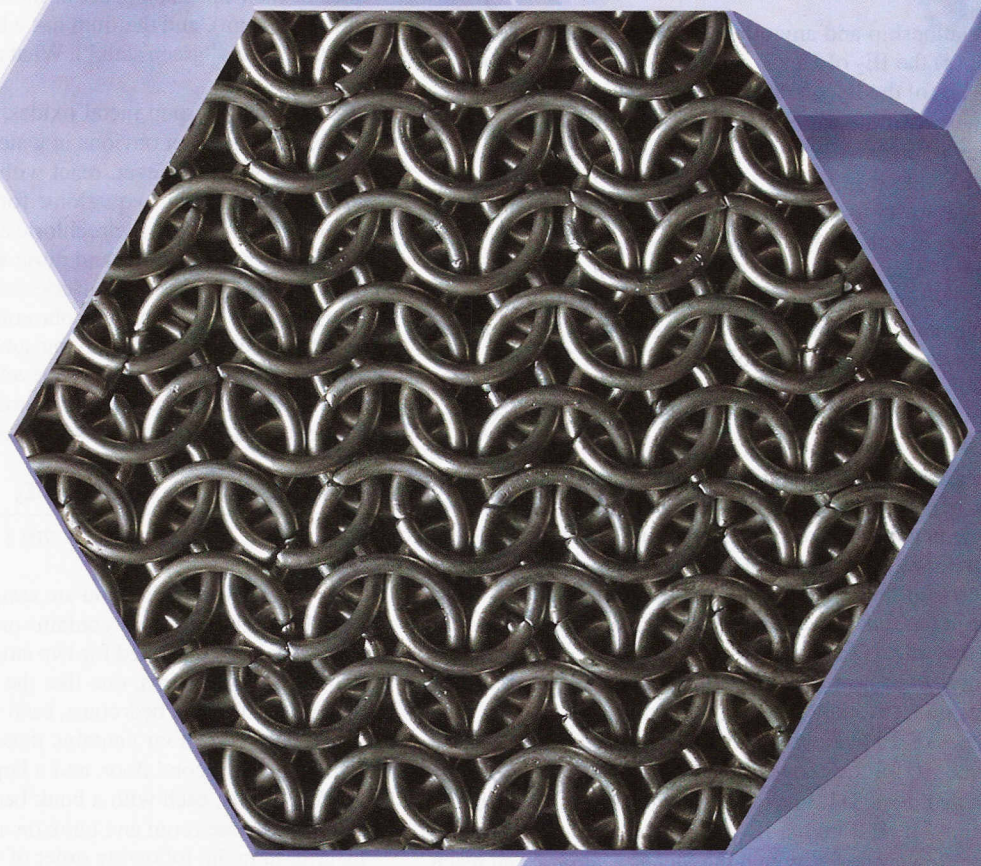
8.106 Draw the partial (valence-level) orbital diagram and write the electron configuration of the atom and monatomic ion of the element with the following ionization energies (in kJ/mol):

IE_1	IE_2	IE_3	IE_4	IE_5	IE_6	IE_7	IE_8
999	2251	3361	4564	7013	8495	27,106	31,669

8.107 As a science major, you are assigned to the "Atomic Dorm" at college. The first floor contains one dorm room with one bedroom that has a bunk bed for two students. The second floor contains two dorm rooms, one like the room on the first floor, and the other with three bedrooms, each with a bunk bed for two students. The third floor contains three dorm rooms, two like the rooms on the second floor, and a larger third room that contains five bedrooms, each with a bunk bed for two students. Entering students choose room and bunk on a first-come, first-serve basis by criteria in the following order of importance:
(1) They want to be on the lowest available floor.
(2) They want to be in a smallest available dorm room.
(3) They want to be in a lower bunk if available.
(a) Which bunk does the 1st student choose? (b) How many students are in top bunks when the 17th student chooses? (c) Which bunk does the 21st student choose? (d) How many students are in bottom bunks when the 25th student chooses?

8.108 On the planet Zog in the Andromeda galaxy, all of the stable elements have been studied. Data for some main-group elements are shown below (Zoggian units are unknown on Earth and, therefore, not shown). Limited communications with the Zoggians have indicated that balloonium is a monatomic gas with two positive charges in its nucleus. Use the data to deduce the names that Earthlings give to these elements:

Name	Atomic Radius	IE_1	EA_1
Balloonium	10	339	0
Inertium	24	297	+4.1
Allotropium	34	143	−28.6
Brinium	63	70.9	−7.6
Canium	47	101	−15.3
Fertilium	25	200	0
Liquidium	38	163	−46.4
Utilium	48	82.4	−6.1
Crimsonium	72	78.4	−2.9



Holding parts together The physical links among the metal loops in this piece of medieval chain mail are an analogy for the chemical links among the metal atoms in each loop. In this chapter, we examine the three types of chemical bonds that connect atoms and consider how each type gives rise to the behavior of the substance.

9.6 **An Introduction to Metallic Bonding**
The Electron-Sea Model
How the Model Explains the Properties of Metals

Why is table salt (or any other ionic substance) a hard, brittle, high-melting solid that conducts a current only when molten or dissolved in water? Why is candle wax (along with most covalent substances) low melting, soft, and nonconducting, while diamond (and some other exceptions) is high melting and extremely hard? And why is copper (and most other metallic substances) shiny, malleable, and able to conduct a current whether molten or solid? The answers lie in the *type of bonding within the substance*. In Chapter 8, we examined the properties of individual atoms and ions. Yet, in virtually all the substances in and around you, these particles are bonded to one another. As you'll see, deeper insight comes with discovering how the properties of atoms influence the types of chemical bonds they form, because these are ultimately responsible for the behavior of substances.

IN THIS CHAPTER . . . We examine how atomic properties give rise to the three major types of bonding—ionic, covalent, and metallic—and how each model of bonding explains the properties of substances. For ionic bonding, we detail the steps and calculate the energy involved in the formation of an ionic solid from its elements. Covalent bonding occurs in the vast majority of compounds. We examine the formation and characteristics—order, energy, and length—of a covalent bond. We explore the range of bonding, from pure covalent to ionic, in terms of electronegativity and bond polarity and see that most bonds fall somewhere between these extremes. Finally, we consider a simple model that explains metallic bonding.

Concepts & Skills to Review

before you study this chapter

- characteristics of ionic and covalent bonding (Section 2.7)
- polar covalent bonds and the polarity of water (Section 4.1)
- Hess's law, ΔH^0_{rxn}, and ΔH^0_f (Sections 6.5 and 6.6)
- atomic and ionic electron configurations (Sections 8.3 and 8.5)
- trends in atomic properties and metallic behavior (Sections 8.4 and 8.5)

9.1 ATOMIC PROPERTIES AND CHEMICAL BONDS

Before we examine the types of chemical bonding, we should ask why atoms bond at all. In general terms, they do so for one overriding reason: *bonding lowers the potential energy between positive and negative particles,* whether those particles are oppositely charged ions or atomic nuclei and the electrons between them. Just as the electron configuration and the strength of the nucleus-electron attraction determine the properties of an atom, the type and strength of chemical bonds determine the properties of a substance.

The Three Types of Chemical Bonding

On the atomic level, we distinguish a metal from a nonmetal on the basis of several properties that correlate with position in the periodic table (Figure 9.1 and

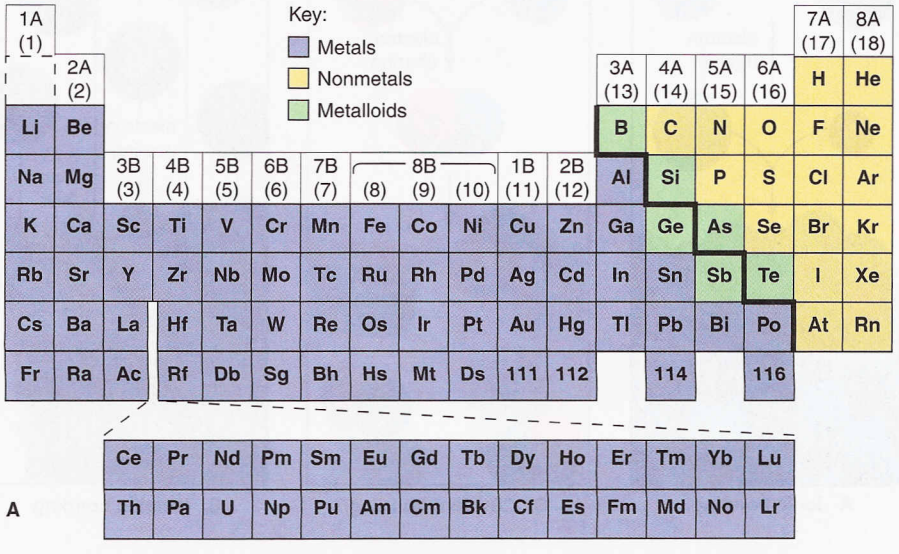

Figure 9.1 A general comparison of metals and nonmetals. A, The key indicates the positions of metals, nonmetals, and metalloids within the periodic table. **B,** The relative magnitudes of some key atomic properties vary from left to right within a period and correlate with whether an element is metallic or nonmetallic.

PROPERTY	METAL ATOM	NONMETAL ATOM
Atomic size	Larger	Smaller
Z_{eff}	Lower	Higher
IE	Lower	Higher
EA	Less negative	More negative

B Relative magnitudes of atomic properties within a period

inside the front cover). Recall from Chapter 8 that, in general, there is a gradation from more metal-like to more nonmetal-like behavior from left to right across a period and from bottom to top within most groups. Three types of bonding result from the three ways these two types of atoms can combine—metal with nonmetal, nonmetal with nonmetal, and metal with metal:

1. *Metal with nonmetal: electron transfer and ionic bonding* (Figure 9.2A). We typically observe **ionic bonding** between atoms with large differences in their tendencies to lose or gain electrons. Such differences occur between reactive metals [Groups 1A(1) and 2A(2)] and nonmetals [Group 7A(17) and the top of Group 6A(16)]. The metal atom (low IE) loses its one or two valence electrons, whereas the nonmetal atom (highly negative EA) gains the electron(s). *Electron transfer* from metal to nonmetal occurs, and each atom forms an ion with a noble gas electron configuration. The electrostatic attraction between these positive and negative ions draws them into the three-dimensional array of an ionic solid, whose chemical formula represents the cation-to-anion ratio (empirical formula).

2. *Nonmetal with nonmetal: electron sharing and covalent bonding* (Figure 9.2B). When two atoms have a small difference in their tendencies to lose or gain electrons, we observe *electron sharing* and **covalent bonding.** This type of bonding most commonly occurs between nonmetal atoms (although a pair of metal atoms can sometimes form a covalent bond also). Each nonmetal atom holds onto its own electrons tightly (high IE) and tends to attract other electrons as well (highly negative EA). The attraction of each nucleus for the valence electrons of the other draws the atoms together. A shared electron pair is considered to be *localized* between the two atoms because it spends most of its time there, linking them in a covalent bond of a particular length and strength. In most cases, separate molecules form when covalent bonding occurs, and the chemical formula reflects the actual numbers of atoms in the molecule (molecular formula).

3. *Metal with metal: electron pooling and metallic bonding* (Figure 9.2C). In general, metal atoms are relatively large, and their few outer electrons are well shielded by filled inner levels. Thus, they lose outer electrons comparatively easily (low IE) but do not gain them very readily (slightly negative or positive EA). These properties lead large numbers of metal atoms to share their valence electrons, but in a way that differs from covalent bonding. In the simplest model of

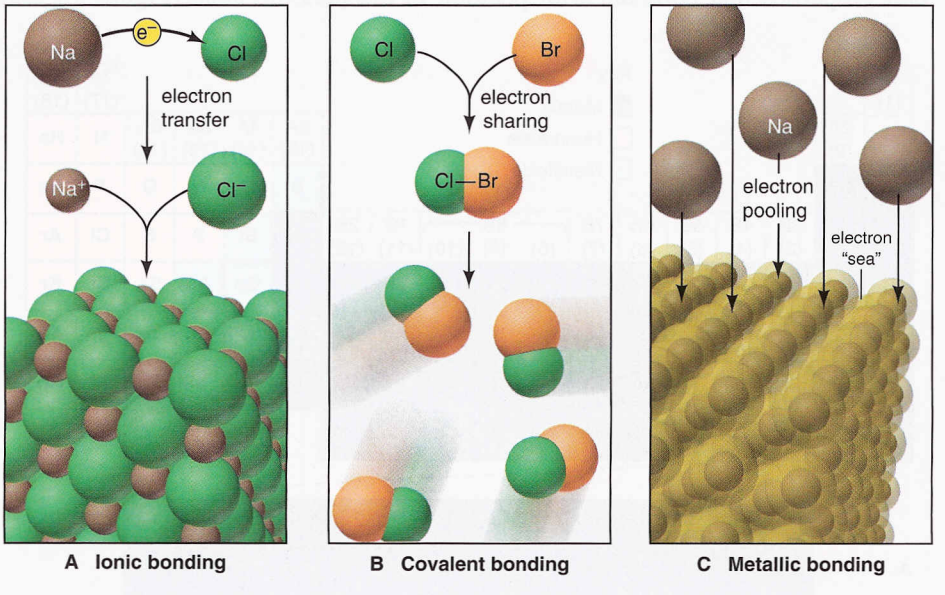

Figure 9.2 The three models of chemical bonding. A, In ionic bonding, metal atoms transfer electron(s) to nonmetal atoms, forming oppositely charged ions that attract each other to form a solid. **B,** In covalent bonding, two atoms share an electron pair localized between their nuclei (shown here as a bond line). Most covalent substances consist of individual molecules, each made from two or more atoms. **C,** In metallic bonding, many metal atoms pool their valence electrons to form a delocalized electron "sea" that holds the metal-ion cores together.

metallic bonding, all the metal atoms in a sample *pool* their valence electrons into an evenly distributed "sea" of electrons that "flows" between and around the metal-ion cores (nucleus plus inner electrons) and attracts them, thereby holding them together. Unlike the localized electrons in covalent bonding, electrons in metallic bonding are *delocalized,* moving freely throughout the piece of metal.

It's important to remember that there are exceptions to these idealized bonding models in the world of real substances. You cannot always predict the bond type solely from the elements' positions in the periodic table. For instance, all binary ionic compounds contain a metal and a nonmetal, but all metals do not form binary ionic compounds with all nonmetals. As just one example, when the metal beryllium [Group 2A(2)] combines with the nonmetal chlorine [Group 7A(17)], the bonding fits the covalent model better than the ionic model. In other words, just as we see a gradation in metallic behavior within groups and periods, we also see a gradation in bonding from one type to another.

Lewis Electron-Dot Symbols: Depicting Atoms in Chemical Bonding

Before turning to the individual models, let's discuss a method for depicting the valence electrons of interacting atoms. In the **Lewis electron-dot symbol** (named for the American chemist G. N. Lewis), the element symbol represents the nucleus *and* inner electrons, and the surrounding dots represent the valence electrons (Figure 9.3). Note that the pattern of dots is the same for elements within a group.

Period	1A(1) ns^1	2A(2) ns^2	3A(13) ns^2np^1	4A(14) ns^2np^2	5A(15) ns^2np^3	6A(16) ns^2np^4	7A(17) ns^2np^5	8A(18) ns^2np^6
2	Li	Be	B	C	N	O	F	Ne
3	Na	Mg	Al	Si	P	S	Cl	Ar

Figure 9.3 Lewis electron-dot symbols for elements in Periods 2 and 3. The element symbol represents the nucleus and inner electrons, and the dots around it represent valence electrons, either paired or unpaired. The number of unpaired dots indicates the number of electrons a metal atom loses, or the number a nonmetal atom gains, or the number of covalent bonds a nonmetal atom usually forms.

It's easy to write the Lewis symbol for any main-group element:

1. Note its A-group number (1A to 8A), which gives the number of valence electrons.
2. Place one dot at a time on the four sides (top, right, bottom, left) of the element symbol.
3. Keep adding dots, pairing the dots until all are used up.

The specific placement of dots is not important; that is, in addition to the one shown in Figure 9.3, the Lewis symbol for nitrogen can *also* be written as

The number and pairing of dots provide information about an element's bonding behavior:

- For a metal, the *total* number of dots is the maximum number of electrons an atom loses to form a cation.
- For a nonmetal, the number of *unpaired* dots is the number of electrons that become paired either through electron gain or through electron sharing. Thus, the number of unpaired dots equals either the number of electrons a nonmetal atom gains in becoming an anion or the number of covalent bonds it usually forms.

The Remarkable Insights of G. N. Lewis
Many of the ideas in this text emerged from the mind of Gilbert Newton Lewis (1875–1946). As early as 1902, nearly a decade *before* Rutherford proposed the nuclear model of the atom, Lewis's notebooks show a scheme that involves the filling of outer electron "shells" to explain the way elements combine. His electron-dot symbols and associated structural formulas (discussed in Chapter 10) have become standards for representing bonding. Among his many other contributions is a more general model for the behavior of acids and bases (which we discuss in Chapter 18).

To illustrate the last point, look at the Lewis symbol for carbon. Rather than one pair of dots and two unpaired dots, as its electron configuration ([He] $2s^2 2p^2$) would indicate, carbon has four unpaired dots because it forms four bonds. That is, in its compounds, carbon's four electrons are paired with four more electrons from its bonding partners for a total of eight electrons around carbon. (In Chapter 10, we'll see that larger nonmetals can form as many bonds as they have dots in the Lewis symbol.)

In his studies of bonding, Lewis generalized much of bonding behavior into the **octet rule:** *when atoms bond, they lose, gain, or share electrons to attain a filled outer level of eight (or two) electrons.* The octet rule holds for nearly all of the compounds of Period 2 elements and a large number of others as well.

SECTION SUMMARY

Nearly all naturally occurring substances consist of atoms or ions bonded to others. Chemical bonding allows atoms to lower their energy. Ionic bonding occurs when metal atoms transfer electrons to nonmetal atoms, and the resulting ions attract each other and form an ionic solid. Covalent bonding most commonly occurs between nonmetal atoms and usually results in molecules. The bonded atoms share a pair of electrons, which remain localized between them. Metallic bonding occurs when many metal atoms pool their valence electrons in a delocalized electron sea that holds all the atoms together. The Lewis electron-dot symbol of an atom depicts the number of valence electrons for a main-group element. In bonding, many atoms lose, gain, or share electrons to attain a filled outer level of eight (or two).

9.2 THE IONIC BONDING MODEL

The central idea of the ionic bonding model is the *transfer of electrons from metal atoms to nonmetal atoms to form ions that come together in a solid ionic compound.* For nearly every monatomic ion of a main-group element, the electron configuration has a filled outer level: either two or eight electrons, the same number as in the nearest noble gas (octet rule).

The transfer of an electron from a lithium atom to a fluorine atom is depicted in three ways in Figure 9.4. In each, Li loses its single outer electron and is left with a filled $n = 1$ level, while F gains a single electron to fill its $n = 2$ level. In this case, each atom is one electron away from its nearest noble gas—He for Li and Ne for F—so the number of electrons lost by each Li equals the number gained by each F. Therefore, equal numbers of Li^+ and F^- ions form, as the formula LiF indicates. That is, in ionic bonding, *the total number of electrons lost by the metal atoms equals the total number of electrons gained by the nonmetal atoms.*

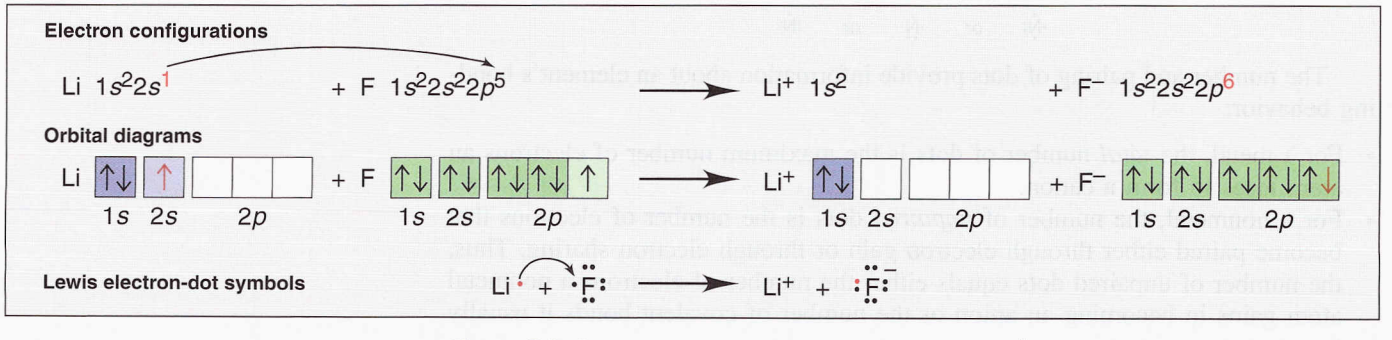

Figure 9.4 Three ways to represent the formation of Li^+ and F^- through electron transfer. The electron being transferred is indicated in red.

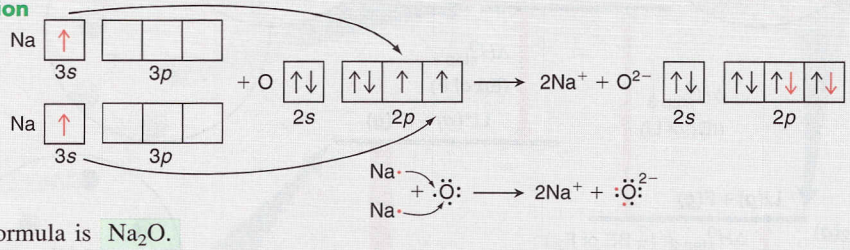
SAMPLE PROBLEM 9.1 Depicting Ion Formation

Problem Use partial orbital diagrams and Lewis symbols to depict the formation of Na^+ and O^{2-} ions from the atoms, and determine the formula of the compound the ions form.

Plan First we draw the orbital diagrams and Lewis symbols for the Na and O atoms. To attain filled outer levels, Na loses one electron and O gains two. Thus, to make the number of electrons lost equal the number gained, two Na atoms are needed for each O atom.

Solution



The formula is Na_2O.

FOLLOW-UP PROBLEM 9.1 Use condensed electron configurations and Lewis symbols to depict the formation of Mg^{2+} and Cl^- ions from the atoms, and write the formula of the ionic compound.

Energy Considerations in Ionic Bonding: The Importance of Lattice Energy

You may be surprised to learn that the electron-transfer process by itself actually *absorbs* energy! In fact, the reason ionic compounds occur at all is because of the enormous *release* of energy that occurs when the ions come together and form the solid. Consider just the electron-transfer process for the formation of lithium fluoride, which involves two steps—a gaseous Li atom loses an electron, and a gaseous F atom gains it:

- The first ionization energy (IE_1) of Li is the energy change that occurs when 1 mol of gaseous Li atoms loses 1 mol of outer electrons:

$$Li(g) \longrightarrow Li^+(g) + e^- \qquad IE_1 = 520 \text{ kJ}$$

- The electron affinity (EA) of F is the energy change that occurs when 1 mol of gaseous F atoms gains 1 mol of electrons:

$$F(g) + e^- \longrightarrow F^-(g) \qquad EA = -328 \text{ kJ}$$

Note that the two-step electron-transfer process *by itself* requires energy:

$$Li(g) + F(g) \longrightarrow Li^+(g) + F^-(g) \qquad IE_1 + EA = 192 \text{ kJ}$$

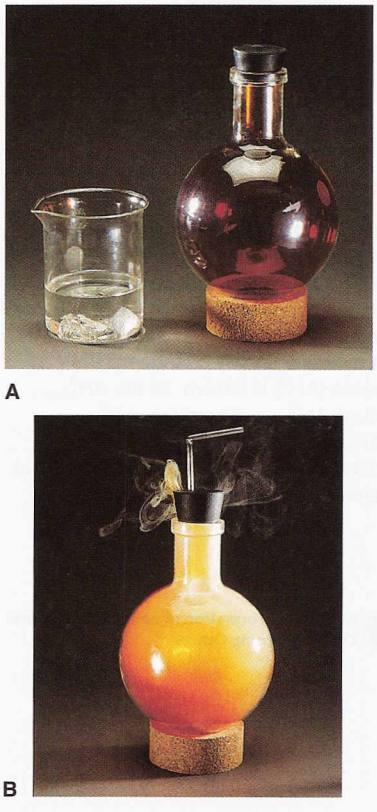
The total energy needed for ion formation is even greater than this because metallic lithium and diatomic fluorine must first be converted to separate gaseous atoms, which also requires energy. Despite this, the standard heat of formation (ΔH_f^0) of solid LiF is −617 kJ/mol; that is, 617 kJ is *released* per mole of LiF(*s*) formed. The case of LiF is typical: despite the endothermic electron transfer, ionic solids form readily, often vigorously. Figure 9.5 shows the formation of NaBr.

Clearly, if the overall reaction of Li(*s*) and $F_2(g)$ to form LiF(*s*) releases energy, there must be some exothermic energy component large enough to overcome the endothermic steps. This component arises from the strong *attraction between oppositely charged ions*. When 1 mol of $Li^+(g)$ and 1 mol of $F^-(g)$ form 1 mol of gaseous LiF molecules, a large quantity of heat is released:

$$Li^+(g) + F^-(g) \longrightarrow LiF(g) \qquad \Delta H^0 = -755 \text{ kJ}$$

Of course, under ordinary conditions, LiF does not consist of gaseous molecules because *much more energy is released when the gaseous ions coalesce into a crystalline solid*. That occurs because each ion attracts others of opposite charge:

$$Li^+(g) + F^-(g) \longrightarrow LiF(s) \qquad \Delta H^0 = -1050 \text{ kJ}$$



A

B

Figure 9.5 The reaction between sodium and bromine. A, Despite the endothermic electron-transfer process, all the Group 1A(1) metals react exothermically with any of the Group 7A(17) nonmetals to form solid alkali-metal halides. The reactants in the example shown are sodium (in beaker under mineral oil) and bromine (dark orange-brown liquid in flask). **B,** The reaction is usually rapid and vigorous.

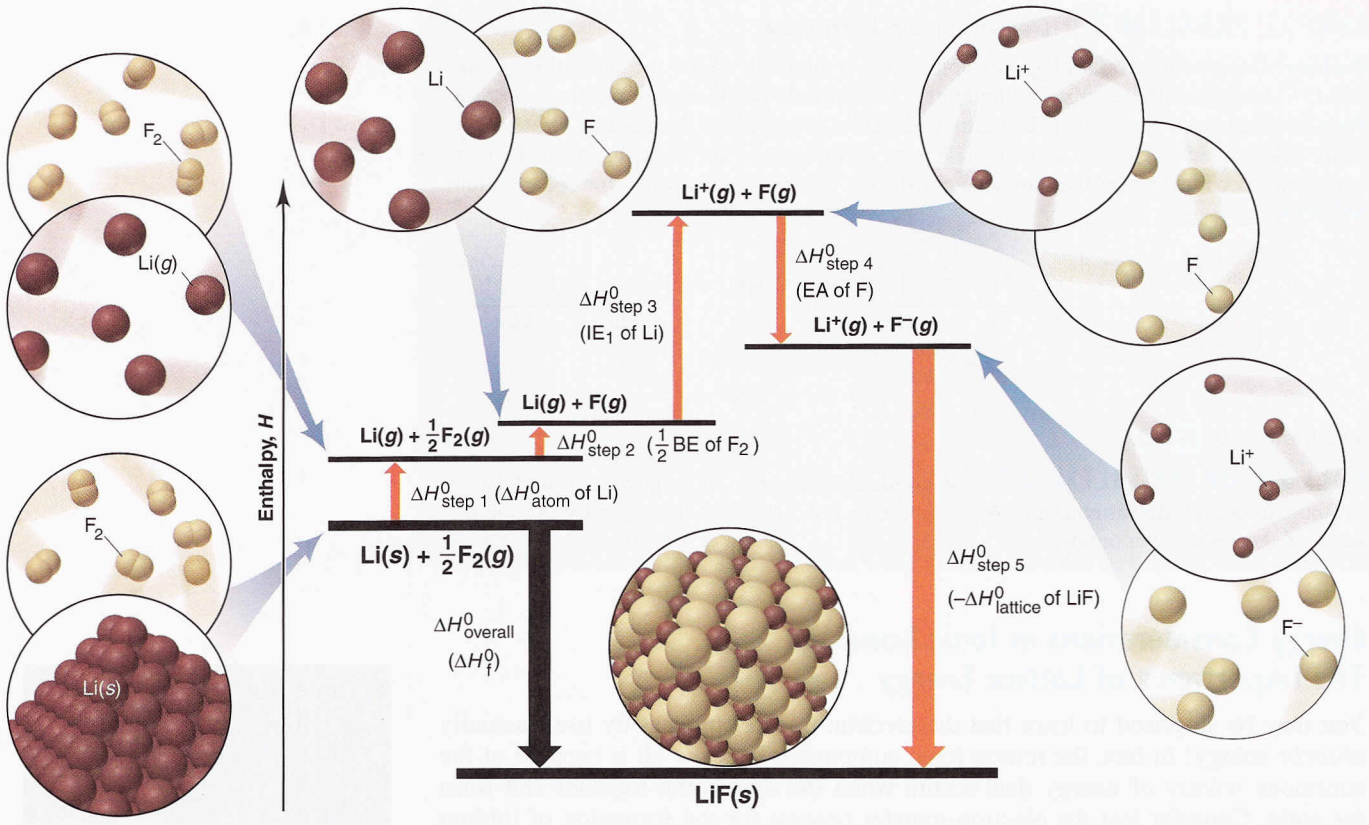


Figure 9.6 The Born-Haber cycle for lithium fluoride. The formation of LiF(*s*) from its elements is shown happening either in one overall reaction *(black arrow)* or in five hypothetical steps, each with its own enthalpy change *(orange arrows)*. The overall enthalpy change for the process (ΔH_f^0) is known, as are $\Delta H^0_{\text{step 1}}$ through $\Delta H^0_{\text{step 4}}$. Therefore, $\Delta H^0_{\text{step 5}}$ ($-\Delta H^0_{\text{lattice}}$ of LiF) can be calculated to find the lattice energy. (ΔH^0_{atom} is the heat of atomization; BE is the bond energy.)

Animation: Formation of an Ionic Compound
Online Learning Center

The negative of this value, 1050 kJ, is the lattice energy of LiF. The **lattice energy** ($\Delta H^0_{\text{lattice}}$) is the enthalpy change that accompanies the separation of 1 mol of ionic solid into gaseous ions. It indicates the strength of ionic interactions and influences melting point, hardness, solubility, and other properties. (You'll see next how we calculate the lattice energy.)

Lattice energy plays the critical role in the formation of ionic compounds, but it cannot be measured directly. One way to determine lattice energy applies Hess's law (see Section 6.5), which states that the enthalpy change of an overall reaction is the sum of the enthalpy changes for the individual reactions that make it up: $\Delta H_{\text{total}} = \Delta H_1 + \Delta H_2 + \cdots$. Lattice energies are calculated by means of a **Born-Haber cycle,** a series of chosen steps from elements to ionic compound for which all the enthalpies* are known except the lattice energy.

Let's go through the Born-Haber cycle for lithium fluoride. Figure 9.6 shows two possible paths, either the direct combination reaction (black arrow) or the multistep path (orange arrows), one step of which involves the unknown lattice energy. Hess's law tells us both paths involve the same overall enthalpy change:

$$\Delta H_f^0 \text{ of LiF}(s) = \text{sum of } \Delta H^0 \text{ values for multistep path}$$

It's important to realize that we *choose hypothetical steps whose enthalpy changes we can measure* to depict the energy components of LiF formation, even though *these are* ***not*** *the actual steps that occur when lithium reacts with fluorine.*

We begin with the elements in their standard states, metallic lithium and gaseous diatomic fluorine. In the multistep process, the elements are converted to individual gaseous atoms (steps 1 and 2), gaseous ions form by electron transfers

*Strictly speaking, ionization energy (IE) and electron affinity (EA) are internal energy changes (ΔE), not enthalpy changes (ΔH), but in these steps, $\Delta H = \Delta E$ because $\Delta V = 0$ (see Section 6.2).

(steps 3 and 4), and the ions come together into a solid (step 5). We identify each ΔH^0 by its step number:

Step 1. Converting 1 mol of solid Li to separate gaseous Li atoms involves breaking metallic bonds, so this step requires energy:

$$\text{Li}(s) \longrightarrow \text{Li}(g) \qquad \Delta H^0_{\text{step 1}} = 161 \text{ kJ}$$

(This process is called *atomization,* and the enthalpy change is ΔH^0_{atom}.)

Step 2. Converting an F_2 molecule to F atoms involves breaking a covalent bond, so it requires energy, which, as we discuss later, is called the *bond energy* (BE). We need 1 mol of F atoms for 1 mol of LiF, so we start with $\frac{1}{2}$ mol of F_2:

$$\tfrac{1}{2}\text{F}_2(g) \longrightarrow \text{F}(g) \qquad \Delta H^0_{\text{step 2}} = \tfrac{1}{2}(\text{BE of F}_2)$$
$$= \tfrac{1}{2}(159 \text{ kJ}) = 79.5 \text{ kJ}$$

Step 3. Removing the 2*s* electron from 1 mol of Li to form 1 mol of Li^+ requires energy:

$$\text{Li}(g) \longrightarrow \text{Li}^+(g) + \text{e}^- \qquad \Delta H^0_{\text{step 3}} = \text{IE}_1 = 520 \text{ kJ}$$

Step 4. Adding an electron to each atom in 1 mol of F to form 1 mol of F^- releases energy:

$$\text{F}(g) + \text{e}^- \longrightarrow \text{F}^-(g) \qquad \Delta H^0_{\text{step 4}} = \text{EA} = -328 \text{ kJ}$$

Step 5. Forming 1 mol of the crystalline ionic solid from the gaseous ions is the step whose enthalpy change (negative of the lattice energy) is unknown:

$$\text{Li}^+(g) + \text{F}^-(g) \longrightarrow \text{LiF}(s) \qquad \Delta H^0_{\text{step 5}} = -\Delta H^0_{\text{lattice}} \text{ of LiF} = ?$$

We know the enthalpy change of the formation reaction,

$$\text{Li}(s) + \tfrac{1}{2}\text{F}_2(g) \longrightarrow \text{LiF}(s) \qquad \Delta H^0_{\text{overall}} = \Delta H^0_f = -617 \text{ kJ}$$

Using Hess's law, we set the known ΔH^0_f equal to the sum of the ΔH^0 values for the steps and calculate the lattice energy:

$$\Delta H^0_f = \Delta H^0_{\text{step 1}} + \Delta H^0_{\text{step 2}} + \Delta H^0_{\text{step 3}} + \Delta H^0_{\text{step 4}} + (-\Delta H^0_{\text{lattice}} \text{ of LiF})$$

Solving for $-\Delta H^0_{\text{lattice}}$ of LiF gives

$$-\Delta H^0_{\text{lattice}} \text{ of LiF} = \Delta H^0_f - (\Delta H^0_{\text{step 1}} + \Delta H^0_{\text{step 2}} + \Delta H^0_{\text{step 3}} + \Delta H^0_{\text{step 4}})$$
$$= -617 \text{ kJ} - [161 \text{ kJ} + 79.5 \text{ kJ} + 520 \text{ kJ} + (-328 \text{ kJ})]$$
$$= -1050 \text{ kJ}$$

So, $\Delta H^0_{\text{lattice}} \text{ of LiF} = -(-1050 \text{ kJ}) = 1050 \text{ kJ}$

Note that *the magnitude of the lattice energy dominates the multistep process.*

The Born-Haber cycle reveals a central point: *ionic solids exist* ***only*** *because the lattice energy exceeds the energetically unfavorable electron transfer.* In other words, the energy *required* for elements to lose or gain electrons is *supplied* by the attraction between the ions they form: energy is expended to form the ions, but it is more than regained when they attract each other and form a solid.

Periodic Trends in Lattice Energy

Because the lattice energy is the result of electrostatic interactions among ions, we expect its magnitude to depend on several factors, including ionic size, ionic charge, and ionic arrangement in the solid. In Chapter 2, you were introduced to Coulomb's law as a fundamental aspect of ionic bonding; in fact, it applies to any situation in which charges attract each other. **Coulomb's law** states that the electrostatic *force* associated with two charges (A and B) is directly proportional to the product of their magnitudes and inversely proportional to the square of the distance between them:

$$\text{Electrostatic force} \propto \frac{\text{charge A} \times \text{charge B}}{\text{distance}^2}$$

Given that energy = force × distance, the electrostatic *energy* is inversely proportional to the *first* power of the distance between the charges:

$$\text{Electrostatic energy} \propto \frac{\text{charge A} \times \text{charge B}}{\text{distance}}$$

In an ionic solid, numerous charged particles are at various distances from one another, so the calculation requires more than just a simple extension of Coulomb's law. Nevertheless, the lattice energy ($\Delta H^0_{\text{lattice}}$) is directly proportional to the electrostatic energy. Cations and anions lie as close to each other as possible, and the distance between them is the distance between their centers, which equals the sum of their radii (see Figure 8.28, p. 320):

$$\text{Electrostatic energy} \propto \frac{\text{cation charge} \times \text{anion charge}}{\text{cation radius} + \text{anion radius}} \propto \Delta H^0_{\text{lattice}} \qquad (9.1)$$

This relationship helps us predict trends in lattice energy and explain the effects of ionic size and charge:

1. *Effect of ionic size.* As we move down a group in the periodic table, the ionic radius increases. Therefore, the electrostatic energy between cations and anions should decrease because the interionic distance is greater; thus, the lattice energies of their compounds should decrease as well. This prediction is borne out by the lattice energies of the alkali-metal halides shown in Figure 9.7. A smooth decrease in lattice energy occurs down a group whether we hold the cation constant (LiF to LiI) or the anion constant (LiF to RbF).

2. *Effect of ionic charge.* When we compare lithium fluoride with magnesium oxide, we find cations of about equal radii (Li^+ = 76 pm and Mg^{2+} = 72 pm) and anions of about equal radii (F^- = 133 pm and O^{2-} = 140 pm). Thus, the

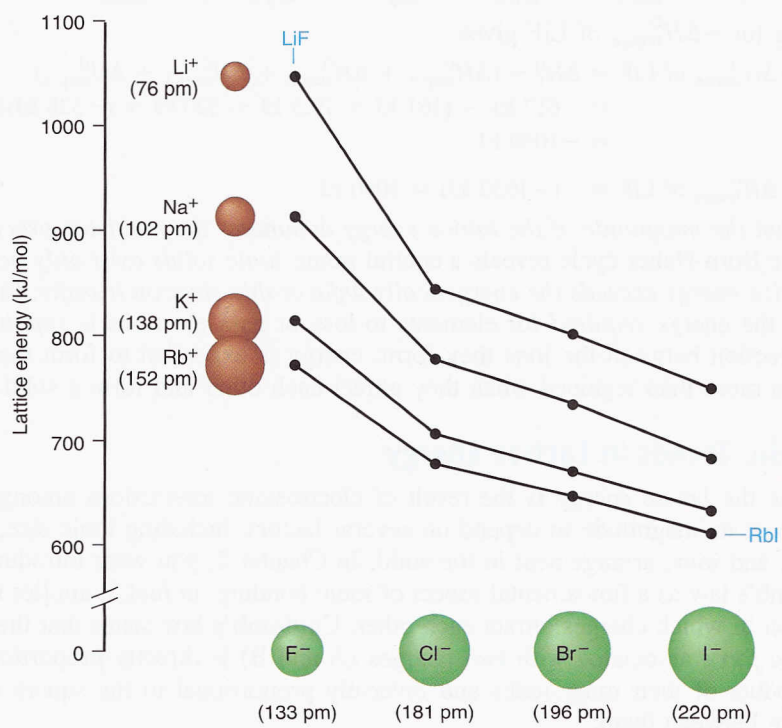

Figure 9.7 Trends in lattice energy. The lattice energies for many of the alkali-metal halides are shown. Each series of four points represents a given Group 1A(1) cation *(left side)* combining with each of the Group 7A(17) anions *(bottom)*. As ionic radii increase, the electrostatic attractions decrease, so the lattice energies of the compounds decrease as well. Thus, LiF (smallest ions shown) has the highest lattice energy and RbI (largest ions) has the lowest.

only significant difference is the ionic charge: LiF contains the singly charged Li^+ and F^- ions, whereas MgO contains the doubly charged Mg^{2+} and O^{2-} ions. The difference in their lattice energies is striking:

$$\Delta H^0_{\text{lattice}} \text{ of LiF} = 1050 \text{ kJ/mol} \quad \text{and} \quad \Delta H^0_{\text{lattice}} \text{ of MgO} = 3923 \text{ kJ/mol}$$

This nearly fourfold increase in $\Delta H^0_{\text{lattice}}$ reflects the fourfold increase in the product of the charges (1×1 vs. 2×2) in the numerator of Equation 9.1.

You may be wondering why ionic solids like MgO, with its 2+ ions, even exist. After all, much more energy is needed to form 2+ ions than 1+ ions. Forming 1 mol of Mg^{2+} involves the sum of the first and second ionization energies for Mg:

$$Mg(g) \longrightarrow Mg^{2+}(g) + 2e^- \qquad \Delta H^0 = IE_1 + IE_2 = 738 \text{ kJ} + 1450 \text{ kJ} = 2188 \text{ kJ}$$

Adding 1 mol of electrons to 1 mol of O atoms (first electron affinity, EA_1) is exothermic, but adding a second mole of electrons (second electron affinity, EA_2) is endothermic because an electron is being added to the negative O^- ion. The overall formation of 1 mol of O^{2-} ions is endothermic:

$$\begin{array}{lll} O(g) + e^- \longrightarrow O^-(g) & \Delta H^0 = EA_1 & = -141 \text{ kJ} \\ O^-(g) + e^- \longrightarrow O^{2-}(g) & \Delta H^0 = EA_2 & = \ 878 \text{ kJ} \\ \hline O(g) + 2e^- \longrightarrow O^{2-}(g) & \Delta H^0 = EA_1 + EA_2 = & \ 737 \text{ kJ} \end{array}$$

In addition, there are the endothermic steps for converting 1 mol of Mg(*s*) to Mg(*g*) (148 kJ) and breaking $\frac{1}{2}$ mol of O_2 molecules into 1 mol of O atoms (249 kJ). Nevertheless, as a result of the ions' 2+ and 2− charges, solid MgO readily forms whenever Mg burns in air ($\Delta H^0_f = -601$ kJ/mol). Clearly, the enormous lattice energy ($\Delta H^0_{\text{lattice}}$ of MgO = 3923 kJ/mol) more than compensates for these endothermic steps.

How the Model Explains the Properties of Ionic Compounds

The first and most important job of any model is to explain the facts. By magnifying our view, we can see how the ionic bonding model accounts for the properties of ionic solids. You may have seen a piece of rock salt (NaCl). It is *hard* (does not dent), *rigid* (does not bend), and *brittle* (cracks without deforming). These properties are due to the powerful attractive forces that hold the ions *in specific positions* throughout the crystal. Moving the ions out of position requires overcoming these forces, so the sample resists denting and bending. If *enough* pressure is applied, ions of like charge are brought next to each other, and repulsive forces crack the sample suddenly (Figure 9.8).

Most ionic compounds *do not* conduct electricity in the solid state but *do* conduct it when melted or when dissolved in water. (Notable exceptions include so-called superionic conductors, such as AgI, and the superconducting ceramics,

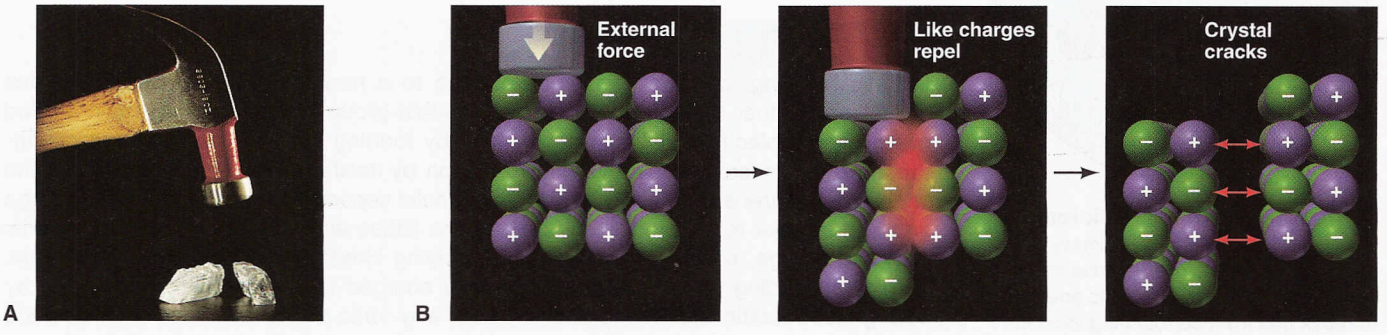

Figure 9.8 Electrostatic forces and the reason ionic compounds crack. **A,** Ionic compounds are hard and will crack, rather than bend, when struck with enough force. **B,** The positive and negative ions in the crystal are arranged to maximize their attractions. When an external force is applied, like charges move near each other, and the repulsions crack the piece apart.

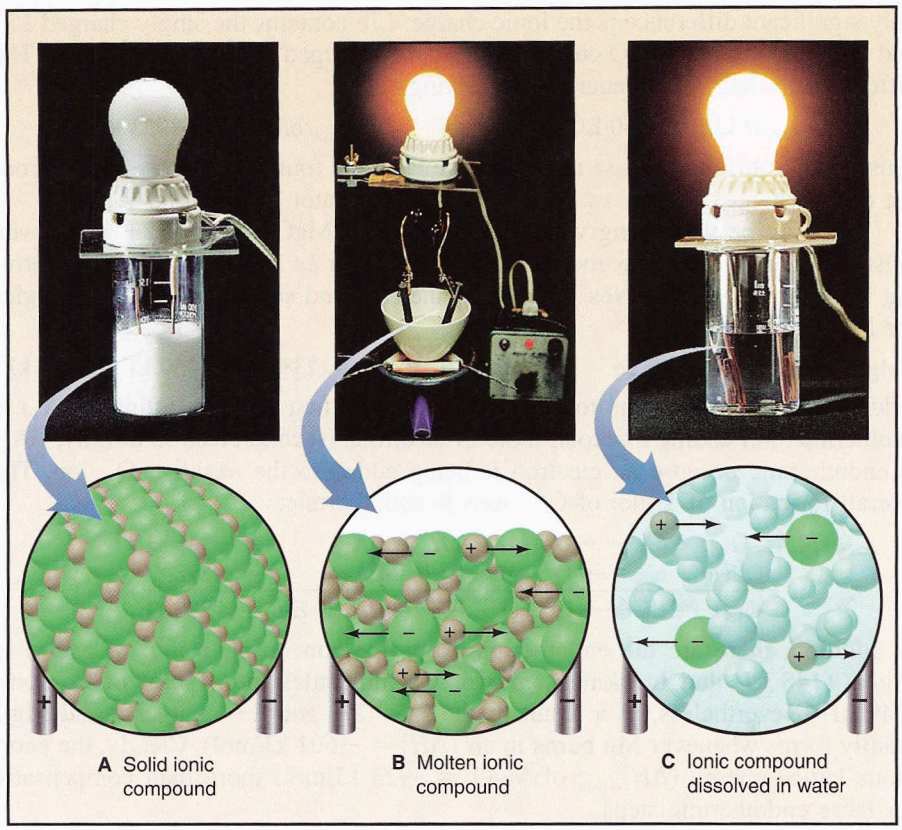

Figure 9.9 Electrical conductance and ion mobility. A, No current flows in the ionic solid because ions are immobile. **B,** In the molten compound, mobile ions flow toward the oppositely charged electrodes and carry a current. **C,** In an aqueous solution of the compound, mobile solvated ions carry a current.

Table 9.1 Melting and Boiling Points of Some Ionic Compounds

Compound	mp (°C)	bp (°C)
CsBr	636	1300
NaI	661	1304
$MgCl_2$	714	1412
KBr	734	1435
$CaCl_2$	782	>1600
NaCl	801	1413
LiF	845	1676
KF	858	1505
MgO	2852	3600

which have remarkable conductivity in the solid state.) According to the ionic bonding model, the solid consists of immobilized ions. When it melts or dissolves, however, the ions are free to move and carry an electric current, as shown in Figure 9.9.

The model also explains that high temperatures are needed to melt and boil an ionic compound (Table 9.1) because freeing the ions from their positions (melting) requires large amounts of energy, and vaporizing them requires even more. In fact, the interionic attraction is so strong that, as Figure 9.10 shows, the vapor consists of **ion pairs,** gaseous ionic molecules rather than individual ions. But keep in mind that in their ordinary (solid) state, ionic compounds consist of rows of alternating ions that extend in all directions, and *no separate molecules exist.*

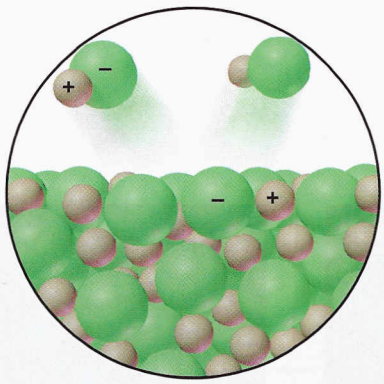

Figure 9.10 Vaporizing an ionic compound. Ionic compounds generally have very high boiling points because the ions must have high enough kinetic energies to break free from surrounding ions. In fact, ionic compounds usually vaporize as ion pairs.

SECTION SUMMARY

In ionic bonding, a metal transfers electrons to a nonmetal, and the resulting ions attract each other strongly to form a solid. Main-group elements often attain a filled outer level of electrons (either eight or two) by forming ions with the electron configuration of the nearest noble gas. Ion formation by itself *requires* energy. However, the lattice energy, the energy *absorbed* when the solid separates into gaseous ions, is large and is the major reason ionic solids exist. The lattice energy, which depends on ionic size and charge, can be determined by applying Hess's law in a Born-Haber cycle. The ionic bonding model pictures oppositely charged ions held rigidly in position by strong electrostatic attractions and explains why ionic solids crack rather than bend and why they conduct electric current only when melted or dissolved. Gaseous ion pairs form when an ionic compound vaporizes, which requires very high temperatures.

9.3 THE COVALENT BONDING MODEL

Look through any large reference source of chemical compounds, such as the *Handbook of Chemistry and Physics,* and you'll quickly find that the number of known covalent compounds dwarfs the number of known ionic compounds. Molecules held together by covalent bonds range from diatomic hydrogen to biological and synthetic macromolecules consisting of hundreds or even many thousands of atoms. We also find covalent bonds in many polyatomic ions. Without doubt, *sharing electrons is the principal way that atoms interact chemically.*

The Formation of a Covalent Bond

A sample of hydrogen gas consists of H_2 molecules. But why *do* the atoms exist bonded in pairs? Look at Figure 9.11 and imagine what happens to two isolated H atoms that approach each other from a distance (move *right* to *left* on the graph). When the atoms are far apart, each behaves as though the other were not present (point 1). As the distance between the nuclei decreases, each nucleus starts to attract the other atom's electron, which lowers the potential energy of the system. Attractions continue to draw the atoms closer, and the system becomes progressively lower in energy (point 2). As attractions increase, however, so do repulsions between the nuclei and between the electrons. At some internuclear distance, maximum attraction is achieved in the face of the increasing repulsion, and the system has its minimum energy (point 3, at the bottom of the energy "well"). Any shorter distance would increase repulsions and cause a rise in potential energy (point 4).* Thus a **covalent bond,** such as the one that holds the atoms together in the H_2 molecule, arises from the balance between nucleus-electron

*In Chapter 11, we discuss valence bond theory, a quantum-mechanical model that explains covalent bonding in terms of the greater amplitude of overlapping atomic orbitals (wave functions) between two nuclei.

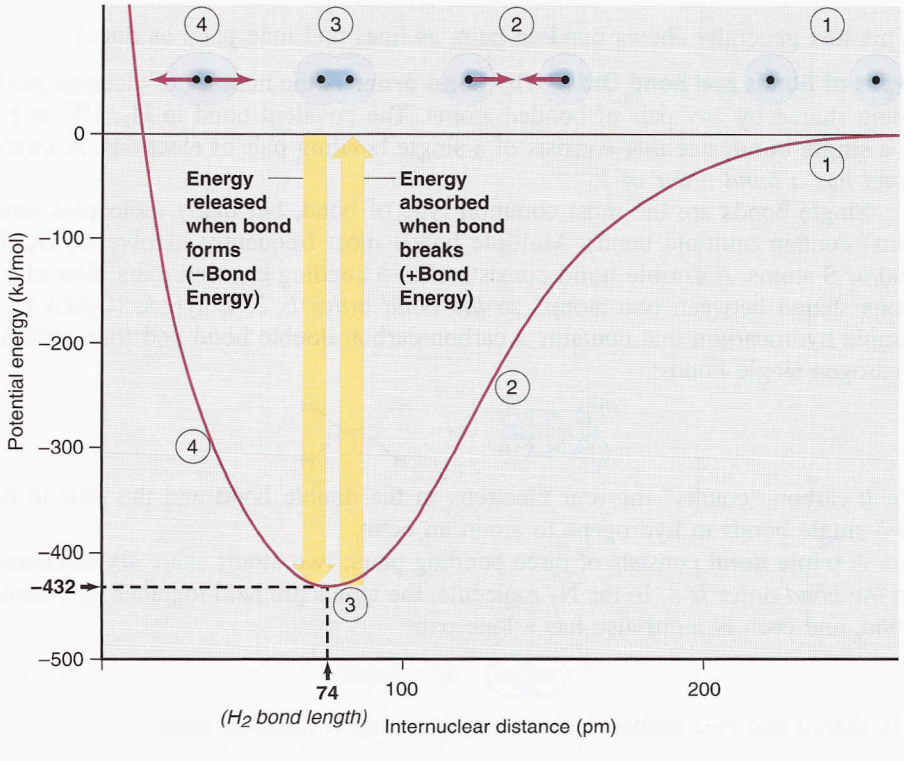

Figure 9.11 Covalent bond formation in H_2. The potential energy of a system of two H atoms is plotted against the distance between the nuclei, with a depiction of the atomic systems above. At point 1, the atoms are too far apart to attract each other. At 2, each nucleus attracts the other atom's electron. At 3, the combination of nucleus-electron attractions and electron-electron and nucleus-nucleus repulsions gives the minimum energy of the system. The energy difference between points 1 and 3 is the H_2 bond energy (432 kJ/mol). It is released when the bond forms and absorbed when the bond breaks. The internuclear distance at point 3 is the H_2 bond length (74 pm). If the atoms move closer, as at point 4, repulsions increase the system's energy and force the atoms apart to point 3 again.

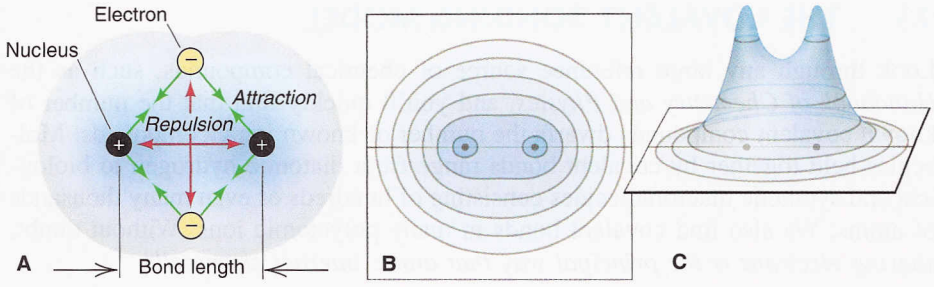

Figure 9.12 Distribution of electron density in H_2. A, At some optimum distance (bond length), attractions balance repulsions. Electron density *(blue shading)* is highest around and between the nuclei. **B,** This *contour map* shows a doubling of electron density with each contour line; the dots represent the nuclei. **C,** This *relief map* depicts the varying electron density of the contour map as peaks. The densest regions, by far, are around the nuclei, but the region between the nuclei—the bonding region—also has higher electron density.

attractions and electron-electron and nucleus-nucleus repulsions. Formation of a bond always results in *greater electron density between the nuclei*. Figure 9.12 depicts this fact in three ways: a cross-section of a space-filling model; an *electron density contour map,* with lines representing regular increments in electron density; and an *electron density relief map* that portrays the contour map three-dimensionally as peaks of electron density.

Bonding Pairs and Lone Pairs In covalent bonding, as in ionic bonding, each atom achieves a full outer (valence) level of electrons, but this is accomplished by different means. *Each atom in a covalent bond "counts" the shared electrons as belonging entirely to itself.* Thus, the two electrons in the shared electron pair of H_2 simultaneously fill the outer level of *both* H atoms. The **shared pair,** or **bonding pair,** is represented by either a pair of dots or a line, H:H or H—H.

An outer-level electron pair that is *not* involved in bonding is called a **lone pair,** or **unshared pair.** The bonding pair in HF fills the outer level of the H atom *and,* together with three lone pairs, fills the outer level of the F atom as well:

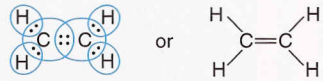
Animation: Formation of a Covalent Bond
Online Learning Center

In F_2 the bonding pair and three lone pairs fill the outer level of *each* F atom:

(This text generally shows bonding pairs as lines and lone pairs as dots.)

Types of Bonds and Bond Order The **bond order** is the number of electron pairs being shared by any pair of bonded atoms. The covalent bond in H_2, HF, or F_2 is a **single bond,** one that consists of a single bonding pair of electrons. A *single bond has a bond order of 1.*

Single bonds are the most common type of bond, but many molecules (and ions) contain multiple bonds. Multiple bonds most frequently involve C, O, N, and/or S atoms. A **double bond** consists of two bonding electron pairs, four electrons shared between two atoms, so *the bond order is 2.* Ethylene (C_2H_4) is a simple hydrocarbon that contains a carbon-carbon double bond and four carbon-hydrogen single bonds:



Each carbon "counts" the four electrons in the double bond and the four in its two single bonds to hydrogens to attain an octet.

A **triple bond** consists of three bonding pairs; two atoms share six electrons, so *the bond order is 3.* In the N_2 molecule, the atoms are held together by a triple bond, and each N atom also has a lone pair:

Six shared and two unshared electrons give *each* N atom an octet.

Properties of a Covalent Bond: Bond Energy and Bond Length

The strength of a covalent bond depends on the magnitude of the mutual attraction between bonded nuclei and shared electrons. The **bond energy (BE)** (also called *bond enthalpy* or *bond strength*) is the energy required to overcome this attraction and is defined as the standard enthalpy change for breaking the bond in 1 mol of gaseous molecules. *Bond breakage is an endothermic process, so the bond energy is always positive:*

$$A{-}B(g) \longrightarrow A(g) + B(g) \qquad \Delta H^0_{\text{bond breaking}} = BE_{A-B} \text{ (always } > 0)$$

Stated in another way, the bond energy is the difference in energy between the separated atoms and the bonded atoms (the potential energy difference between points 1 and 3 in Figure 9.11; the depth of the energy well). The same amount of energy that is absorbed to break the bond is released when it forms. *Bond formation is an exothermic process, so the sign of the enthalpy change is negative:*

$$A(g) + B(g) \longrightarrow A{-}B(g) \qquad \Delta H^0_{\text{bond forming}} = -BE_{A-B} \text{ (always } < 0)$$

Because bond energies depend on characteristics of the bonded atoms—their electron configurations, nuclear charges, and atomic radii—each type of bond has its own bond energy. Bond energies for some common bonds are listed in Table 9.2. *Stronger bonds are lower in energy (have a deeper energy well); weaker bonds are higher in energy (have a shallower energy well).* The energy of a given type of bond varies slightly from molecule to molecule (except for symmetrical diatomic molecules such as H_2), and even within the same molecule, so the tabulated value is an *average* bond energy.

Table 9.2 Average Bond Energies (kJ/mol)

Bond	Energy	Bond	Energy	Bond	Energy	Bond	Energy
Single Bonds

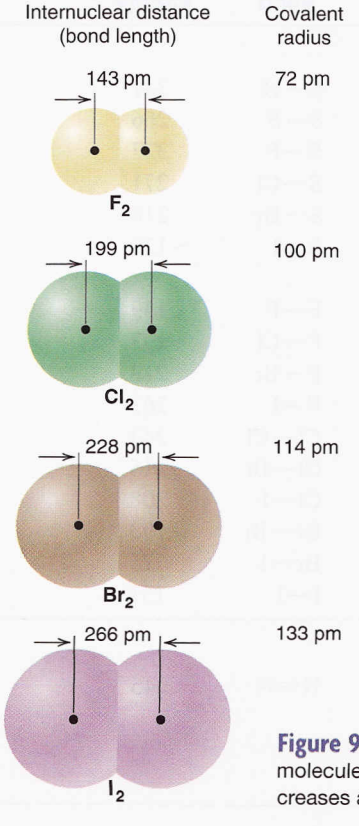
C=O	123	O_2	121	C≡O	113		



A covalent bond has a **bond length,** the distance between the nuclei of two bonded atoms. In Figure 9.11, bond length is shown as the distance between the nuclei at the point of minimum energy. Table 9.3 shows the lengths of some covalent bonds. Here, too, the values represent *average* bond lengths for the given bond in different substances. Bond length is related to the sum of the radii of the bonded atoms. In fact, most atomic radii are calculated from measured bond lengths (see Figure 8.14C, p. 305). Bond lengths for a series of similar bonds increase with atomic size, as shown in Figure 9.13 for the halogens.

A close relationship exists among bond order, bond length, and bond energy. Two nuclei are more strongly attracted to two shared electron pairs than to one: the atoms are drawn closer together *and* are more difficult to pull apart. Therefore, *for a given pair of atoms, a higher bond order results in a shorter bond length and a higher bond energy.* So, as Table 9.4 shows, for a given pair of atoms, *a shorter bond is a stronger bond.*

In some cases, we can extend this relationship among atomic size, bond length, and bond strength by holding one atom in the bond constant and varying the other atom within a group or period. For example, the trend in carbon-halogen single bond lengths, C—I > C—Br > C—Cl, parallels the trend in atomic size, I > Br > Cl, and is opposite to the trend in bond energy, C—Cl > C—Br > C—I. Thus, for *single bonds,* longer bonds are usually weaker.

Figure 9.13 Bond length and covalent radius. Within a series of similar molecules, such as the diatomic halogen molecules, bond length increases as covalent radius increases.

Table 9.4 The Relation of Bond Order, Bond Length, and Bond Energy

Bond	Bond Order	Average Bond Length (pm)	Average Bond Energy (kJ/mol)
C—O	1	143	358
C=O	2	123	745
C≡O	3	113	1070
C—C	1	154	347
C=C	2	134	614

N=N	2	122	418
N≡N	3	110	945

SAMPLE PROBLEM 9.2 Comparing Bond Length and Bond Strength

Problem Using the periodic table, but not Tables 9.2 and 9.3, rank the bonds in each set in order of *decreasing* bond length and bond strength:
(a) S—F, S—Br, S—Cl **(b)** C=O, C—O, C≡O

Plan In part (a), S is singly bonded to three different halogen atoms, so all members of the set have a bond order of 1. Bond length increases and bond strength decreases as the halogen's atomic radius increases, and that size trend is clear from the periodic table. In all the bonds in part (b), the same two atoms are involved, but the bond orders differ. In this case, bond strength increases and bond length decreases as bond order increases.

Solution **(a)** Atomic size increases down a group, so F < Cl < Br.

Bond length: S—Br > S—Cl > S—F

Bond strength: S—F > S—Cl > S—Br

(b) By ranking the bond orders, C≡O > C=O > C—O, we obtain

Bond length: C—O > C=O > C≡O

Bond strength: C≡O > C=O > C—O

Check From Tables 9.2 and 9.3, we see that the rankings are correct.

Comment Remember that for bonds involving pairs of different atoms, as in part (a), *the relationship between length and strength holds* only *for single bonds* and not in every case, so apply it carefully.

FOLLOW-UP PROBLEM 9.2 Rank the bonds in each set in order of *increasing* bond length and bond strength: **(a)** Si—F, Si—C, Si—O; **(b)** N=N, N—N, N≡N.

How the Model Explains the Properties of Covalent Substances

The covalent bonding model proposes that electron sharing between pairs of atoms leads to strong, localized bonds, usually within individual molecules. At first glance, however, it seems that the model is inconsistent with some of the familiar physical properties of covalent substances. After all, most are gases (such as methane and ammonia), liquids (such as benzene and water), or low-melting solids (such as sulfur and paraffin wax). Covalent bonds are strong (~200 to 500 kJ/mol), so why do covalent substances melt and boil at such low temperatures?

To answer this question, we must distinguish between two different sets of forces: (1) the *strong covalent bonding forces* holding the atoms together within the molecule (those we have been discussing), and (2) the *weak intermolecular forces* holding the molecules near each other in the macroscopic sample. It is these weak forces *between* the molecules, not the strong covalent bonds *within* each molecule, that are responsible for the physical properties of covalent substances.

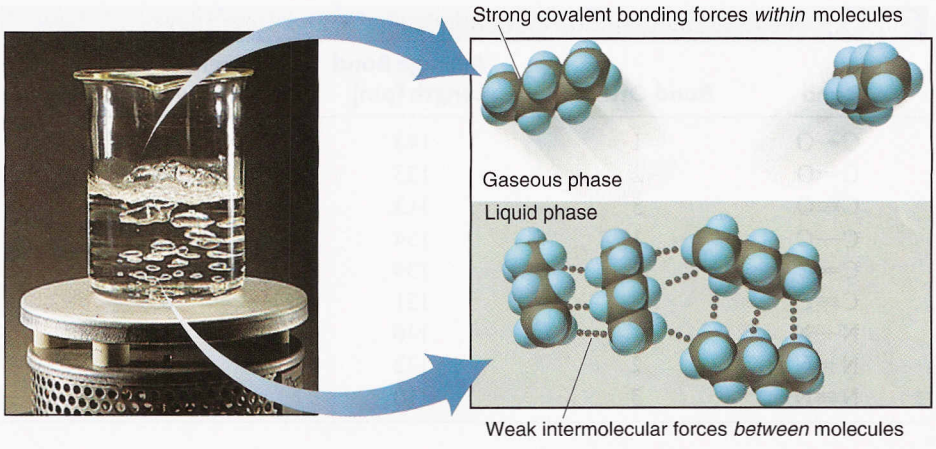

Figure 9.14 Strong forces within molecules and weak forces between them. When pentane boils, weak forces *between* molecules (intermolecular forces) are overcome, but the strong covalent bonds holding the atoms together within each molecule remain unaffected. Thus, the pentane molecules leave the liquid phase as intact units.

Consider, for example, what happens when pentane (C_5H_{12}) boils. As Figure 9.14 shows, the weak interactions *between* the pentane molecules are affected, not the strong C—C and C—H covalent bonds *within* each molecule.

Some covalent substances, called *network covalent solids,* do not consist of separate molecules. Rather, they are held together by covalent bonds that extend in three dimensions *throughout* the sample. If the model is correct, the properties of these substances *should* reflect the strength of their covalent bonds, and this is indeed the case. Two examples, quartz and diamond, are shown in Figure 9.15. Quartz (SiO_2) is very hard and melts at 1550°C. It is composed of silicon and oxygen atoms connected by covalent bonds that extend throughout the sample; no separate SiO_2 molecules exist. Diamond has covalent bonds connecting each of its carbon atoms to four others throughout the sample. It is the hardest substance known and melts at around 3550°C. Clearly, covalent bonds *are* strong, but because most covalent substances consist of separate molecules with weak forces between them, their physical properties do not reflect this bond strength. (We discuss intermolecular forces in detail in Chapter 12.)

Unlike ionic compounds, most covalent substances are poor electrical conductors, even when melted or when dissolved in water. An electric current is carried by either mobile electrons or mobile ions. In covalent substances the electrons are localized as either shared or unshared pairs, so they are not free to move, and no ions are present. The Tools of the Laboratory essay describes a tool used widely for studying the types of bonds in covalent substances.

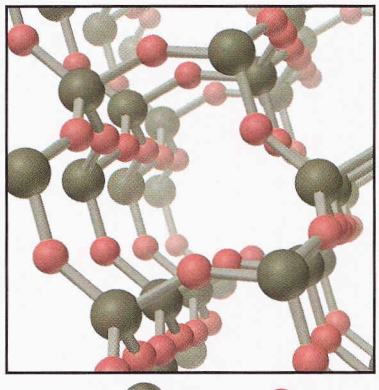

Figure 9.15 Covalent bonds of network covalent solids. A, In quartz (SiO_2), each Si atom is bonded covalently to four O atoms and each O atom is bonded to two Si atoms in a pattern that extends throughout the sample. Because no separate SiO_2 molecules are present, the melting point of quartz is very high, and it is very hard. **B,** In diamond, each C atom is covalently bonded to four other C atoms throughout the crystal. Diamond is the hardest natural substance known and has an extremely high melting point.

SECTION SUMMARY

A shared pair of valence electrons attracts the nuclei of two atoms and holds them together in a covalent bond while filling each atom's outer level. The number of shared pairs between the two atoms is the bond order. For a given type of bond, the bond energy is the average energy required to completely separate the bonded atoms; the bond length is the average distance between their nuclei. For a given pair of bonded atoms, bond order is directly related to bond energy and inversely related to bond length. Substances that consist of separate molecules are generally soft and low melting because of the weak forces between molecules. Solids held together by covalent bonds extending in three dimensions throughout the sample are extremely hard and high melting. Most covalent substances have low electrical conductivity because electrons are localized and ions are absent. The atoms in a covalent bond vibrate, and the energy of these vibrations can be studied with IR spectroscopy.

Infrared Spectroscopy

Infrared (IR) spectroscopy is an instrumental technique used primarily to study the molecular structure of covalently bonded molecules. Found in most research laboratories, the IR spectrometer is an essential part of the chemist's instrumental toolbox—along with the UV-visible spectrophotometer, mass spectrometer, and NMR spectrometer (described in Chapter 15)—for investigating and identifying organic and biological compounds.

The key components of an IR spectrometer are the same as those of similar instruments (see Figure B7.3, p. 270). The source emits radiation of many wavelengths, and those in the IR region are selected and directed at the sample. For organic compounds, the sample is typically either a pure liquid or a solid mixed with an inorganic salt such as KBr. The sample absorbs certain wavelengths of the IR radiation more than others, and an IR spectrum is generated.

What property of a molecule is displayed in its IR spectrum? All molecules, whether occurring in a gas, a liquid, or a solid, undergo continual rotations and vibrations. Consider, for instance, a sample of ethane gas. The $H_3C—CH_3$ molecules zoom throughout the container, colliding with the walls and each other. If we could look closely at one molecule, however, and disregard its motion through space, we would see the whole molecule rotating and its two CH_3 groups rotating relative to each other about the C—C bond. More important to IR spectroscopy, we would also see each of the bonded atoms vibrating, that is, moving closer to and farther from each other, as though the bonds were flexible springs: stretching and compressing, twisting, bending, rocking, and wagging (Figure B9.1). (Thus, the length of a given bond within a particular kind of molecule is actually the *average* distance between nuclei, analogous to the average length of a spring stretching and compressing.)

The energies of IR photons fall in the same range as the energies of these molecular vibrations. Each vibrational motion has its own natural frequency, which is based on the type of motion, the masses of the atoms, and the strength of the bond between them. These frequencies correspond to wavelengths between 2.5 and 25 μm, a part of the IR region of the electromagnetic spectrum (see Figure 7.3, p. 259). The energy of each of these vibrations is quantized. Just as an atom can absorb a photon whose energy corresponds to the difference between two quantized *electron* energy levels, a molecule can absorb an IR photon whose energy corresponds to the difference between two of its quantized *vibrational* energy levels.

The IR spectrum is particularly useful for compound identification because of two related factors. First, *each kind of bond has a characteristic range of IR wavelengths it can absorb*. For example, a C—C bond absorbs IR photons in a different wavelength range from those absorbed by a C=C bond, a C—H bond, a C=O bond, and so forth. Furthermore, groups of atoms that characterize particular types of organic compounds—alcohol, carboxylic acid, ether, and so forth—absorb in slightly different wavelength regions.

(continued)

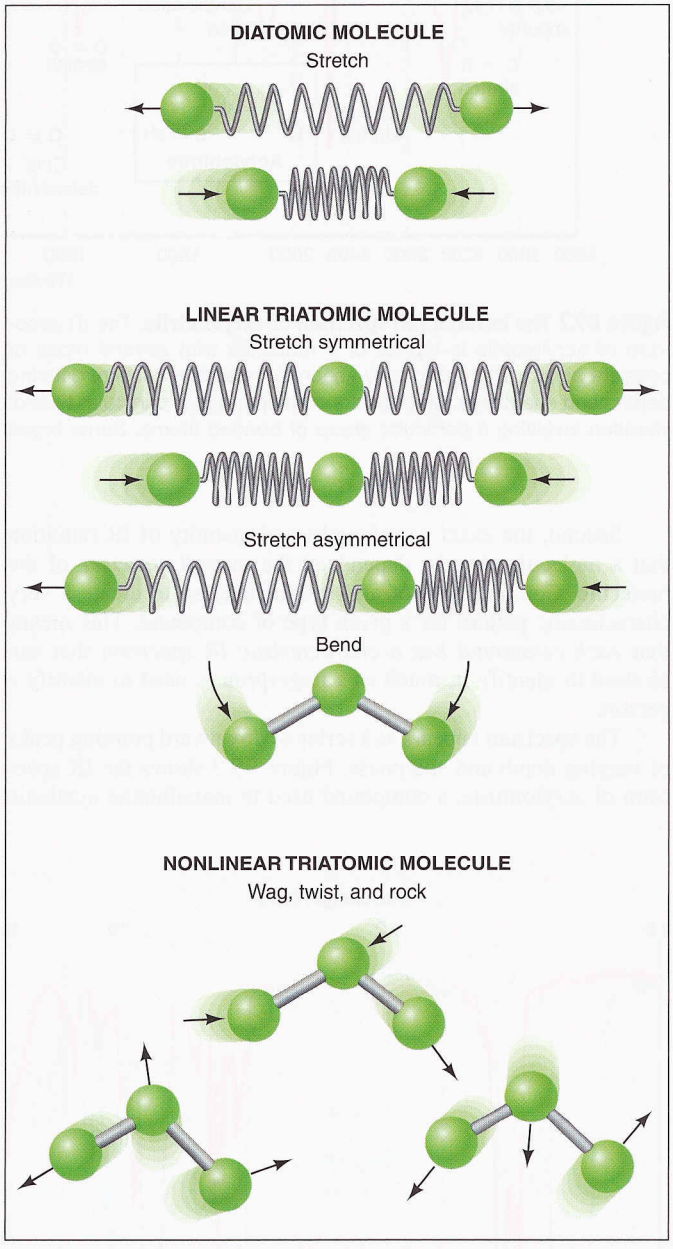

Figure B9.1 Some vibrational motions in general diatomic and triatomic molecules.

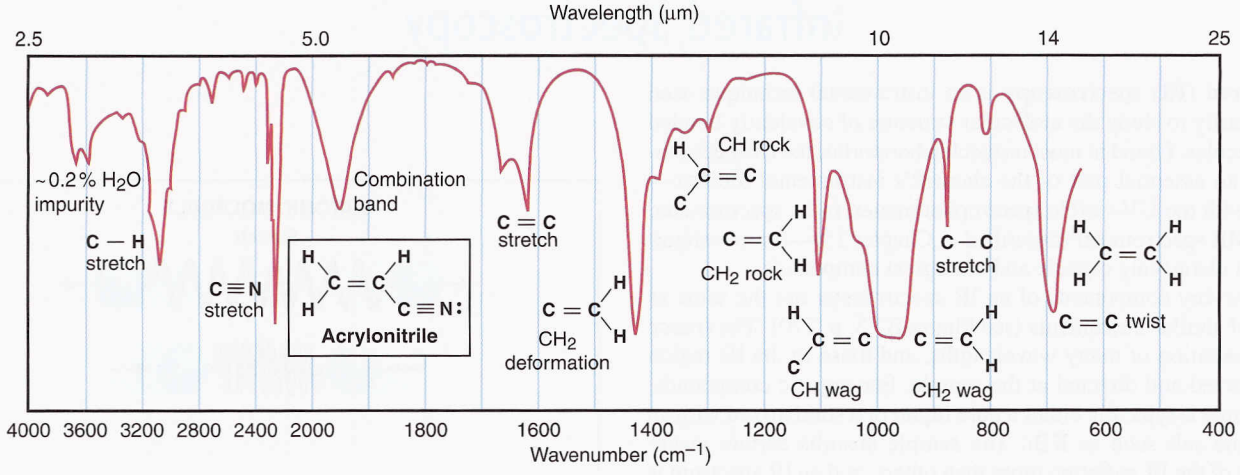

Figure B9.2 The infrared (IR) spectrum of acrylonitrile. The IR spectrum of acrylonitrile is typical of a molecule with several types of covalent bonds. There are many absorption bands (peaks) of differing depths and sharpness. Most peaks correspond to a particular type of vibration involving a particular group of bonded atoms. Some broad peaks (for example, "combination band") represent several overlapping types of vibrations. The spectrum is reproducible and unique for acrylonitrile. (The bottom axis shows wavenumbers, the inverse of wavelength, so its units are those of length^{-1}. The scale expands to the right of 2000 cm^{-1}.)

Second, the exact wavelengths and quantity of IR radiation that a molecule absorbs depend on the *overall structure* of the molecule. Combinations of absorptions overlap to create a very characteristic pattern for a given type of compound. This means that *each compound has a characteristic IR spectrum* that can be used to identify it, much as a fingerprint is used to identify a person.

The spectrum appears as a series of downward pointing peaks of varying depth and sharpness. Figure B9.2 shows the IR spectrum of acrylonitrile, a compound used to manufacture synthetic rubber and plastics. No other compound has exactly the same IR spectrum.

Constitutional (structural) isomers are easily distinguished by their IR spectra. These compounds have the same molecular formula but different structural formulas. We might expect very different isomers such as diethyl ether and 2-butanol to have very different IR spectra because their molecular structures are so dissimilar (Figure B9.3). However, even relatively similar compounds, such as 1,3-dimethylbenzene and 1,4-dimethylbenzene, have clearly different spectra (Figure B9.4).

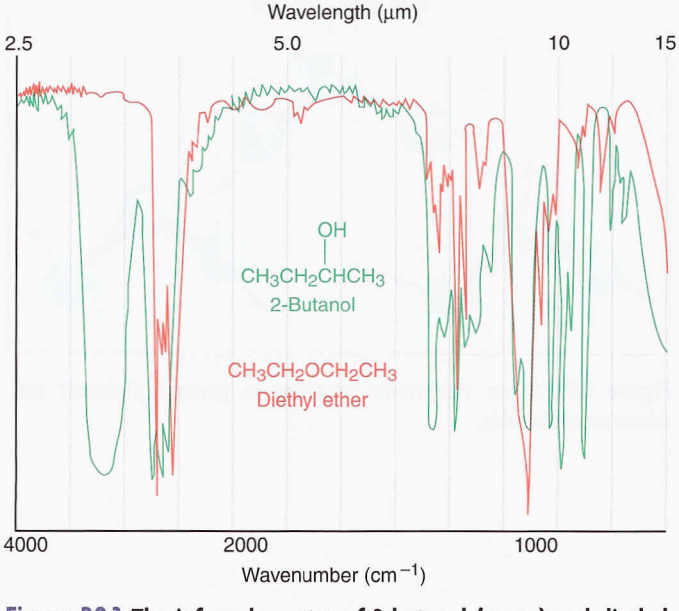

Figure B9.3 The infrared spectra of 2-butanol (*green*) and diethyl ether (*red*).

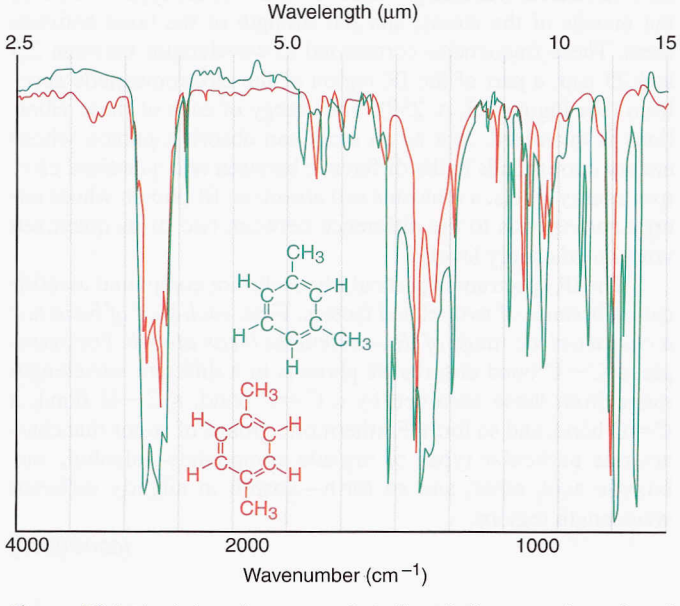

Figure B9.4 The infrared spectra of 1,3-dimethylbenzene (*green*) and 1,4-dimethylbenzene (*red*).

9.4 BOND ENERGY AND CHEMICAL CHANGE

The relative strengths of the bonds in reactants and products of a chemical change determine whether heat is released or absorbed. In fact, as you'll see in Chapter 20, it is one of two essential factors determining whether the change occurs at all. In this section, we'll discuss the importance of bond energy in chemical change, especially in the combustion of fuels and foods.

Changes in Bond Strengths: Where Does ΔH^0_{rxn} Come From?

In Chapter 6, we discussed the heat involved in a chemical change (ΔH^0_{rxn}), but we never stopped to ask a central question. When, for example, 1 mol of H_2 and 1 mol of F_2 react at 298 K, 2 mol of HF form and 546 kJ of heat is released:

$$H_2(g) + F_2(g) \longrightarrow 2HF(g) + 546 \text{ kJ}$$

Where does this heat come from? We find the answer through a very close-up view of the molecules and their energy components.

A system's internal energy has kinetic energy (E_k) and potential energy (E_p) components. Let's examine the contributions to these components to see which one changes during the reaction of H_2 and F_2 to form HF.

Of the various contributions to the kinetic energy, the most important come from the molecules moving through space, rotating, and vibrating and, of course, from the electrons moving within the atoms. Of the various contributions to the potential energy, the most important are electrostatic forces between the vibrating atoms, between nucleus and electrons (and between electrons) in each atom, between protons and neutrons in each nucleus, and, of course, between nuclei and shared electron pair in each bond.

The kinetic energy doesn't change during the reaction because the first three contributions—moving through space, rotating, and vibrating—are proportional to the temperature, which is constant at 298 K; and electron motion is not affected by a reaction. Of the potential energy contributions, those within the atoms and nuclei don't change, and vibrational forces vary only slightly as the bonded atoms change. The only significant change in energy in a chemical reaction is in the strength of attraction of the nuclei for the shared electron pair, that is, in the bond energy.

In other words, the answer to "Where does the heat come from?" is that it doesn't really "come from" anywhere: *the energy released or absorbed during a chemical change is due to differences between the reactant bond energies and the product bond energies.*

Using Bond Energies to Calculate ΔH^0_{rxn}

We can think of a reaction as a two-step process in which *heat is absorbed (ΔH^0 is positive) to break reactant bonds to form separate atoms and is released (ΔH^0 is negative) when the atoms rearrange to form product bonds.* The sum (symbolized by Σ) of these enthalpy changes is the heat of reaction, ΔH^0_{rxn}:

$$\Delta H^0_{rxn} = \Sigma \Delta H^0_{\text{reactant bonds broken}} + \Sigma \Delta H^0_{\text{product bonds formed}} \qquad (9.2)$$

- In an exothermic reaction, the total ΔH^0 for product bonds formed is *greater* than that for reactant bonds broken, so the sum, ΔH^0_{rxn}, is *negative*.
- In an endothermic reaction, the total ΔH^0 for product bonds formed is *less* than that for reactant bonds broken, so the sum, ΔH^0_{rxn}, is *positive*.

An equivalent form of Equation 9.2 uses bond energies:

$$\Delta H^0_{rxn} = \Sigma \text{BE}_{\text{reactant bonds broken}} - \Sigma \text{BE}_{\text{product bonds formed}}$$

The minus sign is needed because all bond energies are positive values.

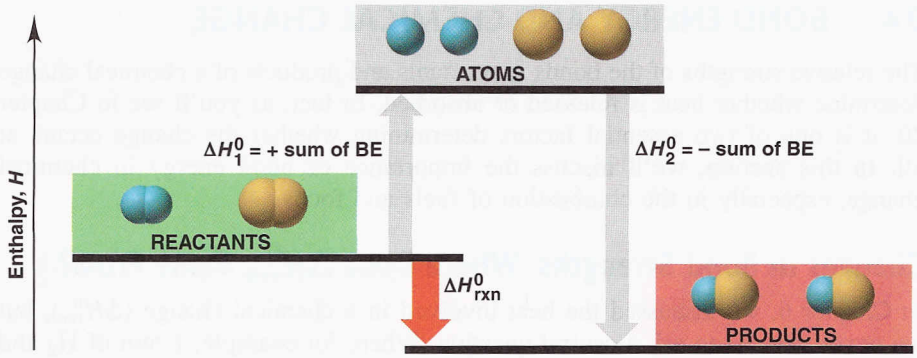

Figure 9.16 Using bond energies to calculate ΔH_{rxn}^0. Any chemical reaction can be divided conceptually into two hypothetical steps: (1) reactant bonds break to yield separate atoms in a step that absorbs heat (+ sum of BE), and (2) the atoms combine to form product bonds in a step that releases heat (− sum of BE). When the total bond energy of the products is greater than that of the reactants, more energy is released than is absorbed, and the reaction is exothermic (as shown); ΔH_{rxn}^0 is negative. When the total bond energy of the products is less than that of the reactants, the reaction is endothermic; ΔH_{rxn}^0 is positive.

When 1 mol of H—H bonds and 1 mol of F—F bonds absorb energy and break, the 2 mol each of H and F atoms form 2 mol of H—F bonds, which releases energy (Figure 9.16). Recall that *weaker bonds (less stable, more reactive) are easier to break than stronger bonds (more stable, less reactive) because they are higher in energy.* Heat is released when HF forms because the bonds in H_2 and F_2 are weaker (less stable) than the bonds in HF (more stable). Put another way, the sum of the bond energies of 1 mol each of H_2 and F_2 is *smaller* than the sum of the bond energy in 2 mol of HF.

We use bond energies to calculate ΔH_{rxn}^0 by assuming that *all the reactant bonds break to give individual atoms, from which all the product bonds form.* Even though the actual reaction may not occur this way—typically, only certain bonds break and form—Hess's law allows us to sum the bond energies (with their appropriate signs) to arrive at the overall heat of reaction. (This method assumes that ΔH_{rxn}^0 is due entirely to changes in bond energy, which requires that all reactants and products be in the same physical state. When phase changes occur, additional heat must be taken into account. We address this topic in Chapter 12.)

Let's use bond energies to calculate ΔH_{rxn}^0 for the combustion of methane and compare it with the value obtained by calorimetry (Section 6.3), which is

$$CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(g) \qquad \Delta H_{rxn}^0 = -802 \text{ kJ}$$

Figure 9.17 shows that all the bonds in CH_4 and O_2 break, and the atoms form the bonds in CO_2 and H_2O. We find the bond energy values in Table 9.2 (p. 341), and use a positive sign for bonds broken and a negative sign for bonds formed:

Bonds broken

$$\begin{aligned} 4 \times \text{C—H} &= (4 \text{ mol})(413 \text{ kJ/mol}) = 1652 \text{ kJ} \\ 2 \times \text{O}_2 &= (2 \text{ mol})(498 \text{ kJ/mol}) = 996 \text{ kJ} \\ \hline \Sigma \Delta H_{\text{reactant bonds broken}}^0 &= 2648 \text{ kJ} \end{aligned}$$

Bonds formed

$$\begin{aligned} 2 \times \text{C=O} &= (2 \text{ mol})(-799 \text{ kJ/mol}) = -1598 \text{ kJ} \\ 4 \times \text{O—H} &= (4 \text{ mol})(-467 \text{ kJ/mol}) = -1868 \text{ kJ} \\ \hline \Sigma \Delta H_{\text{product bonds formed}}^0 &= -3466 \text{ kJ} \end{aligned}$$

Applying Equation 9.2 gives

$$\begin{aligned} \Delta H_{rxn}^0 &= \Sigma \Delta H_{\text{reactant bonds broken}}^0 + \Sigma \Delta H_{\text{product bonds formed}}^0 \\ &= 2648 \text{ kJ} + (-3466 \text{ kJ}) = -818 \text{ kJ} \end{aligned}$$

Why is there a discrepancy between the bond energy value (−818 kJ) and the calorimetric value (−802 kJ)? Variations in experimental method always introduce small discrepancies, but there is a more basic reason in this case. Because bond energies are *average* values obtained from many different compounds, the energy of the bond *in a particular substance* is usually close, but not equal, to this average. For example, the tabulated C—H bond energy of 413 kJ/mol is the

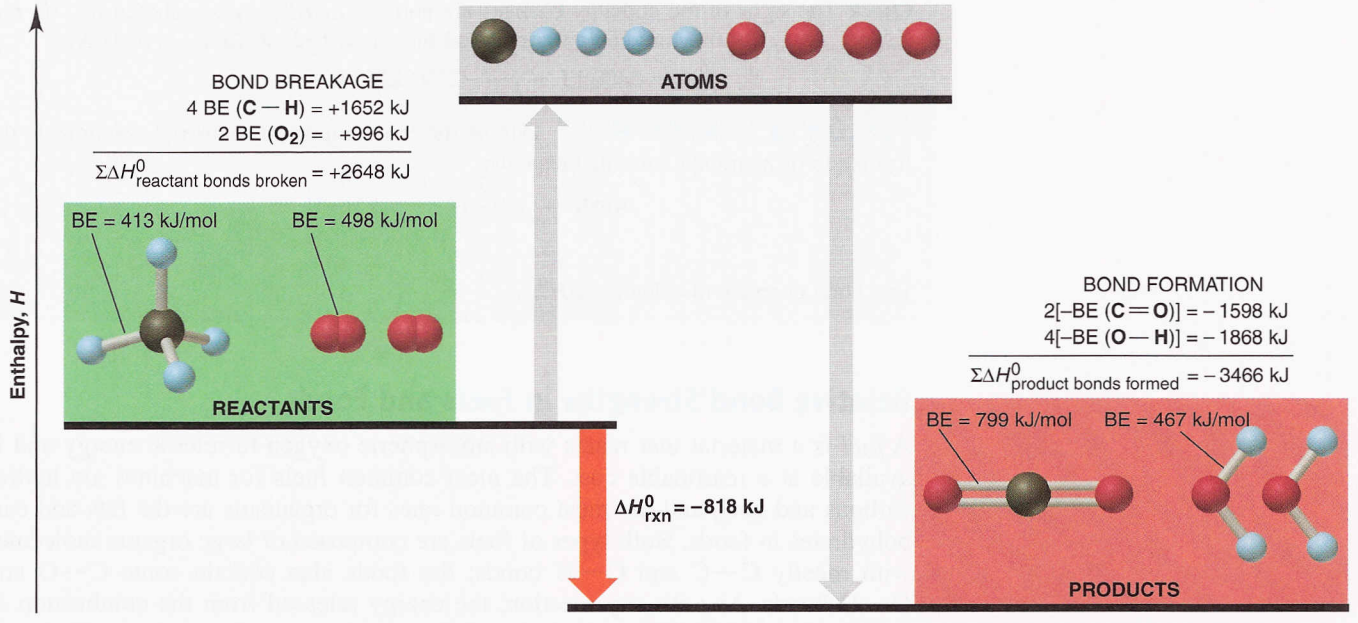

Figure 9.17 Using bond energies to calculate ΔH^0_{rxn} of methane. Treating the combustion of methane as a hypothetical two-step process (see Figure 9.16) means breaking all the bonds in the reactants and forming all the bonds in the products.

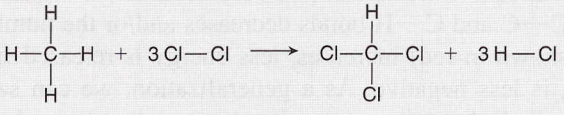
average value of C—H bonds in many different molecules. In fact, 415 kJ is actually required to break 1 mol of C—H bonds in methane, or 1660 kJ for 4 mol of these bonds, which gives a ΔH^0_{rxn} even closer to the calorimetric value. Thus, it isn't surprising to find a discrepancy between the two ΔH^0_{rxn} values. What is surprising—and satisfying in its confirmation of bond theory—is that the values are so close.

SAMPLE PROBLEM 9.3 Using Bond Energies to Calculate ΔH^0_{rxn}

Problem Calculate ΔH^0_{rxn} for the chlorination of methane to form chloroform:



Plan We assume that, in the reaction, all the reactant bonds break and all the product bonds form. We find the bond energies in Table 9.2 (p. 341) and substitute the two sums, with correct signs, into Equation 9.2.

Solution Finding the standard enthalpy changes for bonds broken and for bonds formed: For bonds broken, the bond energy values are

$$\begin{aligned} 4 \times \text{C—H} &= (4\text{ mol})(413\text{ kJ/mol}) = 1652\text{ kJ} \\ 3 \times \text{Cl—Cl} &= (3\text{ mol})(243\text{ kJ/mol}) = 729\text{ kJ} \\ \Sigma\Delta H^0_{\text{bonds broken}} &= 2381\text{ kJ} \end{aligned}$$

For bonds formed, the values are

$$\begin{aligned} 3 \times \text{C—Cl} &= (3\text{ mol})(-339\text{ kJ/mol}) = -1017\text{ kJ} \\ 1 \times \text{C—H} &= (1\text{ mol})(-413\text{ kJ/mol}) = -413\text{ kJ} \\ 3 \times \text{H—Cl} &= (3\text{ mol})(-427\text{ kJ/mol}) = -1281\text{ kJ} \\ \Sigma\Delta H^0_{\text{bonds formed}} &= -2711\text{ kJ} \end{aligned}$$

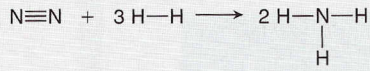
Calculating ΔH^0_{rxn}:

$$\Delta H^0_{rxn} = \Sigma\Delta H^0_{\text{bonds broken}} + \Sigma\Delta H^0_{\text{bonds formed}} = 2381\text{ kJ} + (-2711\text{ kJ}) = -330\text{ kJ}$$

Check The signs of the enthalpy changes are correct: $\Sigma\Delta H^0_{\text{bonds broken}}$ should be >0, and $\Sigma\Delta H^0_{\text{bonds formed}}$ <0. More energy is released than absorbed, so ΔH^0_{rxn} is negative:

$$\sim 2400 \text{ kJ} + [\sim(-2700 \text{ kJ})] = -300 \text{ kJ}$$

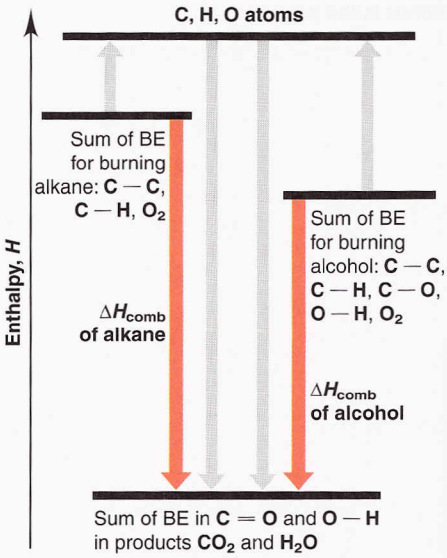
FOLLOW-UP PROBLEM 9.3 One of the most important industrial reactions is the formation of ammonia from its elements:



Use bond energies to calculate ΔH^0_{rxn}.

Relative Bond Strengths in Fuels and Foods

A *fuel* is a material that reacts with atmospheric oxygen to release energy and is available at a reasonable cost. The most common fuels for machines are hydrocarbons and coal, and the most common ones for organisms are the fats and carbohydrates in foods. Both types of fuels are composed of large organic molecules with mostly C—C and C—H bonds; the foods also contain some C—O and O—H bonds. As with any reaction, the energy released from the combustion of a fuel arises from differences in bond energies between the reactants (fuel plus oxygen) and the products (CO_2 and H_2O). When the fuel reacts with O_2, the bonds break, and the C, H, and O atoms form C=O and O—H bonds in the products. Because the reaction is exothermic, we know that the total strength of the bonds in the products is greater than that of the bonds in the reactants. In other words, the bonds in CO_2 and H_2O are stronger (lower in energy, more stable) than those in gasoline (or salad oil) and O_2 (weaker, higher in energy, less stable).



Fuels with more weak bonds yield more energy than fuels with fewer weak bonds. When an alkane burns, C—C and C—H bonds break; when an alcohol burns, C—O and O—H bonds break as well. A look at the bond energy values in Table 9.2 (p. 341) shows that the sum for C—C and C—H bonds (760 kJ/mol) is less than the sum for C—O and O—H bonds (825 kJ/mol). Fuels with relatively more of the weaker bonds will release more energy because it takes less energy to break them apart before the atoms rearrange to form the products (see margin). Table 9.5 demonstrates this point for some small organic compounds. As the number of C—C and C—H bonds decreases and/or the number of C—O and O—H bonds (shown in red) increases, less energy is released from combustion; that is, ΔH_{comb} is less negative. As a generalization, we can say that the fewer bonds to O in a fuel, the more energy it releases when burned.

Table 9.5 Heats of Combustion (ΔH_{comb}) of Some Carbon Compounds

	Two-Carbon Compounds		One-Carbon Compounds	
	Ethane (C_2H_6)	Ethanol (C_2H_5OH)	Methane (CH_4)	Methanol (CH_3OH)
Structural Formula				Sum of C—C and C—H bonds	7	6	4	3
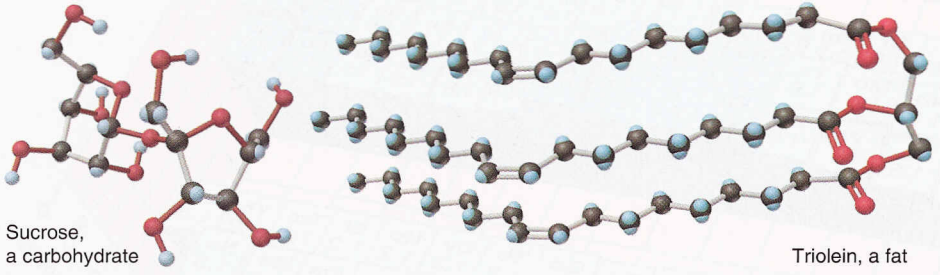
Sum of C—O and O—H bonds	0	2	0	2
ΔH_{comb} (kJ/mol)	−1560	−1367	−890	−727
ΔH_{comb} (kJ/g)	−51.88	−29.67	−55.5	−22.7

Both fats and carbohydrates serve as high-energy foods—carbohydrates for shorter term release and fats for longer term storage. Fats consist of chains of carbon atoms (C—C bonds) attached to hydrogen atoms (C—H bonds), with few, if any, C—O and O—H bonds (shown in red below). In contrast, carbohydrates have far fewer C—C and C—H bonds and many more C—O and O—H bonds. Both kinds of foods are metabolized in the body to CO_2 and H_2O. Fats "contain more Calories" per gram than carbohydrates do because fats have more weaker bonds and fewer stronger bonds—that is, fewer bonds to O. Thus, fats should release more energy than carbohydrates, which Table 9.6 confirms.



Sucrose, a carbohydrate

Triolein, a fat

Table 9.6 Heats of Combustion of Some Fats and Carbohydrates

Substance	ΔH_{comb} (kJ/g)
Fats	
Vegetable oil	−37.0
Margarine	−30.1
Butter	−30.0
Carbohydrates	
Table sugar (sucrose)	−16.2
Brown rice	−14.9
Maple syrup	−10.4

SECTION SUMMARY

The only component of internal energy that changes significantly during a reaction is the energy of the bonds in reactants and products; this change in bond energy is quantified as ΔH^0_{rxn}. A reaction involves breaking reactant bonds and forming product bonds. Applying Hess's law, we use tabulated bond energies to calculate ΔH^0_{rxn}. Bonds in fuels and foods are weaker (less stable, higher energy) than bonds in waste products. Fuels with more weak bonds release more energy than fuels with fewer.

9.5 BETWEEN THE EXTREMES: ELECTRONEGATIVITY AND BOND POLARITY

Scientific models are idealized descriptions of reality. As we've discussed them so far, the ionic and covalent bonding models portray compounds as being formed by *either* complete electron transfer *or* complete electron sharing. However, the great majority of compounds have bonds that are more accurately thought of as partially ionic and partially covalent (Figure 9.18). Let's explore the actual continuum in bonding that lies between these extremes.

Electronegativity

One of the most important concepts in chemical bonding is **electronegativity (EN),** the relative ability of a bonded atom to attract the shared electrons.* More than 50 years ago, the American chemist Linus Pauling developed the most common scale of relative EN values for the elements. Here is an example to show the basis of Pauling's approach. We might expect the bond energy of the HF bond to be the average of the energies of an H—H bond (432 kJ/mol) and an F—F bond (159 kJ/mol), or 296 kJ/mol. However, the actual bond energy of H—F is 565 kJ/mol, or 269 kJ/mol *higher* than the average. Pauling reasoned that this difference is due to an *electrostatic (charge) contribution* to the H—F bond energy. If F attracts the shared electron pair more strongly than H, that is, if F is more

*Electronegativity is not the same as electron affinity (EA), although many elements with a high EN also have a highly negative EA. Electronegativity refers to a bonded atom attracting the shared electron pair; electron affinity refers to a separate atom in the gas phase gaining an electron to form a gaseous anion.

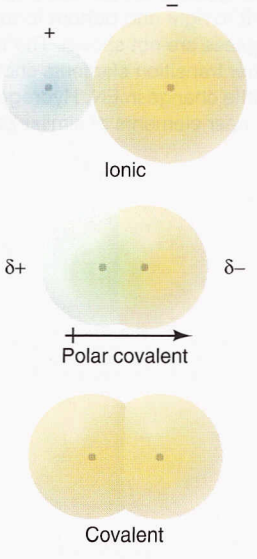


Figure 9.18 The prevalence of electron sharing. The extremes of pure ionic *(top)* and pure covalent *(bottom)* bonding occur rarely, if ever. Much more common is the unequal electron sharing seen in polar covalent bonding.

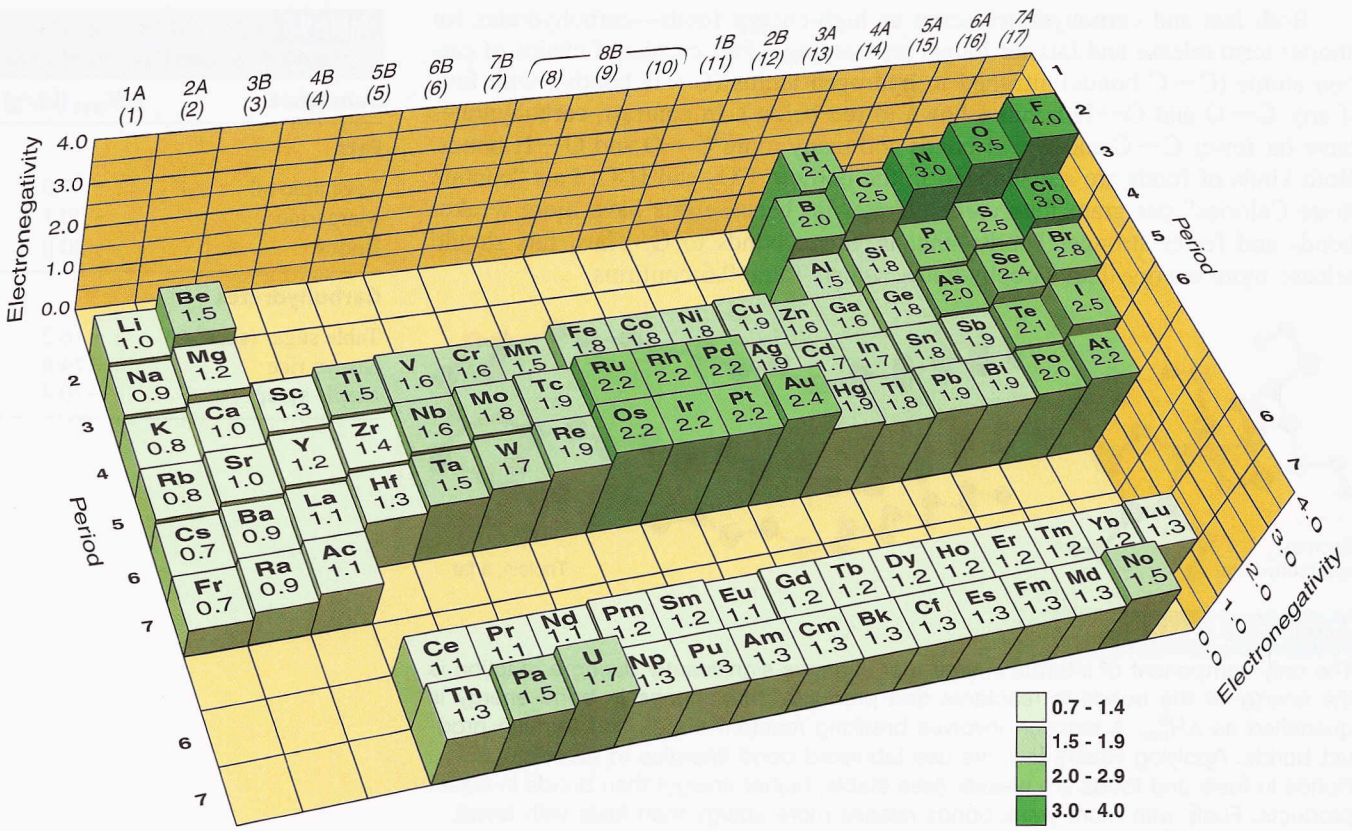

Figure 9.19 The Pauling electronegativity (EN) scale. The EN is shown by the height of the post with the value on top. The key indicates arbitrary EN cutoffs. In the main groups, EN generally *increases* from left to right and bottom to top. The noble gases are not shown. The transition and inner transition elements show relatively little change in EN. Hydrogen is shown near elements of similar EN.

electronegative than H, the electrons will spend more time closer to F. This unequal sharing of electrons makes the F end of the bond partially negative and the H end partially positive, and the attraction between these partial charges *increases* the energy required to break the bond.

From similar studies with the remaining hydrogen halides and many other compounds, Pauling arrived at the scale of *relative EN values* shown in Figure 9.19. These values are not measured quantities but are based on Pauling's assignment of the highest EN value, 4.0, to fluorine.

Trends in Electronegativity Because the nucleus of a smaller atom is closer to the shared pair than that of a larger atom, it attracts the bonding electrons more strongly. So, in general, electronegativity is inversely related to atomic size. As Figure 9.20 makes clear for the main-group elements, *electronegativity generally increases up a group and across a period.* The figure includes the atomic size (on top of each post) and shows that this size decreases with the electronegativity increase. In Pauling's electronegativity scale, and in any of several others that have been devised, *nonmetals are more electronegative than metals.* The most electronegative element is fluorine, with oxygen a close second. Thus, except when it bonds with fluorine, oxygen always pulls bonding electrons toward itself. The least electronegative element (also referred to as the most *electropositive*) is francium, in the lower left corner of the periodic table, but it is radioactive and extremely rare, so for all practical purposes, cesium is the most electropositive.*

*In 1934, the American physicist Robert S. Mulliken developed an approach to electronegativity based solely on atomic properties: EN = (IE − EA)/2. By this approach as well, fluorine, with a high ionization energy (IE) and a large negative electron affinity (EA), has a high EN; and cesium, with a low IE and a small EA, has a low EN.

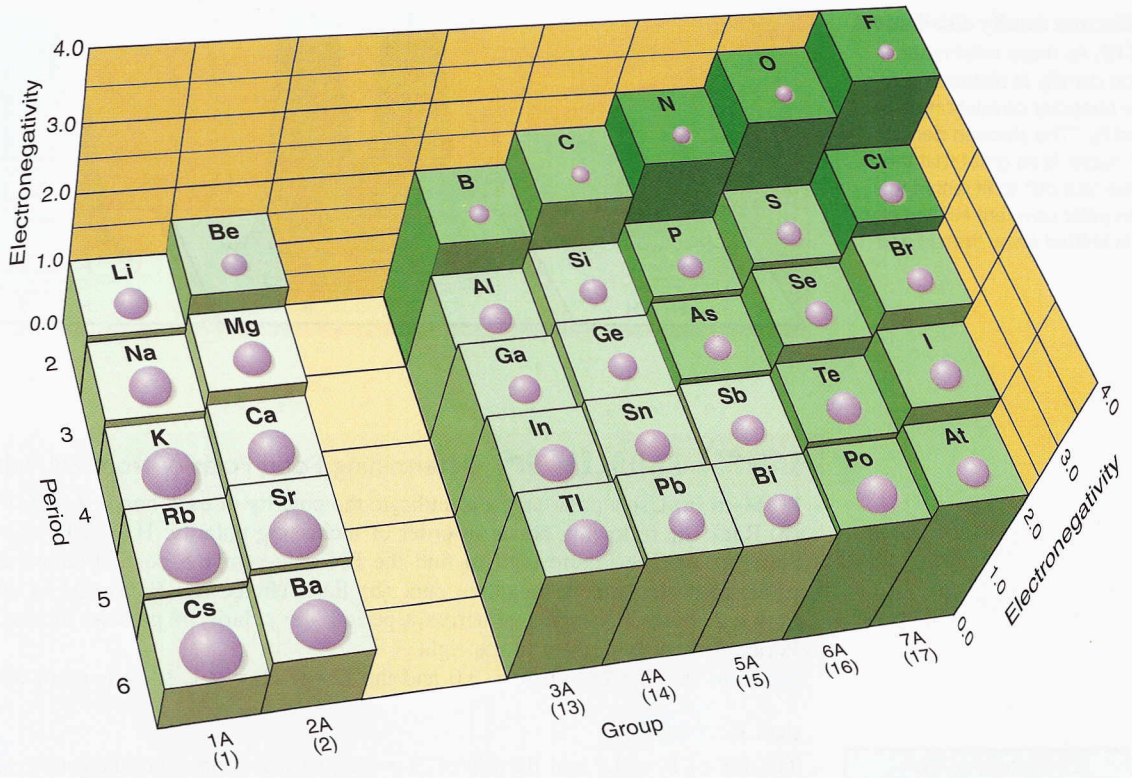

Figure 9.20 Electronegativity and atomic size. The electronegativities of the main-group elements from Periods 2 to 6 (excluding the noble gases) are shown as posts of different heights. On top of each post is a hemisphere showing the relative atomic size.

Electronegativity and Oxidation Number One important use of electronegativity is in determining an atom's oxidation number (O.N.; see Section 4.5):

1. The more electronegative atom in a bond is assigned *all* the *shared* electrons; the less electronegative atom is assigned *none*.
2. Each atom in a bond is assigned *all* of its *unshared* electrons.
3. The oxidation number is given by

$$\text{O.N.} = \text{no. of valence } e^- - (\text{no. of shared } e^- + \text{no. of unshared } e^-)$$

In HCl, for example, Cl is more electronegative than H. It has 7 valence electrons but is assigned 8 (2 shared + 6 unshared), so its oxidation number is $7 - 8 = -1$. The H atom has 1 valence electron and is assigned none, so its oxidation number is $1 - 0 = +1$.

Polar Covalent Bonds and Bond Polarity

In HF, atoms of different electronegativities form a bond, so the bonding pair is shared *un*equally. This unequal distribution of electron density means the bond has partially negative and positive poles. Such a **polar covalent bond** is depicted by a polar arrow ($\longrightarrow$) pointing toward the negative pole or by $\delta+$ and $\delta-$ symbols, where the lowercase Greek letter delta, δ, represents a partial charge:

In the H—H and F—F bonds, the atoms are identical, so the bonding pair is shared equally, and a **nonpolar covalent bond** results. By knowing the EN values of the atoms in a bond, we can find the direction of the bond polarity. Figure 9.21 (next page) compares the distribution of electron density in H_2, F_2, and HF.

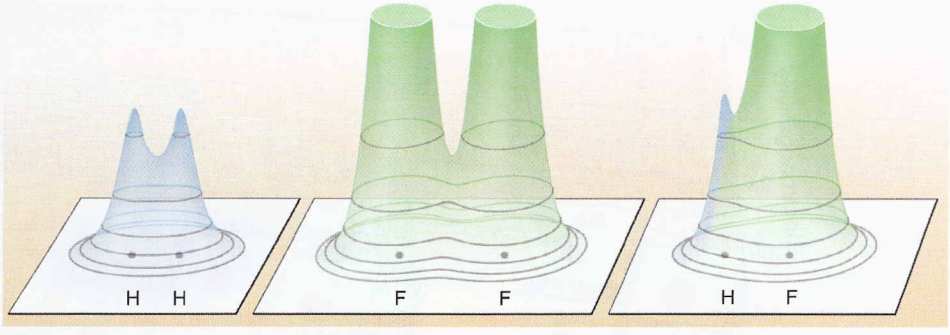

Figure 9.21 Electron density distributions in H_2, F_2, and HF. As these relief maps show, electron density is distributed equally in the nonpolar covalent molecules H_2 and F_2. (The electron density around the F nuclei is so great that the peaks must be "cut off" to fit within the figure.) But, in polar covalent HF, the electron density is shifted away from H and toward F.

SAMPLE PROBLEM 9.4 Determining Bond Polarity from EN Values

Problem **(a)** Use a polar arrow to indicate the polarity of each bond: N—H, F—N, I—Cl. **(b)** Rank the following bonds in order of increasing polarity: H—N, H—O, H—C.

Plan **(a)** We use Figure 9.19 to find the EN values of the bonded atoms and point the polar arrow toward the negative end. **(b)** Each choice has H bonded to an atom from Period 2. Since EN increases across a period, the polarity is greatest for the bond whose Period 2 atom is farthest to the right.

Solution **(a)** The EN of N = 3.0 and the EN of H = 2.1, so N is more electronegative than H: $\overset{\longleftarrow}{\text{N—H}}$

The EN of F = 4.0 and the EN of N = 3.0, so F is more electronegative: $\overset{\longleftarrow}{\text{F—N}}$

The EN of I = 2.5 and the EN of Cl = 3.0, so I is less electronegative: $\overset{\longrightarrow}{\text{I—Cl}}$

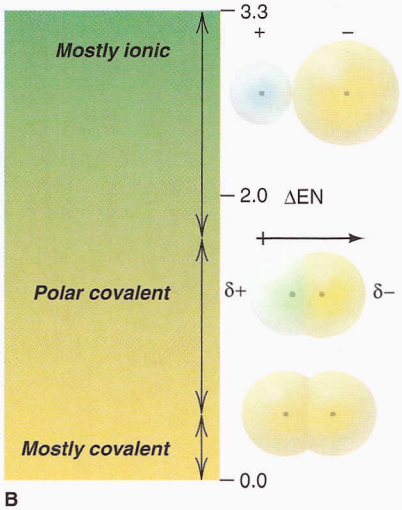
(b) The order of increasing EN is C < N < O, and each has a higher EN than H. Therefore, O pulls most on the electron pair shared with H, and C pulls least; so the order of bond polarity is H—C < H—N < H—O.

Comment In Chapter 10, you'll see that the polarity of the bonds in a molecule contributes to the overall polarity of the molecule, which is a major factor determining the magnitudes of several physical properties.

FOLLOW-UP PROBLEM 9.4 Arrange each set of bonds in order of increasing polarity, and indicate bond polarity with δ+ and δ− symbols:
(a) Cl—F, Br—Cl, Cl—Cl **(b)** Si—Cl, P—Cl, S—Cl, Si—Si

ΔEN	IONIC CHARACTER
>1.7	Mostly ionic
0.4-1.7	Polar covalent
<0.4	Mostly covalent
0	Nonpolar covalent

A



B

Figure 9.22 Boundary ranges for classifying ionic character of chemical bonds. **A,** The electronegativity difference (ΔEN) between bonded atoms shows cutoff values that act as a general guide to a bond's relative ionic character. **B,** The gradation in ionic character across the entire bonding range is shown as shading from ionic *(green)* to covalent *(yellow)*.

The Partial Ionic Character of Polar Covalent Bonds

If you ask "Is an X—Y bond ionic or covalent?" the answer in almost every case is "Both, partially!" A better question is "*To what extent* is the bond ionic or covalent?" The existence of partial charges means that a polar covalent bond behaves as if it were partially ionic. The **partial ionic character** of a bond is related directly to the **electronegativity difference (ΔEN),** the difference between the EN values of the bonded atoms: *a greater ΔEN results in larger partial charges and a higher partial ionic character.* Consider these three fluorine-containing molecules: ΔEN for LiF(*g*) is 4.0 − 1.0 = 3.0; for HF(*g*), it is 4.0 − 2.1 = 1.9; and for F_2(*g*), it is 4.0 − 4.0 = 0. Thus, the bond in LiF has more ionic character than the H—F bond, which has more than the F—F bond.

Various attempts have been made to classify the ionic character of bonds, but they all use arbitrary cutoff values, which is inconsistent with the gradation of ionic character observed experimentally. One approach uses ΔEN values to divide bonds into ionic, polar covalent, and nonpolar covalent. Based on a range of ΔEN values from 0 (completely nonpolar) to 3.3 (highly ionic), some approximate guidelines appear in Figure 9.22.

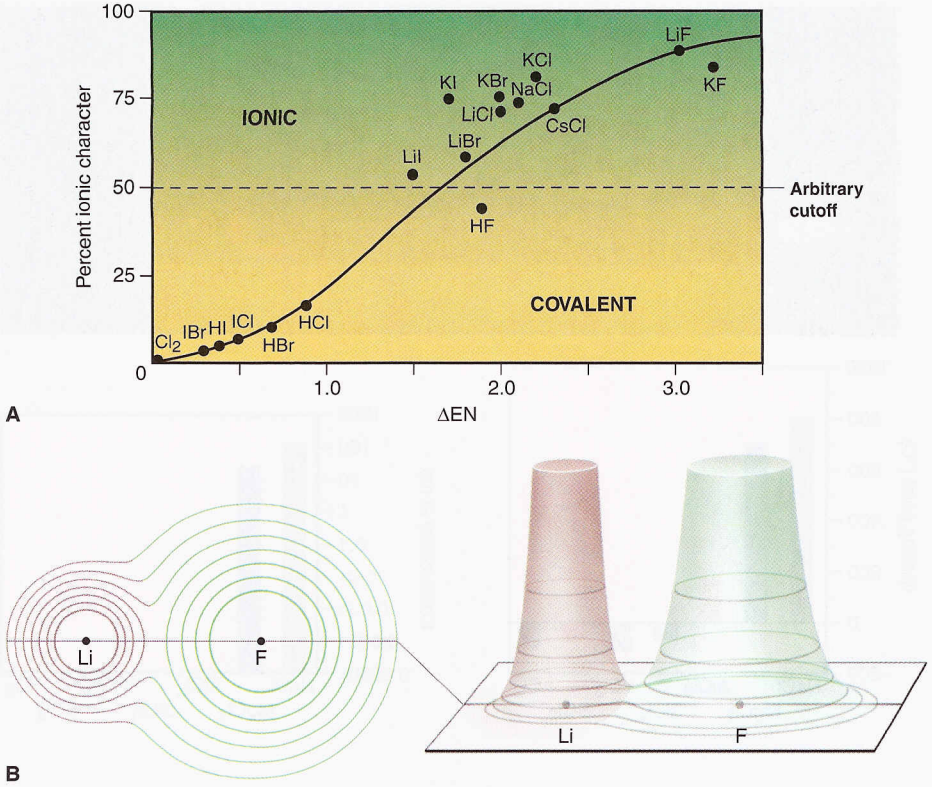


Figure 9.23 Percent ionic character as a function of electronegativity difference (ΔEN). **A,** The percent ionic character is plotted against ΔEN for some gaseous diatomic molecules. Note that, in general, ΔEN correlates with ionic character. (The arbitrary cutoff for an ionic compound is >50% ionic character.) **B,** Even in highly ionic LiF, significant overlap occurs between the ions, indicating some covalent character. The contour map *(left)* and relief map *(right)* depict this overlap.

Another approach calculates the *percent ionic character* of a bond by comparing the actual behavior of a polar molecule in an electric field with the behavior it would show if the electron were transferred completely (a pure ionic bond). A value of 50% ionic character divides substances we call "ionic" from those we call "covalent." Such methods show 43% ionic character for the H—F bond and expected decreases for the other hydrogen halides: H—Cl is 19% ionic, H—Br 11%, and H—I 4%. A plot of percent ionic character vs. ΔEN for a variety of gaseous diatomic molecules is shown in Figure 9.23A. The specific values are not important, but note that *percent ionic character generally increases with ΔEN.* Another point to note is that whereas some molecules, such as $Cl_2(g)$, have 0% ionic character, none has 100% ionic character. Thus, *electron sharing occurs to some extent in every bond,* even one between an alkali metal and a halogen, as electron density contour and relief maps show in Figure 9.23B.

The Continuum of Bonding Across a Period

A metal and a nonmetal—elements from opposite sides of the periodic table—have a relatively large ΔEN and typically interact by electron transfer to form an ionic compound. Two nonmetals—elements from the same side of the table—have a small ΔEN and interact by electron sharing to form a covalent compound. When we combine the nonmetal chlorine with each of the other elements in Period 3, starting with sodium, we should observe a steady decrease in ΔEN and a gradation in bond type from ionic through polar covalent to nonpolar covalent.

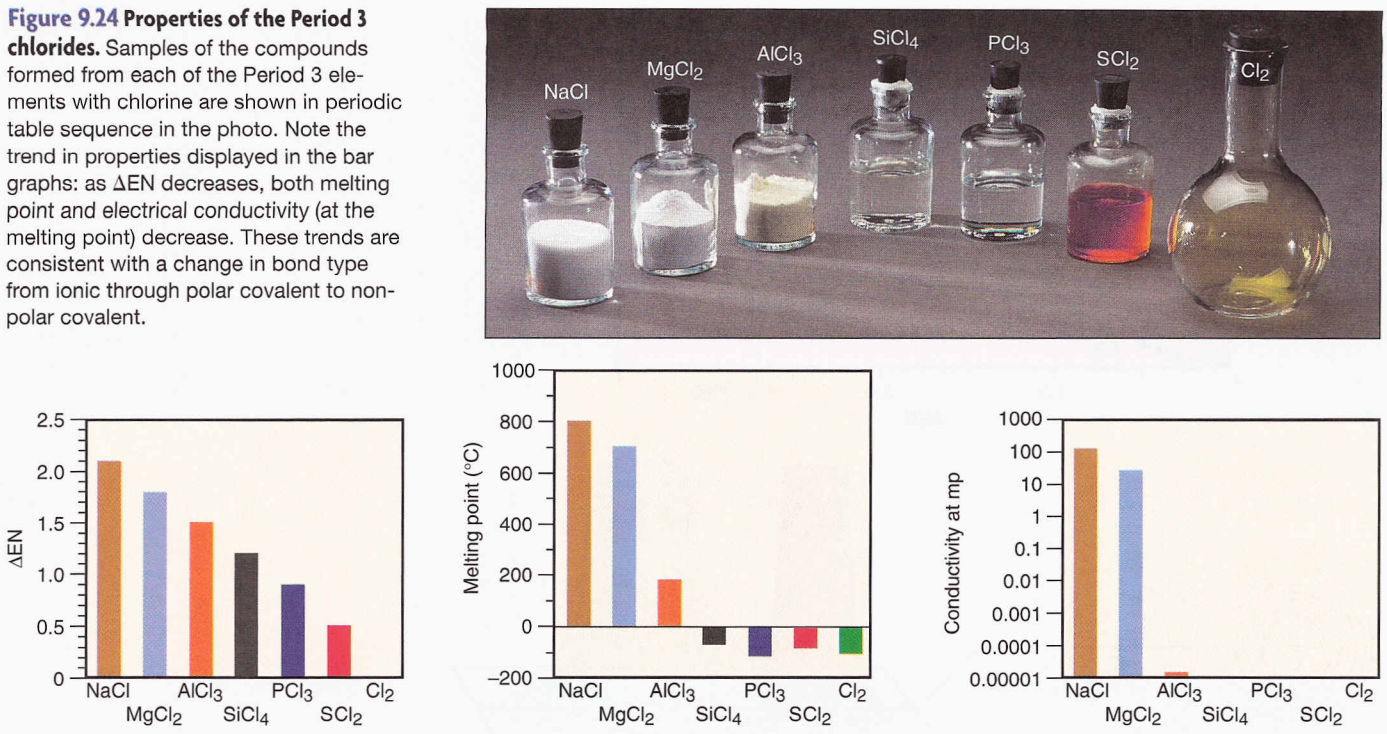

Figure 9.24 Properties of the Period 3 chlorides. Samples of the compounds formed from each of the Period 3 elements with chlorine are shown in periodic table sequence in the photo. Note the trend in properties displayed in the bar graphs: as ΔEN decreases, both melting point and electrical conductivity (at the melting point) decrease. These trends are consistent with a change in bond type from ionic through polar covalent to nonpolar covalent.

Figure 9.24 shows samples of the common Period 3 chlorides—NaCl, $MgCl_2$, $AlCl_3$, $SiCl_4$, PCl_3, and SCl_2, as well as Cl_2—and some key macroscopic properties, while Figure 9.25 shows an electron density relief map of a bond in each of these substances. Note the steady increase in covalent character, as shown by the height of the electron density between the peaks—the bonding region—as we move from ionic NaCl to nonpolar covalent Cl_2.

The first compound in the series is sodium chloride, a white (colorless) crystalline solid with typical ionic properties—high melting point and high electrical conductivity when molten. Having, in addition, a ΔEN of 2.1, NaCl is ionic by any criterion. However, note that, as with LiF (Figure 9.23B), a small but significant covalent region appears in the relief map for NaCl. Magnesium chloride is still considered ionic, with a ΔEN of 1.8, but it has a lower melting point and lower conductivity, as well as a slightly higher bonding region in the relief map.

Aluminum chloride is still less ionic. Rather than having a three-dimensional lattice of Al^{3+} and Cl^- ions, it consists of extended layers of highly polar Al—Cl covalent bonds, as shown by its ΔEN value of 1.5. Weak forces between layers of bonded atoms result in a much lower melting point, and the low electrical conductivity of molten $AlCl_3$ is consistent with a scarcity of ions. And, once again, we see a higher electron density between the nuclei.

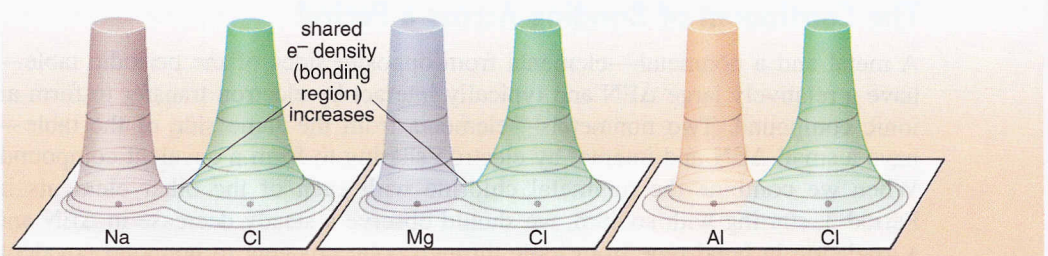

Figure 9.25 Electron density distributions in bonds of the Period 3 chlorides. The relief maps show the electron density for one bond of each chloride. Note the small, but steady, increase in the height of the bonding region between the nuclei, which indicates greater covalent character.

Silicon tetrachloride's melting point is very low because of weak forces *between* its separate molecules, and it has no measurable electrical conductivity. Each molecule has strong Si—Cl bonds with a ΔEN value of 1.2, near the middle of the polar covalent region. With a ΔEN value of 0.9, phosphorus trichloride continues the trend toward lower bond polarity, as evidenced by its very low melting point. The bonds in sulfur dichloride are even less polar (ΔEN = 0.5). Finally, nonpolar, diatomic chlorine is the only one of these substances that is a gas at room temperature. The relief maps show the expected increasing height of the electron density in the bonding region.

Thus, *as ΔEN becomes smaller, the bond becomes more covalent,* with greater electron density between the nuclei, and the macroscopic properties of the Period 3 chlorides and Cl_2 change from those of a solid consisting of ions to those of a gas consisting of individual molecules.

SECTION SUMMARY

An atom's electronegativity refers to its ability to pull bonded electrons toward it, which generates partial charges at the ends of the bond. Electronegativity increases across a period and decreases down a group, the reverse of the trends in atomic size. The greater the ΔEN for the two atoms in a bond, the more polar the bond is and the greater its ionic character. For chlorides of Period 3 elements, there is a gradation of bond type from ionic to polar covalent to nonpolar covalent.

9.6 AN INTRODUCTION TO METALLIC BONDING

The third type of chemical bonding we consider is metallic bonding, which occurs among large numbers of metal atoms. In this section, you'll see a simple, qualitative model; a more detailed one is presented in Chapter 12.

The Electron-Sea Model

In reactions with nonmetals, reactive metals (such as Na) transfer their outer electrons and form ionic solids (such as NaCl). Two metal atoms can also share their valence electrons in a covalent bond and form gaseous, diatomic molecules (such as Na_2). But what holds the atoms together in a piece of sodium metal? The **electron-sea model** of metallic bonding proposes that all the metal atoms in the sample contribute their valence electrons to form an electron "sea" that is delocalized throughout the piece. The metal ions (the nuclei with their core electrons) are submerged within this electron sea in an orderly array (see Figure 9.2C).

In contrast to ionic bonding, the metal ions are not held in place as rigidly as in an ionic solid. In contrast to covalent bonding, no particular pair of metal atoms is bonded through a localized pair of electrons. Rather, *the valence electrons are shared among all the atoms in the sample.* The piece of metal is held together by the mutual attraction of the metal cations for the mobile, highly delocalized valence electrons.

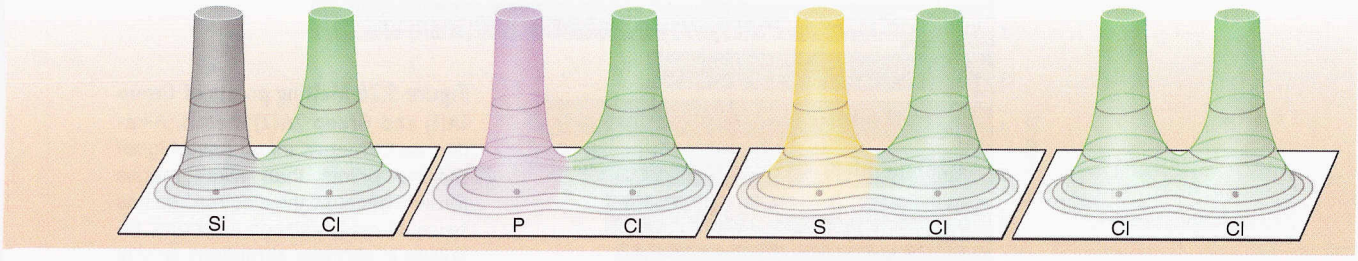

Table 9.7 Melting and Boiling Points of Some Metals

Element	mp (°C)	bp (°C)
Lithium (Li)	180	1347
Tin (Sn)	232	2623
Aluminum (Al)	660	2467
Barium (Ba)	727	1850
Silver (Ag)	961	2155
Copper (Cu)	1083	2570
Uranium (U)	1130	3930

Although there are metallic compounds, two or more metals typically form **alloys,** solid mixtures with variable composition. Many familiar metallic materials are alloys, such as those used for car parts, airplane bodies, building and bridge supports, coins, jewelry, and dental work.

How the Model Explains the Properties of Metals

Although the physical properties of metals vary over a wide range, most are solids with moderate to high melting points and much higher boiling points (Table 9.7). Metals typically bend or dent rather than crack or shatter. Many can be flattened into sheets (malleable) and pulled into wires (ductile). Unlike typical ionic and covalent substances, metals conduct heat and electricity well in *both* the solid and liquid states.

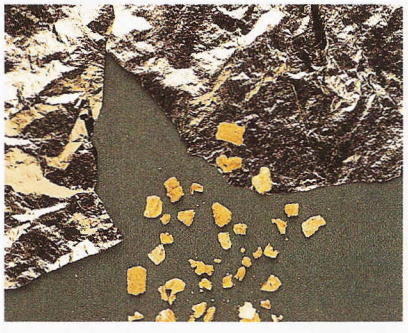
Two features of the electron-sea model that account for these properties are the *regularity,* but not rigidity, of the metal-ion array and the *mobility* of the valence electrons. The melting and boiling points of metals are related to the energy of the metallic bonding. Melting points are only moderately high because the attractions between moveable cations and electrons need not be broken during melting. Boiling a metal requires each cation and its electron(s) to break away from the others, so the boiling points are quite high. Gallium provides a striking example: it melts in your hand (mp 29.8°C) but doesn't boil until the temperature reaches over 2400°C.

Periodic trends are also consistent with the electron-sea model. As Figure 9.26 shows, the alkaline earth metals [Group 2A(2)] have higher melting points than the alkali metals [Group 1A(1)]. The 2A metal atoms have two valence electrons and form 2+ cations. Greater attraction between these cations and twice as many valence electrons means stronger metallic bonding than for the 1A metal atoms, so higher temperatures are needed to melt the 2A solids.

Mechanical and conducting properties are also explained by the model. When a piece of metal is deformed by a hammer, the metal ions slide past each other through the electron sea and end up in new positions. Thus, the metal-ion cores do not repel each other (Figure 9.27). Compare this behavior with the repulsions that occur when an ionic solid is struck (see Figure 9.8, p. 337).

Metals are good conductors of electricity because they have mobile electrons. When a piece of metal is attached to a battery, electrons flow from one terminal into the metal and replace electrons flowing from the metal into the other terminal. Irregularities in the array of metal atoms reduce this conductivity. Ordinary copper wire used to carry an electric current, for example, is more than 99.99% pure because traces of other atoms can drastically restrict the flow of electrons.

Mobile electrons also make metals good conductors of heat. Place your hand on a piece of metal and a piece of wood that are both at room temperature. The metal feels colder because it conducts body heat away from your hand much faster than the wood. The delocalized electrons in the metal disperse the heat from your hand more quickly than the localized electron pairs in the covalent bonds of wood.



The Amazing Malleability of Gold All the Group 1B(11) metals—copper, silver, and gold—are soft enough to be machined easily, but gold is in a class by itself. One gram of gold forms a cube 0.37 cm on a side or a sphere the size of a small ball-bearing. It is so ductile that it can be drawn into a wire 20 μm thick and 165 m long, and so malleable that it can be hammered into a 1.0-m^2 sheet that is only 230 atoms (about 70 nm) thick!

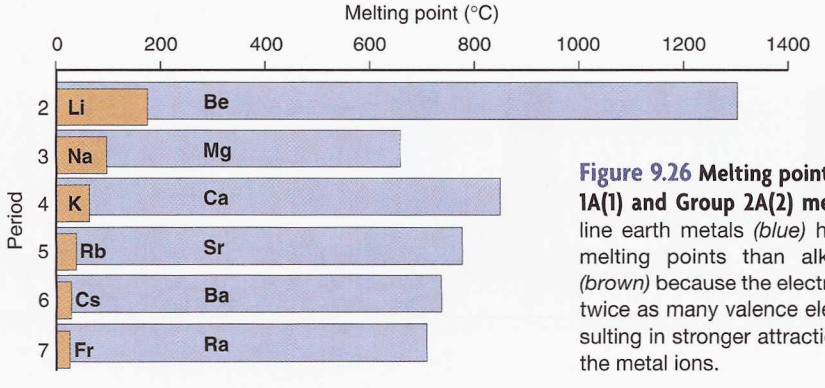


Figure 9.26 Melting points of Group 1A(1) and Group 2A(2) metals. Alkaline earth metals *(blue)* have higher melting points than alkali metals *(brown)* because the electron sea has twice as many valence electrons, resulting in stronger attractions among the metal ions.

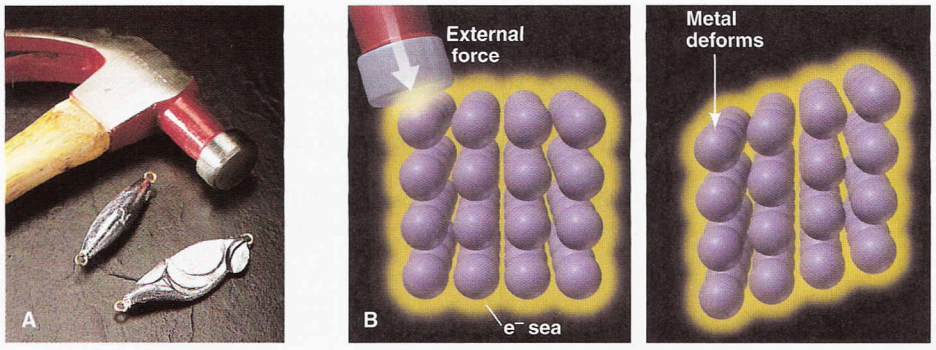

Figure 9.27 The reason metals deform.
A, An external force applied to a piece of metal deforms but doesn't break it.
B, The external force merely moves metal ions past each other through the electron sea.

SECTION SUMMARY

According to the electron-sea model, the valence electrons of the metal atoms in a sample are highly delocalized and attract all the metal cations, holding them together. Metals have only moderately high melting points because the metal ions remain attracted to the electron sea even if their relative positions change. Boiling requires completely overcoming these bonding attractions, so metals have very high boiling points. Metals can be deformed because the electron sea prevents repulsions among the cations. Metals conduct electricity and heat because their electrons are mobile.

Chapter Perspective

Our theme in this chapter has been that the type of chemical bonding—ionic, covalent, metallic, or some blend of these—is governed by the properties of the bonding atoms. This fundamental idea reappears as we investigate the forces that give rise to the properties of liquids, solids, and solutions (Chapters 12 and 13), the behavior of the main-group elements (Chapter 14), and the organic chemistry of carbon (Chapter 15). But first, you'll see in Chapter 10 how the relative placement of atoms and the arrangement of bonding and lone pairs gives a molecule its characteristic shape and how that shape influences the compound's properties. Then, in Chapter 11, you'll see how covalent bonding theory explains the nature of the bond itself and the properties of compounds.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. How differences in atomic properties lead to differences in bond type; the basic distinctions among the three types of bonding (9.1)
2. The essential features of ionic bonding: electron transfer to form ions, and their electrostatic attraction to form a solid (9.2)
3. How lattice energy is ultimately responsible for formation of ionic compounds (9.2)
4. How ionic compound formation is conceptualized as occurring in hypothetical steps (Born-Haber cycle) to calculate lattice energy (9.2)
5. How Coulomb's law explains the periodic trends in lattice energy (9.2)
6. Why ionic compounds are brittle and high melting and conduct electricity only when molten or dissolved in water (9.2)
7. How nonmetal atoms form a covalent bond (9.3)
8. How bonding and lone electron pairs fill the outer (valence) level of each atom in a molecule (9.3)
9. The interrelationships among bond order, bond length, and bond energy (9.3)
10. How the distinction between bonding and nonbonding forces explains the properties of covalent molecules and network covalent solids (9.3)
11. How changes in bond strength account for the heat of reaction (9.4)
12. How a reaction can be divided conceptually into bond-breaking and bond-forming steps (9.4)
13. The periodic trends in electronegativity and the inverse relation of EN values to atomic sizes (9.5)
14. How bond polarity arises from differences in electronegativity of bonded atoms; the direction of bond polarity (9.5)
15. The change in partial ionic character with ΔEN and the change in bonding from ionic to polar covalent to nonpolar covalent across a period (9.5)
16. The role of delocalized electrons in metallic bonding (9.6)
17. How the electron-sea model explains why metals bend, have very high boiling points, and conduct electricity in solid or molten form (9.6)

Learning Objectives *(continued)*

Master These Skills

1. Using Lewis electron-dot symbols to depict main-group atoms (9.1)
2. Depicting the formation of ions with electron configurations, orbital diagrams, and Lewis symbols, and writing the formula of the ionic compound (SP 9.1)
3. Calculating lattice energy from the enthalpies of the steps to ionic compound formation (9.2)
4. Ranking similar covalent bonds according to their length and strength (SP 9.2)
5. Using bond energies to calculate ΔH^0_{rxn} (SP 9.3)
6. Determining bond polarity from EN values (SP 9.4)

Key Terms

Key Equations and Relationships

9.1 Relating the energy of attraction to the lattice energy (336):

$$\text{Electrostatic energy} \propto \frac{\text{cation charge} \times \text{anion charge}}{\text{cation radius} + \text{anion radius}} \propto \Delta H^0_{\text{lattice}}$$

9.2 Calculating heat of reaction from enthalpy changes or bond energies (347):

$$\Delta H^0_{rxn} = \Sigma \Delta H^0_{\text{reactant bonds broken}} + \Sigma \Delta H^0_{\text{product bonds formed}}$$

Or $\Delta H^0_{rxn} = \Sigma \text{BE}_{\text{reactant bonds broken}} - \Sigma \text{BE}_{\text{product bonds formed}}$

Highlighted Figures and Tables

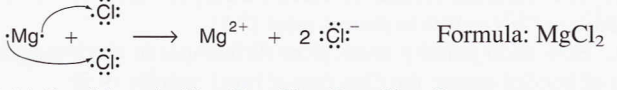
Brief Solutions to Follow-up Problems

9.1 $Mg\ ([Ne]\ 3s^2) + 2Cl\ ([Ne]\ 3s^2 3p^5) \longrightarrow Mg^{2+}\ ([Ne]) + 2Cl^-\ ([Ne]\ 3s^2 3p^6)$



Formula: $MgCl_2$

9.2 (a) Bond length: Si—F < Si—O < Si—C
Bond strength: Si—C < Si—O < Si—F
(b) Bond length: N≡N < N=N < N—N
Bond strength: N—N < N=N < N≡N

9.3 $N{\equiv}N + 3\,H{-}H \longrightarrow 2\,H{-}\underset{\displaystyle H}{\underset{|}{N}}{-}H$

$\Sigma \Delta H^0_{\text{bonds broken}} = 1\,N{\equiv}N + 3\,H{-}H$
$= 945\text{ kJ} + 1296\text{ kJ} = 2241\text{ kJ}$
$\Sigma \Delta H^0_{\text{bonds formed}} = 6\,N{-}H = -2346\text{ kJ}$
$\Delta H^0_{rxn} = -105\text{ kJ}$

9.4 (a) $Cl{-}Cl < \overset{\delta+}{Br}{-}\overset{\delta-}{Cl} < \overset{\delta+}{Cl}{-}\overset{\delta-}{F}$
(b) $Si{-}Si < \overset{\delta+}{S}{-}\overset{\delta-}{Cl} < \overset{\delta+}{P}{-}\overset{\delta-}{Cl} < \overset{\delta+}{Si}{-}\overset{\delta-}{Cl}$

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Atomic Properties and Chemical Bonds

Concept Review Questions

9.1 In general terms, how does each of the following atomic properties influence the metallic character of the main-group elements in a period?
(a) Ionization energy
(b) Atomic radius
(c) Number of outer electrons
(d) Effective nuclear charge

9.2 Both nitrogen and bismuth are members of Group 5A(15). Which is more metallic? Explain your answer in terms of atomic properties.

9.3 What is the relationship between the tendency of a main-group element to form a monatomic ion and its position in the periodic table? In what part of the table are the main-group elements that typically form cations? Anions?

Skill-Building Exercises *(grouped in similar pairs)*

9.4 Which member of each pair is *more* metallic?
(a) Na or Cs (b) Mg or Rb (c) As or N

9.5 Which member of each pair is *less* metallic?
(a) I or O (b) Be or Ba (c) Se or Ge

9.6 State the type of bonding—ionic, covalent, or metallic—you would expect in each: (a) $CsF(s)$; (b) $N_2(g)$; (c) $Na(s)$.

9.7 State the type of bonding—ionic, covalent, or metallic—you would expect in each: (a) $ICl_3(g)$; (b) $N_2O(g)$; (c) $LiCl(s)$.

9.8 State the type of bonding—ionic, covalent, or metallic—you would expect in each: (a) $O_3(g)$; (b) $MgCl_2(s)$; (c) $BrO_2(g)$.

9.9 State the type of bonding—ionic, covalent, or metallic—you would expect in each: (a) $Cr(s)$; (b) $H_2S(g)$; (c) $CaO(s)$.

9.10 Draw a Lewis electron-dot symbol for each atom:
(a) Rb (b) Si (c) I

9.11 Draw a Lewis electron-dot symbol for each atom:
(a) Ba (b) Kr (c) Br

9.12 Draw a Lewis electron-dot symbol for each atom:
(a) Sr (b) P (c) S

9.13 Draw a Lewis electron-dot symbol for each atom:
(a) As (b) Se (c) Ga

9.14 Give the group number and general electron configuration of an element with each electron-dot symbol:
(a) $\cdot\ddot{\underset{\cdot}{\ddot{X}}}:$ (b) $\ddot{X}\cdot$

9.15 Give the group number and general electron configuration of an element with each electron-dot symbol:
(a) $\cdot\ddot{\underset{\cdot}{\ddot{X}}}:$ (b) $\cdot\ddot{X}\cdot$

The Ionic Bonding Model

(Sample Problem 9.1)

Concept Review Questions

9.16 If energy is required to form monatomic ions from metals and nonmetals, why do ionic compounds exist?

9.17 In general, how does the lattice energy of an ionic compound depend on the charges and sizes of the ions?

9.18 When gaseous Na^+ and Cl^- ions form gaseous NaCl ion pairs, 548 kJ/mol of energy is released. Why, then, does NaCl occur as a solid under ordinary conditions?

9.19 To form S^{2-} ions from gaseous sulfur atoms requires 214 kJ/mol, but these ions exist in solids such as K_2S. Explain.

Skill-Building Exercises *(grouped in similar pairs)*

9.20 Use condensed electron configurations and Lewis electron-dot symbols to depict the monatomic ions formed from each of the following atoms, and predict the formula of the compound the ions produce:
(a) Ba and Cl (b) Sr and O (c) Al and F (d) Rb and O

9.21 Use condensed electron configurations and Lewis electron-dot symbols to depict the monatomic ions formed from each of the following atoms, and predict the formula of the compound the ions produce:
(a) Cs and S (b) O and Ga (c) N and Mg (d) Br and Li

9.22 Identify the main group to which X belongs in each ionic compound formula: (a) XF_2; (b) MgX; (c) X_2SO_4.

9.23 Identify the main group to which X belongs in each ionic compound formula: (a) X_3PO_4; (b) $X_2(SO_4)_3$; (c) $X(NO_3)_2$.

9.24 Identify the main group to which X belongs in each ionic compound formula: (a) X_2O_3; (b) XCO_3; (c) Na_2X.

9.25 Identify the main group to which X belongs in each ionic compound formula: (a) CaX_2; (b) Al_2X_3; (c) XPO_4.

9.26 For each pair, choose the compound with the higher lattice energy, and explain your choice:
(a) BaS or CsCl (b) LiCl or CsCl

9.27 For each pair, choose the compound with the higher lattice energy, and explain your choice:
(a) CaO or CaS (b) BaO or SrO

9.28 For each pair, choose the compound with the lower lattice energy, and explain your choice:
(a) CaS or BaS (b) NaF or MgO

9.29 For each pair, choose the compound with the lower lattice energy, and explain your choice:
(a) NaF or NaCl (b) K_2O or K_2S

9.30 Use the following to calculate the $\Delta H^0_{lattice}$ of NaCl:

$Na(s) \longrightarrow Na(g)$	$\Delta H^0 = 109$ kJ
$Cl_2(g) \longrightarrow 2Cl(g)$	$\Delta H^0 = 243$ kJ
$Na(g) \longrightarrow Na^+(g) + e^-$	$\Delta H^0 = 496$ kJ
$Cl(g) + e^- \longrightarrow Cl^-(g)$	$\Delta H^0 = -349$ kJ
$Na(s) + \frac{1}{2}Cl_2(g) \longrightarrow NaCl(s)$	$\Delta H^0_f = -411$ kJ

Compared with the lattice energy of LiF (1050 kJ/mol), is the magnitude of the value for NaCl what you expected? Explain.

9.31 Use the following to calculate the $\Delta H^0_{\text{lattice}}$ of MgF_2:

$Mg(s) \longrightarrow Mg(g)$	$\Delta H^0 = 148$ kJ
$F_2(g) \longrightarrow 2F(g)$	$\Delta H^0 = 159$ kJ
$Mg(g) \longrightarrow Mg^+(g) + e^-$	$\Delta H^0 = 738$ kJ
$Mg^+(g) \longrightarrow Mg^{2+}(g) + e^-$	$\Delta H^0 = 1450$ kJ
$F(g) + e^- \longrightarrow F^-(g)$	$\Delta H^0 = -328$ kJ
$Mg(s) + F_2(g) \longrightarrow MgF_2(s)$	$\Delta H^0_f = -1123$ kJ

Compared with the lattice energy of LiF (1050 kJ/mol) or the lattice energy you calculated for NaCl in Problem 9.30, does the relative magnitude of the value for MgF_2 surprise you? Explain.

Problems in Context

9.32 Aluminum oxide (Al_2O_3) is a widely used industrial abrasive (emery, corundum), for which the specific application depends on the hardness of the crystal. What does this hardness imply about the magnitude of the lattice energy? Would you have predicted from the chemical formula that Al_2O_3 is hard? Explain.

9.33 Born-Haber cycles were used to obtain the first reliable values for electron affinity by considering the EA value as the unknown and using a theoretically calculated value for the lattice energy. Use a Born-Haber cycle for KF and the following values to calculate a value for the electron affinity of fluorine:

$K(s) \longrightarrow K(g)$	$\Delta H^0 = 90$ kJ
$K(g) \longrightarrow K^+(g) + e^-$	$\Delta H^0 = 419$ kJ
$F_2(g) \longrightarrow 2F(g)$	$\Delta H^0 = 159$ kJ
$K(s) + \frac{1}{2}F_2(g) \longrightarrow KF(s)$	$\Delta H^0_f = -569$ kJ
$K^+(g) + F^-(g) \longrightarrow KF(s)$	$\Delta H^0 = -821$ kJ

The Covalent Bonding Model

(Sample Problem 9.2)

Concept Review Questions

9.34 Describe the interactions that occur between individual chlorine atoms as they approach each other and form Cl_2. What combination of forces gives rise to the energy holding the atoms together and to the final internuclear distance?

9.35 Define bond energy using the H—Cl bond as an example. When this bond breaks, is energy absorbed or released? Is the accompanying ΔH value positive or negative? How do the magnitude and sign of this ΔH value relate to the value that accompanies H—Cl bond formation?

9.36 For single bonds between similar types of atoms, how does the strength of the bond relate to the sizes of the atoms? Explain.

9.37 How does the energy of the bond between a given pair of atoms relate to the bond order? Why?

9.38 When liquid benzene (C_6H_6) boils, does the gas consist of molecules, ions, or separate atoms? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

9.39 Using the periodic table only, arrange the members of each of the following sets in order of increasing bond *strength:*

(a) Br—Br, Cl—Cl, I—I (b) S—H, S—Br, S—Cl

(c) C=N, C—N, C≡N

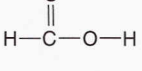
9.40 Using the periodic table only, arrange the members of each of the following sets in order of increasing bond *length:*

(a) H—F, H—I, H—Cl (b) C—S, C=O, C—O

(c) N—H, N—S, N—O

Problems in Context

9.41 Formic acid (HCOOH) has the structural formula shown at right.



It is secreted by certain species of ants when they bite. Rank the relative strengths of (a) the C—O and C=O bonds, and (b) the H—C and H—O bonds. Explain these rankings.

9.42 In Figure B9.2, p. 346, the peak labeled "C=C stretch" occurs at a shorter wavelength than that labeled "C—C stretch," as it does in the IR spectrum of any substance with those bonds. Explain the relative positions of these peaks. In what relative position along the wavelength scale of Figure B9.2 would you expect to find a peak for a C≡C stretch? Explain.

Bond Energy and Chemical Change

(Sample Problem 9.3)

Concept Review Questions

9.43 Write a solution plan (without actual numbers, but including the bond energies you would use and how you would combine them algebraically) for calculating the total enthalpy change of the following reaction:

$$H_2(g) + O_2(g) \longrightarrow H_2O_2(g)\ (H—O—O—H)$$

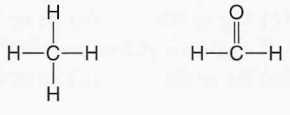
9.44 The text points out that, for similar types of substances, one with weaker bonds is usually more reactive than one with stronger bonds. Why is this generally true?

9.45 Why is there a discrepancy between a heat of reaction obtained from calorimetry and one obtained from bond energies?

Skill-Building Exercises *(grouped in similar pairs)*

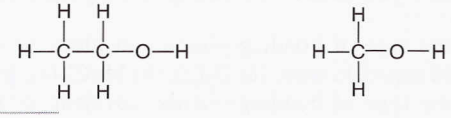
9.46 Which of the following gases would you expect to have the greater heat of combustion per mole? Why?

methane or formaldehyde

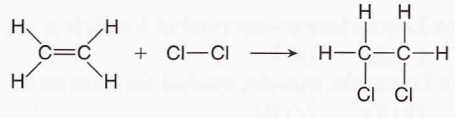


9.47 Which of the following two fuel candidates would you expect to have the greater heat of combustion per mole? Why?

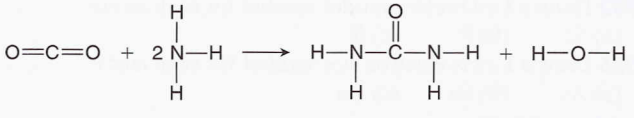
ethanol or methanol



9.48 Use bond energies to calculate the heat of reaction:

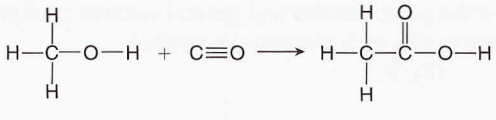


9.49 Use bond energies to calculate the heat of reaction:



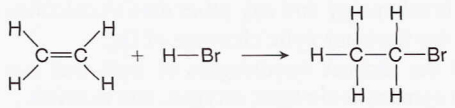
Problems in Context

9.50 An important industrial route to extremely pure acetic acid is the reaction of methanol with carbon monoxide:



Use bond energies to calculate the heat of reaction.

9.51 Sports trainers treat sprains and soreness with ethyl bromide. It is manufactured by reacting ethylene with hydrogen bromide:



Use bond energies to find the enthalpy change for this reaction.

Between the Extremes: Electronegativity and Bond Polarity

(Sample Problem 9.4)

Concept Review Questions

9.52 Describe the vertical and horizontal trends in electronegativity (EN) among the main-group elements. According to Pauling's scale, what are the two most electronegative elements? The two least electronegative elements?

9.53 What is the general relationship between IE_1 and EN for the elements? Why?

9.54 Is the H—O bond in water nonpolar covalent, polar covalent, or ionic? Define each term, and explain your choice.

9.55 How does electronegativity differ from electron affinity?

9.56 How is the partial ionic character of a bond in a diatomic molecule related to ΔEN for the bonded atoms? Why?

Skill-Building Exercises *(grouped in similar pairs)*

9.57 Using the periodic table only, arrange the elements in each set in order of *increasing* EN: (a) S, O, Si; (b) Mg, P, As.

9.58 Using the periodic table only, arrange the elements in each set in order of *increasing* EN: (a) I, Br, N; (b) Ca, H, F.

9.59 Using the periodic table only, arrange the elements in each set in order of *decreasing* EN: (a) N, P, Si; (b) Ca, Ga, As.

9.60 Using the periodic table only, arrange the elements in each set in order of *decreasing* EN: (a) Br, Cl, P; (b) I, F, O.

9.61 Use Figure 9.19, p. 352, to indicate the polarity of each bond with *polar arrows:* (a) N—B; (b) N—O; (c) C—S; (d) S—O; (e) N—H; (f) Cl—O.

9.62 Use Figure 9.19, p. 352, to indicate the polarity of each bond with *polar arrows:* (a) Br—Cl; (b) F—Cl; (c) H—O; (d) Se—H; (e) As—H; (f) S—N.

9.63 Which is the more polar bond in each of the following pairs from Problem 9.61: (a) or (b); (c) or (d); (e) or (f)?

9.64 Which is the more polar bond in each of the following pairs from Problem 9.62: (a) or (b); (c) or (d); (e) or (f)?

9.65 Are the bonds in each of the following substances ionic, nonpolar covalent, or polar covalent? Arrange the substances with polar covalent bonds in order of increasing bond polarity:
(a) S_8 (b) RbCl (c) PF_3 (d) SCl_2 (e) F_2 (f) SF_2

9.66 Are the bonds in each of the following substances ionic, nonpolar covalent, or polar covalent? Arrange the substances with polar covalent bonds in order of increasing bond polarity:
(a) KCl (b) P_4 (c) BF_3 (d) SO_2 (e) Br_2 (f) NO_2

9.67 Rank the members of each set of compounds in order of *increasing* ionic character of their bonds. Use *polar arrows* to indicate the bond polarity of each:
(a) HBr, HCl, HI (b) H_2O, CH_4, HF (c) SCl_2, PCl_3, $SiCl_4$

9.68 Rank the members of each set of compounds in order of *decreasing* ionic character of their bonds. Use *partial charges* to indicate the bond polarity of each:
(a) PCl_3, PBr_3, PF_3 (b) BF_3, NF_3, CF_4 (c) SeF_4, TeF_4, BrF_3

Problems in Context

9.69 The energy of the C—C bond is 347 kJ/mol, and that of the Cl—Cl bond is 243 kJ/mol. Which of the following values might you expect for the C—Cl bond energy? Explain.
(a) 590 kJ/mol (sum of the values given)
(b) 104 kJ/mol (difference of the values given)
(c) 295 kJ/mol (average of the values given)
(d) 339 kJ/mol (greater than the average of the values given)

An Introduction to Metallic Bonding

Concept Review Questions

9.70 (a) List four physical characteristics of a solid metal.
(b) List two chemical characteristics that lead to an element being classified as a metal.

9.71 Briefly account for the following relative values:
(a) The melting point of sodium is 89°C, whereas that of potassium is 63°C.
(b) The melting points of Li and Be are 180°C and 1287°C, respectively.
(c) Lithium boils more than 1100°C higher than it melts.

9.72 Magnesium metal is easily deformed by an applied force, whereas magnesium fluoride is shattered. Why do these two solids behave so differently?

Comprehensive Problems

9.73 Geologists have a rule of thumb: when molten rock cools and solidifies, crystals of compounds with the smallest lattice energies appear at the bottom of the mass. Suggest a reason for this.

9.74 Acetylene gas (ethyne; HC≡CH) burns with oxygen in an oxyacetylene torch to produce carbon dioxide, water vapor, and the heat needed to weld metals. The heat of combustion of acetylene is 1259 kJ/mol. (a) Calculate the C≡C bond energy, and compare your value with that in Table 9.2, p. 341. (b) When 500.0 g of acetylene burns, how many kilojoules of heat are given off? (c) How many grams of CO_2 are produced? (d) How many liters of O_2 at 298 K and 18.0 atm are consumed?

9.75 Use Lewis electron-dot symbols to represent the formation of (a) BrF_3 from bromine and fluorine atoms; (b) AlF_3 from aluminum and fluorine atoms.

9.76 Even though so much energy is required to form a metal cation with a 2+ charge, the alkaline earth metals form halides with general formula MX_2, rather than MX. Let's see why.
(a) Use the following data to calculate the ΔH_f^0 of MgCl:

$Mg(s) \longrightarrow Mg(g)$	$\Delta H^0 = 148$ kJ
$Cl_2(g) \longrightarrow 2Cl(g)$	$\Delta H^0 = 243$ kJ
$Mg(g) \longrightarrow Mg^+(g) + e^-$	$\Delta H^0 = 738$ kJ
$Cl(g) + e^- \longrightarrow Cl^-(g)$	$\Delta H^0 = -349$ kJ

$\Delta H^0_{lattice}$ of MgCl = 783.5 kJ/mol

(b) Is MgCl favored energetically relative to its elements? Explain.
(c) Use Hess's law to calculate ΔH^0 for the conversion of MgCl to $MgCl_2$ and Mg (ΔH_f^0 of $MgCl_2 = -641.6$ kJ/mol).
(d) Is MgCl favored energetically relative to $MgCl_2$? Explain.

9.77 The first 21 ionization energies (IEs) for zinc (in MJ/mol) are 0.939, 1.80, 3.97, 5.94, 8.26, 10.8, 13.4, 17.4, 20.3, 23.8, 27.4, 31.1, 42.0, 45.4, 49.0, 54.2, 57.9, 61.9, 69.8, 73.8, and 186.
(a) Draw a graph of IE vs. number of electrons removed.
(b) Explain the general trend in the curve and the reason for any significant deviations from this trend.

9.78 Gases react explosively with one another if the heat released as some product forms is sufficient to cause more reactant to react, and so on. The rapid heat release expands the gases, and a thermal explosion results. Use bond energies to calculate ΔH^0 of the following reactions, and predict which occurs explosively:
(a) $H_2(g) + Cl_2(g) \longrightarrow 2HCl(g)$
(b) $H_2(g) + I_2(g) \longrightarrow 2HI(g)$
(c) $2H_2(g) + O_2(g) \longrightarrow 2H_2O(g)$

9.79 By using photons of specific wavelengths, chemists can dissociate gaseous HI to produce H atoms with certain speeds. When HI dissociates, the H atoms move away rapidly, whereas the relatively heavy I atoms move more slowly.
(a) What is the longest wavelength (in nm) that can dissociate a molecule of HI?
(b) If a photon of 254 nm is used, what is the excess energy (in J) over that needed for the dissociation?
(c) If all this excess energy is carried away by the H atom as kinetic energy, what is its speed (in m/s)?

9.80 Carbon dioxide is a linear molecule. Its vibrational motions include symmetrical stretching, bending, and asymmetrical stretching (see Figure B9.1, p. 345), and their frequencies are $4.02\times10^{13}\ s^{-1}$, $2.00\times10^{13}\ s^{-1}$, and $7.05\times10^{13}\ s^{-1}$, respectively. (a) In what region of the electromagnetic spectrum are these frequencies? (b) Calculate the energy (in J) of each vibration. Which occurs most readily (takes the least energy)?

9.81 In developing the concept of electronegativity, Pauling used the term *excess bond energy* for the difference between the actual bond energy of X—Y and the average bond energies of X—X and Y—Y (see text discussion for the case of HF). Based on the values in Figure 9.19, p. 352, which of the following substances contains bonds with *no* excess bond energy?
(a) PH_3 (b) CS_2 (c) BrCl (d) BH_3 (e) Se_8

9.82 Use condensed electron configurations to predict the relative hardnesses and melting points of rubidium ($Z = 37$), vanadium ($Z = 23$), and cadmium ($Z = 48$).

9.83 Without stratospheric ozone (O_3), harmful solar radiation would cause gene alterations. Ozone forms when O_2 breaks and each O atom reacts with another O_2 molecule. It is destroyed by reaction with Cl atoms formed when the C—Cl bond in synthetic chemicals breaks. Find the wavelengths of light that can break the C—Cl bond and the bond in O_2.

9.84 "Inert" xenon actually forms many compounds, especially with highly electronegative oxygen and fluorine. The ΔH_f^0 values for xenon difluoride, tetrafluoride, and hexafluoride are −105, −284, and −402 kJ/mol, respectively. Find the average bond energy of the Xe—F bonds in each fluoride.

9.85 The HF bond length is 92 pm, 16% shorter than the sum of the covalent radii of H (37 pm) and F (72 pm). Suggest a reason for this difference. Similar calculations show that the difference becomes smaller down the group from HF to HI. Explain.

9.86 There are two main types of covalent bond breakage. In homolytic breakage (as in Table 9.2, p. 341), each atom in the bond gets one of the shared electrons. In some cases, the electronegativity of adjacent atoms affects the bond energy. In heterolytic breakage, one atom gets both electrons and the other gets none; thus, a cation and an anion form.
(a) Why is the C—C bond in $H_3C—CF_3$ (423 kJ/mol) stronger than the bond in $H_3C—CH_3$ (376 kJ/mol)?
(b) Use bond energy and any other data to calculate the heat of reaction for the heterolytic cleavage of O_2.

9.87 Find the longest wavelengths of light that can cleave the bonds in elemental nitrogen, oxygen, and fluorine.

9.88 The work function (ϕ) of a metal is the minimum energy needed to remove an electron from its surface. (a) Is it easier to remove an electron from a gaseous silver atom or from the surface of solid silver ($\phi = 7.59\times10^{-19}$ J; IE = 731 kJ/mol)? (b) Explain the results in terms of the electron-sea model of metallic bonding.

9.89 Lattice energies can also be calculated for covalent solids using a Born-Haber cycle, and the network solid silicon dioxide has one of the highest. Silicon dioxide is found in pure crystalline form as transparent rock quartz. Much harder than glass, this material was once prized for making lenses for optical devices and expensive spectacles. Use Appendix B and the following data to calculate $\Delta H^0_{lattice}$ of SiO_2:

$Si(s) \longrightarrow Si(g)$	$\Delta H^0 = 454$ kJ
$Si(g) \longrightarrow Si^{4+}(g) + 4e^-$	$\Delta H^0 = 9949$ kJ
$O_2(g) \longrightarrow 2O(g)$	$\Delta H^0 = 498$ kJ
$O(g) + 2e^- \longrightarrow O^{2-}(g)$	$\Delta H^0 = 737$ kJ

9.90 We can write equations for the formation of methane from ethane (C_2H_6) with its C—C bond, from ethene (C_2H_4) with its C=C bond, and from ethyne (C_2H_2) with its C≡C bond:

$C_2H_6(g) + H_2(g) \longrightarrow 2CH_4(g)$	$\Delta H^0_{rxn} = -65.07$ kJ/mol
$C_2H_4(g) + 2H_2(g) \longrightarrow 2CH_4(g)$	$\Delta H^0_{rxn} = -202.21$ kJ/mol
$C_2H_2(g) + 3H_2(g) \longrightarrow 2CH_4(g)$	$\Delta H^0_{rxn} = -376.74$ kJ/mol

Given that the average C—H bond energy in CH_4 is 415 kJ/mol, use Table 9.2 (p. 341) values to calculate the average C—H bond energy in ethane, in ethene, and in ethyne.

9.91 Carbon-carbon bonds form the "backbone" of nearly every organic and biological molecule. The average bond energy of the C—C bond is 347 kJ/mol. Calculate the frequency and wavelength of the least energetic photon that can break an average C—C bond. In what region of the electromagnetic spectrum is this radiation?

9.92 In a future hydrogen-fuel economy, the cheapest source of H_2 will certainly be water. It takes 467 kJ to produce 1 mol of H atoms from water. What is the frequency, wavelength, and minimum energy of a photon that can free an H atom from water?

9.93 The Sun's emissions include infrared, visible, and ultraviolet radiation. Some of this radiation can damage skin tissue, and sunscreens are made to block it. (a) What is the ratio of the energies of yellow light of 575 nm to UV light of 300 nm? (b) What is the ratio of the energies of yellow light of 575 nm to IR radiation of 1000 nm? (c) Can any of these three types of radiation break a C—C bond? (d) A C—H bond?

9.94 Dimethyl ether (CH_3OCH_3) and ethanol (CH_3CH_2OH) are constitutional isomers (see Table 3.4, p. 100). (a) Use Table 9.2, p. 341, to calculate ΔH^0_{rxn} for the formation of each compound as a gas from methane and oxygen; water vapor also forms. (b) State which reaction is more exothermic. (c) Calculate ΔH^0_{rxn} for the conversion of ethanol to dimethyl ether.

Interconnecting shapes As in this puzzle based on M.C. Escher's *Sun and Moon*, the shapes of many everyday objects fit together to perform a function—key and lock, mortise and tenon, hand and glove. Similarly, an organism's molecules fit together to trigger the processes of life. In this chapter, you learn to depict molecules as two-dimensional structural formulas and then to visualize them as three-dimensional objects.

The Shapes of Molecules

10.1 **Depicting Molecules and Ions with Lewis Structures**
- Using the Octet Rule
- Resonance
- Formal Charge
- Exceptions to the Octet Rule

10.2 **Valence-Shell Electron-Pair Repulsion (VSEPR) Theory and Molecular Shape**
- Electron-Group Arrangements and Molecular Shapes
- Molecular Shape with Two Electron Groups
- Shapes with Three Electron Groups
- Shapes with Four Electron Groups
- Shapes with Five Electron Groups
- Shapes with Six Electron Groups
- Using VSEPR Theory to Determine Molecular Shape
- Shapes with More Than One Central Atom

10.3 **Molecular Shape and Molecular Polarity**
- Bond Polarity, Bond Angle, and Dipole Moment
- Molecular Polarity and Behavior

Concepts & Skills to Review

before you study this chapter

- electron configurations of main-group elements (Section 8.3)
- electron-dot symbols (Section 9.1)
- the octet rule (Section 9.1)
- bond order, bond length, and bond energy (Sections 9.3, 9.4)
- polar covalent bonds and bond polarity (Section 9.5)

Now that you understand how atoms bond, you can explore an idea essential to chemistry—*and* biology! The printed page, covered with atomic symbols, lines, and pairs of dots, makes it easy to forget the amazing, three-dimensional reality of molecular shape. In any molecule, each atom, bonding pair, and lone pair has its own position in space relative to the others, determined by the attractive and repulsive forces that govern all matter. With definite angles and distances between the nuclei, a molecule is an independent, minute architecture, extending throughout its tiny volume of space. Whether we consider the details of simple reactions, the properties of synthetic materials, or the intricate life-sustaining processes of living cells, molecular shape is a crucial factor.

IN THIS CHAPTER . . . We first see how to convert the *molecular* formula of a compound into a flat *structural* formula that shows atom attachments and electron-pair location within the molecule. Using the theory that converts these two-dimensional structural formulas into three-dimensional shapes, we describe the five basic classes of shapes that most simple molecules adopt and then see the ways these combine to form the shapes of more complex molecules. You'll learn how shape and bond polarity create a polarity for the entire molecule and glimpse the influence of molecular shape on biological function.

10.1 DEPICTING MOLECULES AND IONS WITH LEWIS STRUCTURES

The first step toward visualizing what a molecule looks like is to convert its molecular formula to its **Lewis structure** (or **Lewis formula**). This two-dimensional structural formula consists of electron-dot symbols that depict each atom and its neighbors, the bonding pairs that hold them together, and the lone pairs that fill each atom's outer level (valence shell).* In many cases, the octet rule (Section 9.1) guides us in allotting electrons to the atoms in a Lewis structure; in many other cases, however, we set the rule aside.

Using the Octet Rule to Write Lewis Structures

To write a Lewis structure from the molecular formula, we decide on the relative placement of the atoms in the molecule (or polyatomic ion)—that is, which atoms are adjacent and become bonded to each other—and distribute the total number of valence electrons as bonding and lone pairs. Let's begin by examining Lewis structures for species that "obey" the octet rule—those in which each atom fills its outer level with eight electrons (or two for hydrogen).

Lewis Structures for Molecules with Single Bonds First, we discuss the steps for writing Lewis structures for molecules that have only single bonds, using nitrogen trifluoride, NF_3, as an example. You may want to refer to Figure 10.1 as we go through the steps.

*A Lewis *structure* may be more correctly called a Lewis *formula* because it provides information about the relative placement of atoms in a molecule or ion and shows which atoms are bonded to each other, but it does ***not*** indicate the three-dimensional shape. Nevertheless, use of the term Lewis *structure* is a convention that we follow.

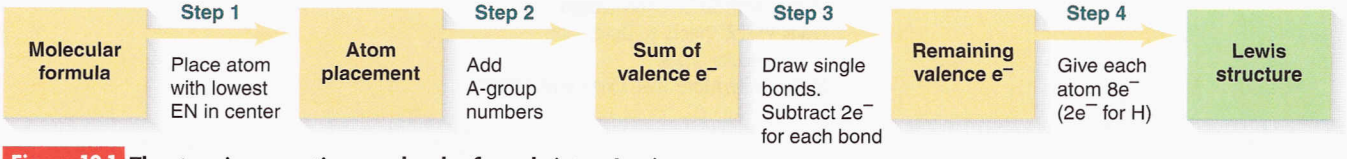

Figure 10.1 The steps in converting a molecular formula into a Lewis structure.

Step 1. Place the atoms relative to each other. For compounds of molecular formula AB_n, place the atom with *lower group number* in the center because it needs more electrons to attain an octet; usually, this is also the atom with the *lower electronegativity*. In NF_3, the N (Group 5A; EN = 3.0) has five electrons so it needs three, whereas each F (Group 7A; EN = 4.0) has seven and so needs only one; thus, N goes in the center with the three F atoms around it:

If the atoms have the same group number, as in SO_3 or ClF_3, place the atom with the *higher period number* in the center. H can form only one bond, so it is *never* a central atom.

Step 2. Determine the total number of valence electrons available. For molecules, add up the valence electrons of all the atoms. (Recall that the number of valence electrons equals the A-group number.) In NF_3, N has five valence electrons, and each F has seven:

$$[1 \times N(5e^-)] + [3 \times F(7e^-)] = 5e^- + 21e^- = 26 \text{ valence } e^-$$

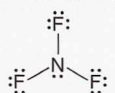
For polyatomic ions, *add* one e^- for each negative charge of the ion, or *subtract* one e^- for each positive charge.

Step 3. Draw a single bond from each surrounding atom to the central atom, and subtract two valence electrons for each bond. There must be at least a single bond between bonded atoms:

Subtract $2e^-$ for each single bond from the total number of valence electrons available (from step 2) to find the number remaining:

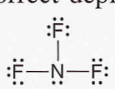
$$3 \text{ N—F bonds} \times 2e^- = 6e^- \quad \text{so} \quad 26e^- - 6e^- = 20e^- \text{ remaining}$$

Step 4. Distribute the remaining electrons in pairs so that each atom ends up with eight electrons (or two for H). First, place lone pairs on the *surrounding (more electronegative) atoms* to give each an octet. If any electrons remain, place them around the central atom. Then check that each atom has $8e^-$:



This is the Lewis structure for NF_3. Always check that the total number of electrons (bonds plus lone pairs) equals the sum of the valence electrons: $6e^-$ in three bonds plus $20e^-$ in ten lone pairs equals 26 valence electrons.

This particular arrangement of F atoms around an N atom resembles the molecular shape of NF_3, as you'll see in Section 10.2. But, Lewis structures do not indicate shape, so an equally correct depiction of NF_3 is



or any other that retains the *same connections among the atoms*—a central N atom connected by single bonds to three surrounding F atoms.

Using these four steps, you can write a Lewis structure for any singly bonded molecule whose central atom is C, N, or O, as well as for some molecules with central atoms from higher periods. Remember that, in nearly all their compounds,

- Hydrogen atoms form one bond.
- Carbon atoms form four bonds.
- Nitrogen atoms form three bonds.
- Oxygen atoms form two bonds.
- Halogens form one bond when they are surrounding atoms; fluorine is always a surrounding atom.

SAMPLE PROBLEM 10.1 Writing Lewis Structures for Molecules with One Central Atom

Problem Write a Lewis structure for CCl_2F_2, one of the compounds responsible for the depletion of stratospheric ozone.

Solution *Step 1.* Place the atoms relative to each other. In CCl_2F_2, carbon has the lowest group number and EN, so it is the central atom. The halogen atoms surround it, but their specific positions are not important (see margin).

Step 2. Determine the total number of valence electrons (from A-group numbers): C is in Group 4A, F is in Group 7A, and Cl is in Group 7A, too. Therefore, we have

$$[1 \times C(4e^-)] + [2 \times F(7e^-)] + [2 \times Cl(7e^-)] = 32 \text{ valence } e^-$$

Step 3. Draw single bonds to the central atom and subtract $2e^-$ for each bond (see margin). Four single bonds use $8e^-$, so $32e^- - 8e^-$ leaves $24e^-$ remaining.

Step 4. Distribute the remaining electrons in pairs, beginning with the surrounding atoms, so that each atom has an octet (see margin).

Check Counting the electrons shows that each atom has an octet. Remember that bonding electrons are counted as belonging to each atom in the bond. The total number of electrons in bonds (8) and lone pairs (24) equals 32 valence electrons. Note that, as expected, C has four bonds and the surrounding halogens have one each.

FOLLOW-UP PROBLEM 10.1 Write a Lewis structure for each of the following:
(a) H_2S **(b)** OF_2 **(c)** $SOCl_2$

A slightly more complex situation occurs when molecules have two or more central atoms bonded to each other, with the other atoms around them.

SAMPLE PROBLEM 10.2 Writing Lewis Structures for Molecules with More than One Central Atom

Problem Write the Lewis structure for methanol (molecular formula CH_4O), an important industrial alcohol that is being used as a gasoline alternative in car engines.

Solution *Step 1.* Place the atoms relative to each other. The H atoms can have only one bond, so C and O must be adjacent to each other. Recall that C has four bonds and O has two, so we arrange the H atoms to show this (see margin).

Step 2. Find the sum of valence electrons:

$$[1 \times C(4e^-)] + [1 \times O(6e^-)] + [4 \times H(1e^-)] = 14e^-$$

Step 3. Add single bonds and subtract $2e^-$ for each bond (see margin). Five bonds use $10e^-$, so $14e^- - 10e^-$ leaves $4e^-$ remaining.

Step 4. Add the remaining electrons in pairs. Carbon already has an octet, and each H shares two electrons with the C; so the four remaining valence electrons form two lone pairs on O. We now have the Lewis structure for methanol (see margin).

Check Each H atom has $2e^-$, and the C and O each have $8e^-$. The total number of valence electrons is $14e^-$, which equals $10e^-$ in bonds plus $4e^-$ in lone pairs. Also note that each H has one bond, C has four, and O has two.

FOLLOW-UP PROBLEM 10.2 Write a Lewis structure for each of the following:
(a) hydroxylamine (NH_3O) **(b)** dimethyl ether (C_2H_6O; no O—H bonds)

Lewis Structures for Molecules with Multiple Bonds Sometimes, you'll find that, after steps 1 to 4, there are not enough electrons for the central atom (or one of the central atoms) to attain an octet. This usually means that a multiple bond is present, and the following additional step is needed:

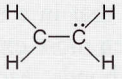
Step 5. Cases involving multiple bonds. If, after step 4, a central atom still does not have an octet, make a multiple bond by changing a lone pair from one of the surrounding atoms into a bonding pair to the central atom.

SAMPLE PROBLEM 10.3 Writing Lewis Structures for Molecules with Multiple Bonds

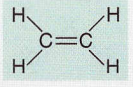
Problem Write Lewis structures for the following:
(a) Ethylene (C_2H_4), the most important reactant in the manufacture of polymers
(b) Nitrogen (N_2), the most abundant atmospheric gas

Plan We show the solution following steps 1 to 4: placing the atoms, counting the total valence electrons, making single bonds, and distributing the remaining valence electrons in pairs to attain octets. Then we continue with step 5, if needed.

Solution **(a)** For C_2H_4. After steps 1 to 4, we have



Step 5. Change a lone pair to a bonding pair. The C on the right has an octet, but the C on the left has only $6e^-$, so we convert the lone pair to another bonding pair between the two C atoms:



(b) For N_2. After steps 1 to 4, we have :N̈—N̈:
Step 5. Neither N has an octet, so we change a lone pair to a bonding pair: :N̈=N:
In this case, moving one lone pair to make a double bond still does not give the N on the right an octet, so we move a lone pair from the left N to make a triple bond: :N≡N:

Check In part (a), each C has four bonds and counts the $4e^-$ in the double bond as part of its own octet. The valence electron total is $12e^-$, all in six bonds. In part (b), each N has three bonds and counts the $6e^-$ in the triple bond as part of its own octet. The valence electron total is $10e^-$, which equals the electrons in three bonds and two lone pairs.

FOLLOW-UP PROBLEM 10.3 Write Lewis structures for each of the following:
(a) CO (the only common molecule in which C has only three bonds) **(b)** HCN **(c)** CO_2

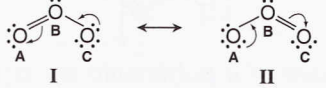
Resonance: Delocalized Electron-Pair Bonding

We can often write more than one Lewis structure, each with the same relative placement of atoms, for a molecule or ion with *double bonds next to single bonds*. Consider ozone (O_3), a serious air pollutant at ground level but a life-sustaining absorber of harmful ultraviolet (UV) radiation in the stratosphere. Two valid Lewis structures (with lettered O atoms for clarity) are

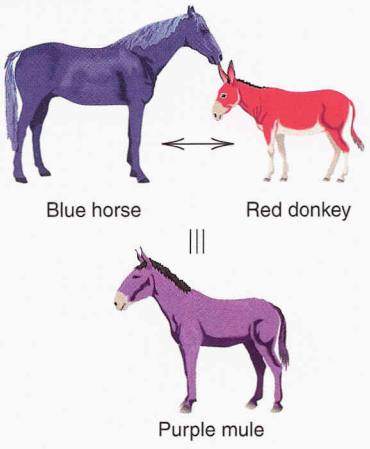
I II

In structure I, oxygen B has a double bond to oxygen A and a single bond to oxygen C. In structure II, the single and double bonds are reversed. These are *not* two different O_3 molecules, just different Lewis structures for the same molecule.

In fact, *neither* Lewis structure depicts O_3 accurately. Bond length and bond energy measurements indicate that the two bonds in O_3 are identical, with properties that lie between those of an O—O bond and an O=O bond, something like a "one-and-a-half" bond. The molecule is shown more correctly with two Lewis structures, called **resonance structures** (or **resonance forms**), and a two-headed resonance arrow (⟷) between them. Resonance structures *have the same relative placement of atoms but different locations of bonding and lone electron pairs*. You can convert one resonance form to another by moving lone pairs to bonding positions, and vice versa:



I ⟷ II

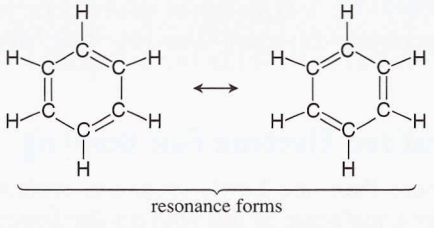


A Purple Mule, Not a Blue Horse and a Red Donkey A mule is a genetic mix, a hybrid, of a horse and a donkey; it is not a horse one instant and a donkey the next. Similarly, the color purple is a mix of two other colors, red and blue, not red one instant and blue the next. In the same sense, a resonance hybrid is one molecular species, not one resonance form this instant and another resonance form the next. The problem is that we cannot depict the hybrid accurately with a single Lewis structure.

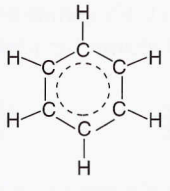
Resonance structures are not real bonding depictions: O_3 does *not* change back and forth from structure I at one instant to structure II the next. The actual molecule is a **resonance hybrid,** an average of the resonance forms.

Our need for more than one Lewis structure to depict the ozone molecule is the result of **electron-pair delocalization.** In a single, double, or triple bond, each electron pair is attracted by the nuclei of the two bonded atoms, and the electron density is greatest in the region between the nuclei: each electron pair is *localized.* In the resonance hybrid for O_3, however, two of the electron pairs (one bonding and one lone pair) are *delocalized:* their density is "spread" over the entire molecule. (Recall from Section 9.6 that in a metal, the electrons are delocalized over the entire sample, which is much more extensive than in a resonance hybrid.) In O_3, this results in two identical bonds, each consisting of a single bond (the localized electron pair) and a *partial bond* (the contribution from one of the delocalized electron pairs). We draw the resonance hybrid with a curved dashed line to show the delocalized pairs:

Electron delocalization diffuses electron density over a greater volume, which reduces electron-electron repulsions and thus stabilizes the molecule. Resonance is very common, and many molecules (and ions) are best depicted as resonance hybrids. Benzene (C_6H_6), for example, has two important resonance forms in which alternating single and double bonds have different positions. The actual molecule has six identical carbon-carbon bonds because there are six C—C bonds and three electron pairs delocalized over all six C atoms, often shown as a dashed circle (or simply a circle):



or

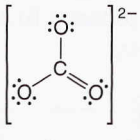


resonance hybrid

Partial bonding, such as that occurring in resonance hybrids, often leads to fractional bond orders. For O_3, we have

$$\text{Bond order} = \frac{3 \text{ electron pairs}}{2 \text{ bonded-atom pairs}} = 1\tfrac{1}{2}$$

The carbon-to-carbon bond order in benzene is 9 electron pairs/6 bonded-atom pairs, or $1\frac{1}{2}$ also. For the carbonate ion, CO_3^{2-}, three resonance structures can be drawn. Each has 4 electron pairs shared among 3 bonded-atom pairs, so the bond order is 4/3, or $1\frac{1}{3}$. One of the three resonance structures for CO_3^{2-} is



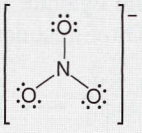
Note that *the Lewis structure of a polyatomic ion is shown in square brackets, with its charge as a right superscript outside the brackets.*

SAMPLE PROBLEM 10.4 Writing Resonance Structures

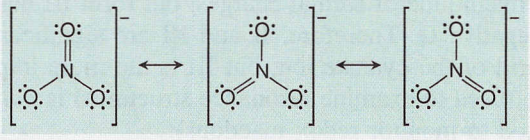
Problem Write resonance structures for the nitrate ion, NO_3^-.

Plan We write a Lewis structure, remembering to add $1e^-$ to the total number of valence electrons because of the $1-$ ionic charge. Then we move lone and bonding pairs to write other resonance forms and connect them with the resonance arrow.

Solution After steps 1 to 4, we have



Step 5. Since N has only $6e^-$, we change one lone pair on an O atom to a bonding pair and form a double bond, which gives each atom an octet. All the O atoms are equivalent, however, so we can move a lone pair from any of the three O atoms and obtain three resonance structures:



Check Each structure has the same relative placement of atoms, an octet around each atom, and $24e^-$ (the sum of the valence electron total and $1e^-$ from the ionic charge distributed in four bonds and eight lone pairs).

Comment Remember that no double bond actually exists in the NO_3^- ion. The ion is a resonance hybrid of these three structures with a bond order of $1\frac{1}{3}$. (You'll see in the upcoming discussion why N can have four bonds here.)

FOLLOW-UP PROBLEM 10.4 One of the three resonance structures for CO_3^{2-} was shown just before Sample Problem 10.4. Draw the other two.

Formal Charge: Selecting the More Important Resonance Structure

In the previous examples, the resonance forms were mixed equally to form the resonance hybrid because the molecules (or ions) had surrounding atoms that were all the same. Often this is not the case, and one resonance form may look more like the hybrid than the others. In other words, because the resonance hybrid is an average of the resonance forms, one form may contribute more and "weight" the average in its favor. One way to select the more important resonance form is to determine each atom's **formal charge,** the charge it would have *if the bonding electrons were shared equally.*

An atom's formal charge is its total number of valence electrons *minus* the number of valence electrons it "owns" in the molecule: it owns *all* of its unshared valence electrons and *half* of its shared valence electrons. Thus,

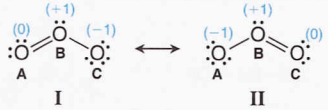
$$\text{Formal charge of atom} = \text{no. of valence } e^- - (\text{no. of unshared valence } e^- + \tfrac{1}{2} \text{ no. of shared valence } e^-) \quad (10.1)$$

For example, in O_3, the formal charge of oxygen A in resonance form I is

$$6 \text{ valence } e^- - (4 \text{ unshared } e^- + \tfrac{1}{2} \text{ of } 4 \text{ shared } e^-) = 6 - 4 - 2 = 0$$

The formal charges of all the atoms in the two O_3 resonance forms are

$O_A[6 - 4 - \frac{1}{2}(4)] = 0$
$O_B[6 - 2 - \frac{1}{2}(6)] = +1$
$O_C[6 - 6 - \frac{1}{2}(2)] = -1$



$O_A[6 - 6 - \frac{1}{2}(2)] = -1$
$O_B[6 - 2 - \frac{1}{2}(6)] = +1$
$O_C[6 - 4 - \frac{1}{2}(4)] = 0$

Forms I and II have the same formal charges but on different O atoms, so they contribute equally to the resonance hybrid. *Formal charges must sum to the actual charge on the species:* zero for a molecule and the ionic charge for an ion.

Note that, in form I, instead of the usual two bonds, O_B has three bonds and O_C has one. Only when an O atom has a zero formal charge does it have its usual number of bonds; the same holds for C in CO, N in NO_3^-, and so forth.

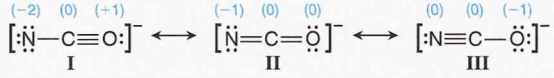
Animation: Formal Charge Calculations
Online Learning Center

Three criteria help us choose the more important resonance structures:

- Smaller formal charges (positive or negative) are preferable to larger ones.
- Like formal charges on adjacent atoms are not desirable.
- A more negative formal charge should reside on a more electronegative atom.

Let's apply these criteria next to the cyanate ion, NCO^-, which has two different atoms around the central one. Three resonance forms with formal charges are

Formal charges:
Resonance forms:



We eliminate form I because it has larger formal charges than the others and a positive formal charge on O, which is more electronegative than N. Forms II and III have the same magnitude of formal charges, but form III has a −1 charge on the more electronegative O. Therefore, II and III are significant contributors to the resonance hybrid of the cyanate ion, but III is the more important.

Formal charge (used to examine resonance structures) is *not* the same as oxidation number (used to monitor redox reactions):

- For a formal charge, bonding electrons are assigned *equally* to the atoms (as if the bonding were *nonpolar covalent*), so each atom has half of them:

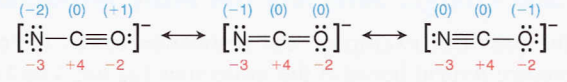
$$\text{Formal charge} = \text{valence } e^- - (\text{lone pair } e^- + \tfrac{1}{2} \text{ bonding } e^-)$$

- For an oxidation number, bonding electrons are assigned *completely* to the more electronegative atom (as if the bonding were *ionic*):

$$\text{Oxidation number} = \text{valence } e^- - (\text{lone pair } e^- + \text{bonding } e^-)$$

Here are the formal charges and oxidation numbers for the three cyanate ion resonance structures:

Formal charges:
Oxidation numbers:

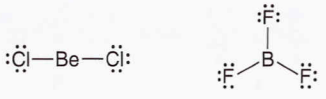


Note that the oxidation numbers *do not* change from one resonance form to another (because the electronegativities *do not* change), but the formal charges *do* change (because the numbers of bonding and lone pairs *do* change).

Lewis Structures for Exceptions to the Octet Rule

The octet rule is a useful guide for most molecules with Period 2 central atoms, but not for every one. Also, many molecules have central atoms from higher periods. As you'll see, some central atoms have fewer than eight electrons around them, and others have more. The most significant octet rule exceptions are for molecules containing electron-deficient atoms, odd-electron atoms, and especially atoms with expanded valence shells.

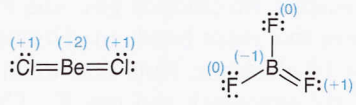
Electron-Deficient Molecules Gaseous molecules containing either beryllium or boron as the central atom are often **electron deficient;** that is, they have *fewer* than eight electrons around the Be or B atom. The Lewis structures of gaseous beryllium chloride* and boron trifluoride are



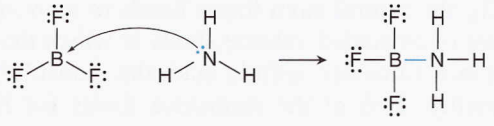
There are only four electrons around beryllium and six around boron. Why don't lone pairs from the surrounding halogen atoms form multiple bonds to the central atoms, thereby satisfying the octet rule? Halogens are much more elec-

*Even though beryllium is an alkaline earth metal [Group 2A(2)], most of its compounds have properties consistent with covalent, rather than ionic, bonding. For example, molten $BeCl_2$ does not conduct electricity, indicating the absence of ions (Chapter 14).

tronegative than beryllium or boron, and formal charges show that the following are unlikely structures:

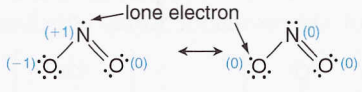


(Some data for BF_3 show a shorter than expected B—F bond. Shorter bonds indicate double-bond character, so the structure with the B=F bond may be a minor contributor to a resonance hybrid.) The main way electron-deficient atoms attain an octet is by forming additional bonds in reactions. When BF_3 reacts with ammonia, for instance, a compound forms in which boron attains its octet:*

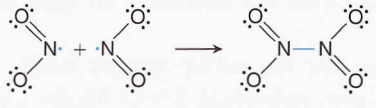


Odd-Electron Molecules A few molecules contain a central atom with an odd number of valence electrons, so they cannot possibly have all their electrons in pairs. Such species, called **free radicals,** contain a lone (unpaired) electron, which makes them paramagnetic (Section 8.5) and extremely reactive. Strictly speaking, Lewis structures are based on an electron-pair model, so they don't apply directly to species with a lone electron, but we'll use formal charges to decide where the lone electron resides. Most odd-electron molecules have a central atom from an odd-numbered group, such as N [Group 5A(15)] or Cl [Group 7A(17)].

Consider nitrogen dioxide (NO_2) as an example. It is a major contributor to urban smog formed when the NO in auto exhaust is oxidized. NO_2 has several resonance forms. Two involve the O atom that is doubly bonded, as in the case of ozone. Several others involve the location of the lone electron. Two of these resonance forms are shown below. The form with the lone electron on the singly bonded O has zero formal charges (right):



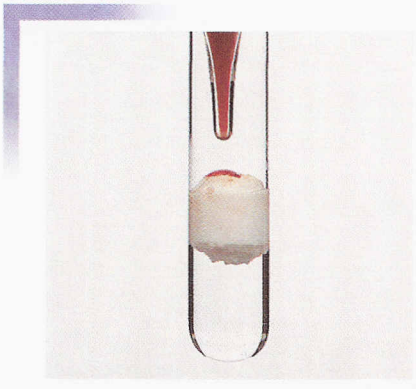
But the form with the lone electron on N (left) must be even more important because of the way NO_2 reacts. Free radicals react with each other to pair up their lone electrons. When two NO_2 molecules collide, the lone electrons pair up to form the N—N bond in dinitrogen tetraoxide (N_2O_4) and each N attains an octet:



Expanded Valence Shells Many molecules and ions have more than eight valence electrons around the central atom. *An atom expands its valence shell to form more bonds,* a process that releases energy. A central atom can accommodate additional pairs by using empty *outer d* orbitals in addition to occupied *s* and *p* orbitals. Therefore, **expanded valence shells** occur only with a *central nonmetal atom from Period 3 or higher,* one in which *d* orbitals are available.

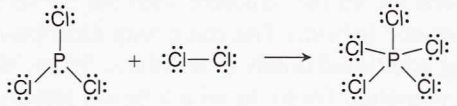
One example is sulfur hexafluoride, SF_6, a remarkably dense and inert gas used as an insulator in electrical equipment. The central sulfur is surrounded by six single bonds, one to each fluorine, for a total of 12 electrons:

*Reactions of the sort shown here, in which one species "donates" an electron pair to another to form a covalent bond, are examples of Lewis acid-base reactions (Chapter 18).

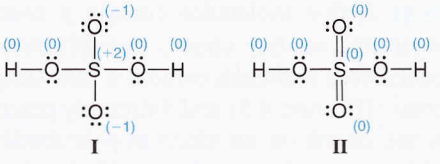


Deadly Free-Radical Activity Free radicals can be extremely dangerous to biological systems because they rupture bonds in cells' biomolecules. If a free radical reacts with a biomolecule, it typically forms a covalent bond to one of the H atoms and removes it, and the biomolecule is left with an unpaired electron, thereby becoming a new free radical. That species repeats the process and creates other species with lone electrons that proliferate to rupture chromosomes and cell membranes. We benefit from this activity when we apply the disinfectant hydrogen peroxide to a cut because it forms free radicals that destroy bacterial membranes. (The photo shows H_2O_2 reacting vigorously with a drop of blood.) On the other hand, recent studies have suggested that several disease states, including certain forms of cancer, may be attributable to free radicals. Also, vitamin E is believed to interrupt free-radical proliferation.

Another example is phosphorus pentachloride, PCl_5, a fuming yellow-white solid used in the manufacture of lacquers and films. PCl_5 is formed when phosphorus trichloride, PCl_3, reacts with chlorine gas. The P in PCl_3 has an octet, but it uses the lone pair to form two more bonds to chlorine and expands its valence shell in PCl_5 to a total of 10 electrons. Note that when PCl_5 forms, *one* Cl—Cl bond breaks (left side of the equation), and *two* P—Cl bonds form (right side), for a net increase of one bond:



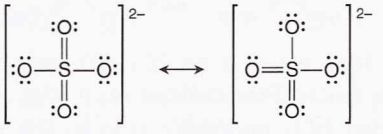
In SF_6 and PCl_5, the central atom forms bonds to *more than four* atoms. But there are many cases of expanded valence shells in which the central atom bonds to *four or fewer* atoms. Consider sulfuric acid, the industrial chemical produced in the greatest quantity. Two of the resonance forms for H_2SO_4, with formal charges, are



I II

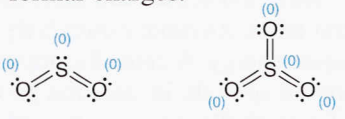
In form II, sulfur has an expanded valence shell of 12 electrons. Based on the formal charge rules, II contributes more than I to the resonance hybrid. More importantly, form II is consistent with observed bond lengths. In gaseous H_2SO_4, the two sulfur-oxygen bonds *with* H atoms attached to O are 157 pm long, whereas the two sulfur-oxygen bonds *without* H atoms attached to O are 142 pm long. This shorter bond indicates double-bond character, which is shown in form II.

When sulfuric acid loses two H^+ ions, it forms the sulfate ion, SO_4^{2-}. All sulfur-oxygen bonds in SO_4^{2-} are 149 pm long, a length that is intermediate between that of the two S=O bonds (~142 pm) and the two S—O bonds (~157 pm) in the parent acid. Two of six resonance forms consistent with these data are



Thus, the SO_4^{2-} ion is a resonance hybrid with four S—O bonds and two more bonding pairs delocalized over the structure; so each sulfur-oxygen bond has a bond order of $1\frac{1}{2}$.

Measurements show that the sulfur-oxygen bonds in SO_2 and SO_3 are all approximately 142 pm long, indicating S=O bonds. Lewis structures consistent with these data have zero formal charges:



Phosphorus often accommodates 10 electrons in its compounds, sulfur 12, and iodine as many as 14.

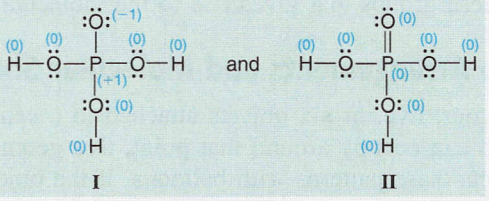
It's important to realize that formal charge is a useful, but not perfect, tool for assessing the importance of contributions to a resonance hybrid. You've already seen that it does not predict the most important resonance form of NO_2. In fact, recent theoretical calculations indicate that, for many species with central atoms from Period 3 or higher, forms with expanded valence shells and zero formal charges may be less important than forms with higher formal charges. But we will continue to apply the formal charge rules because it is usually the simplest approach consistent with experimental data.

SAMPLE PROBLEM 10.5 Writing Lewis Structures for Octet Rule Exceptions

Problem Write Lewis structures for (a) H_3PO_4 (pick the most likely structure); (b) $BFCl_2$.

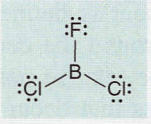
Plan We write each Lewis structure and examine it for exceptions to the octet rule. In (a), the central atom is P, which is in Period 3, so it can use *d* orbitals to have more than an octet. Therefore, we can write more than one Lewis structure. We use formal charges to decide if one resonance form is more important. In (b), the central atom is B, which can have fewer than an octet of electrons.

Solution **(a)** For H_3PO_4, two possible Lewis structures, with formal charges, are



Structure II has lower formal charges, so it is the more important resonance form.

(b) For $BFCl_2$, the Lewis structure leaves B with only six electrons surrounding it:



Comment In (a), structure II is also consistent with bond length measurements, which show one shorter (152 pm) phosphorus-oxygen bond and three longer (157 pm) ones.

FOLLOW-UP PROBLEM 10.5 Write the most likely Lewis structure for **(a)** $POCl_3$; **(b)** ClO_2; **(c)** XeF_4.

SECTION SUMMARY

A stepwise process is used to convert a molecular formula into a Lewis structure, a *two-dimensional* representation of a molecule (or ion) that shows the relative placement of atoms and distribution of valence electrons among bonding and lone pairs. When two or more Lewis structures can be drawn for the same relative placement of atoms, the actual structure is a hybrid of those resonance forms. Formal charges are often useful for determining the most important contributor to the hybrid. Electron-deficient molecules (central Be or B) and odd-electron species (free radicals) have less than an octet around the central atom but often attain an octet in reactions. In a molecule (or ion) with a central atom from Period 3 or higher, the atom can hold more than eight electrons by using *d* orbitals to expand its valence shell.

10.2 VALENCE-SHELL ELECTRON-PAIR REPULSION (VSEPR) THEORY AND MOLECULAR SHAPE

Virtually every biochemical process hinges to a great extent on the shapes of interacting molecules. Every medicine you take, odor you smell, or flavor you taste depends on part or all of one molecule fitting physically together with another. This universal importance of molecular shape in the functioning of each organism carries over to the ecosystem. Biologists have learned of complex interactions regulating behaviors, such as mating, defense, navigation, and feeding, that depend on one molecule's shape matching up with that of another. In this section, we discuss a model for understanding and predicting molecular shape.

The Lewis structure of a molecule is something like the blueprint of a building: a flat drawing showing the relative placement of parts (atom cores), structural connections (groups of bonding valence electrons), and various attachments (nonbonding lone pairs of valence electrons). To construct the molecular shape

Animation: VSEPR
Online Learning Center

Animation: VSEPR Theory and the Shape of Molecules
Online Learning Center

from the Lewis structure, chemists employ ***v*alence-shell *e*lectron-*p*air *r*epulsion (VSEPR) theory.** Its basic principle is that *each group of valence electrons around a central atom is located as far away as possible from the others in order to minimize repulsions.* We define a "group" of electrons as any number of electrons that occupy a localized region around an atom. Thus, an electron group may consist of a single bond, a double bond, a triple bond, a lone pair, or even a lone electron.* Each of these groups of valence electrons repels the other groups to maximize the angles between them. It is the three-dimensional arrangement of nuclei joined by these groups that gives rise to the molecular shape.

Electron-Group Arrangements and Molecular Shapes

When two, three, four, five, or six objects attached to a central point maximize the space that each can occupy around that point, five geometric patterns result. Figure 10.2A depicts these patterns with balloons. If the objects are the valence-electron groups of a central atom, their repulsions maximize the space each occupies and give rise to the five *electron-group arrangements* of minimum energy seen in the great majority of molecules and polyatomic ions.

The electron-group arrangement is defined by the valence-electron groups, both bonding and nonbonding, around the central atom. On the other hand, the **molecular shape** is defined by the relative positions of the atomic nuclei. Figure 10.2B shows the molecular shapes that occur when *all* the surrounding electron groups are *bonding* groups. When some are *nonbonding* groups, different molecular shapes occur. Thus, *the same electron-group arrangement can give rise to different molecular shapes:* some with all bonding groups (as in Figure 10.2B) and others with bonding and nonbonding groups. To classify molecular shapes, we assign each a specific AX_mE_n designation, where m and n are integers, A is the central atom, X is a surrounding atom, and E is a nonbonding valence-electron group (usually a lone pair).

The **bond angle** is the angle formed by the nuclei of two surrounding atoms with the nucleus of the central atom at the vertex. The angles shown for the shapes

*The two electron pairs in a double bond (or the three pairs in a triple bond) occupy separate orbitals, so they remain near each other and act as one electron group (see Chapter 11).

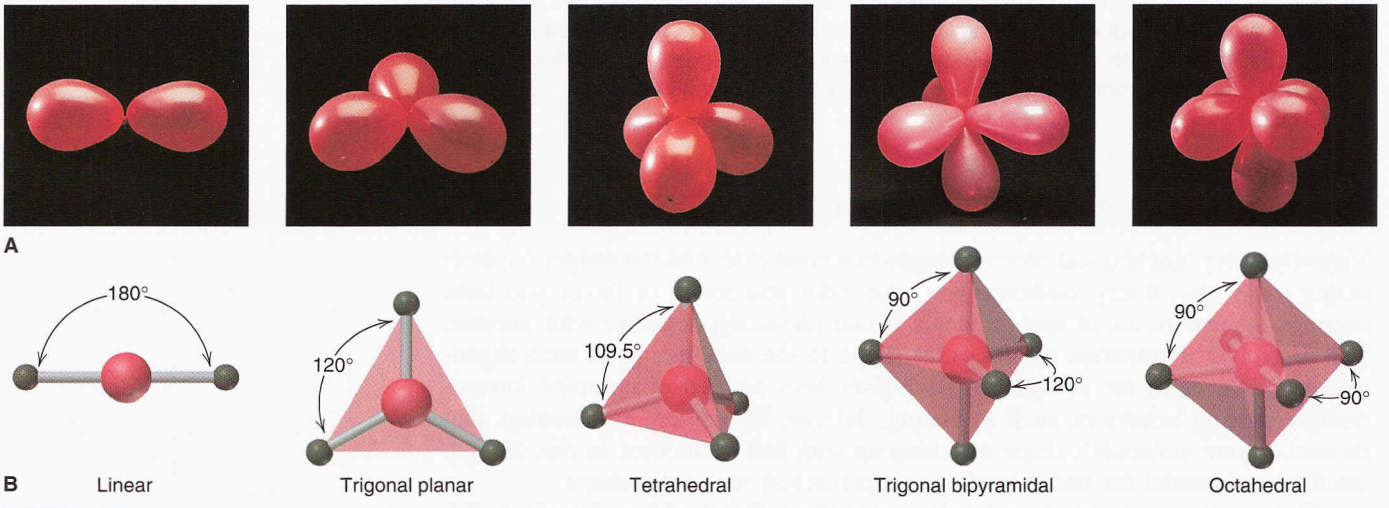


Figure 10.2 Electron-group repulsions and the five basic molecular shapes. A, As an analogy for electron-group arrangements, two to six attached balloons form five geometric orientations such that each balloon occupies as much space as possible. **B,** Mutually repelling electron groups attached to a central atom (*red*) occupy as much space as possible. If each is a bonding group to a surrounding atom (*dark gray*), these molecular shapes and bond angles are observed. The shape has the same name as the electron-group arrangement.

in Figure 10.2B are *ideal* bond angles, those predicted by simple geometry alone. These are observed when all the bonding electron groups around a central atom are identical and are connected to atoms of the same element. When this is not the case, the bond angles deviate from the ideal angles, as you'll see shortly.

It's important to realize that we use the VSEPR model to account for the molecular shapes observed by means of various laboratory instruments. In almost every case, VSEPR predictions are in accord with actual observations. (We discuss some of these observational methods in Chapter 12.)

The Molecular Shape with Two Electron Groups (Linear Arrangement)

When two electron groups attached to a central atom are oriented as far apart as possible, they point in opposite directions. The **linear arrangement** of electron groups results in a molecule with a **linear shape** and a bond angle of 180°. Figure 10.3 shows the general form (top) and shape (middle) with VSEPR shape class (AX_2), and the formulas of some linear molecules.

Gaseous beryllium chloride ($BeCl_2$) is a linear molecule (AX_2). Gaseous Be compounds are electron deficient, with only two electron pairs around the central Be atom:

In carbon dioxide, the central C atom forms two double bonds with the O atoms:

Each double bond acts as a separate electron group and is oriented 180° away from the other, so CO_2 is linear. Notice that the lone pairs on the O atoms of CO_2 or on the Cl atoms of $BeCl_2$ are not involved in the molecular shape: only electron groups around the *central* atom influence shape.

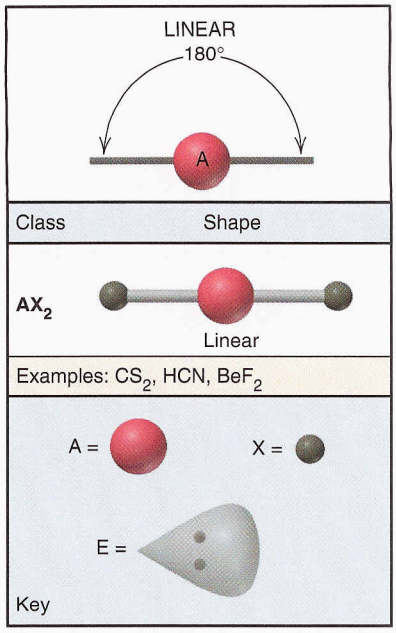

Figure 10.3 The single molecular shape of the linear electron-group arrangement. The key (*bottom*) for A, X, and E also refers to Figures 10.4, 10.5, 10.7, and 10.8.

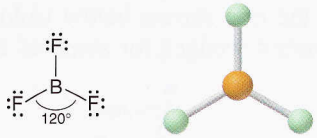
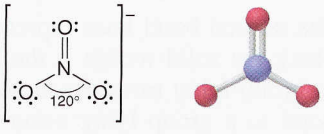
Molecular Shapes with Three Electron Groups (Trigonal Planar Arrangement)

Three electron groups around the central atom repel each other to the corners of an equilateral triangle, which gives the **trigonal planar arrangement,** shown in Figure 10.4, and an ideal bond angle of 120°. This arrangement has two possible molecular shapes, one with three surrounding atoms and the other with two atoms and one lone pair. It provides our first opportunity to see the effects of double bonds and lone pairs on bond angles.

When the three electron groups are bonding groups, the molecular shape is *trigonal planar* (AX_3). Boron trifluoride (BF_3), another electron-deficient molecule, is an example. It has six electrons around the central B atom in three single bonds to F atoms. The nuclei lie in a plane, and each F—B—F angle is 120°:



The nitrate ion (NO_3^-) is one of several polyatomic ions with the trigonal planar shape. One of three resonance forms of the nitrate ion (Sample Problem 10.4) is



The resonance hybrid has three identical bonds of bond order $1\frac{1}{3}$, so the ideal bond angle is observed.

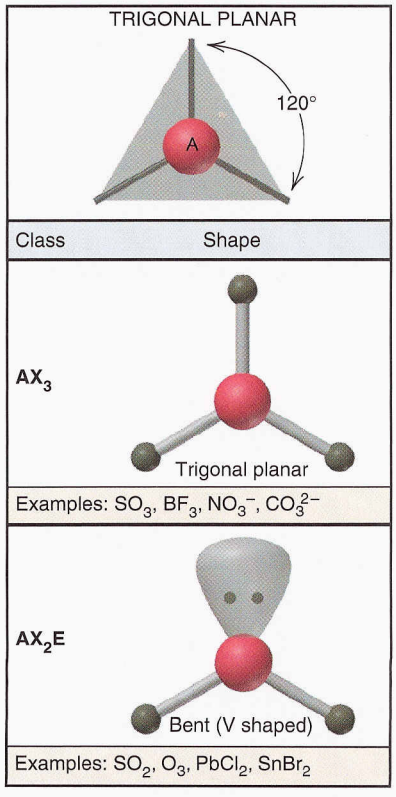


Figure 10.4 The two molecular shapes of the trigonal planar electron-group arrangement.

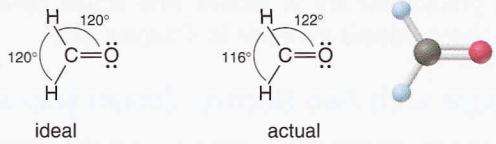
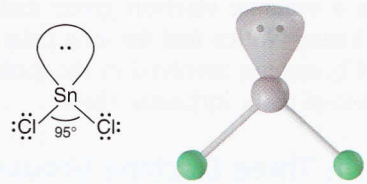
Effect of Double Bonds How do bond angles deviate from the ideal angles when the surrounding atoms and electron groups are not identical? Consider formaldehyde (CH_2O), a substance with many uses, including the manufacture of Formica countertops, the production of methanol, and the preservation of cadavers. Its trigonal planar shape is due to two types of surrounding atoms (O and H) and two types of electron groups (single and double bonds):



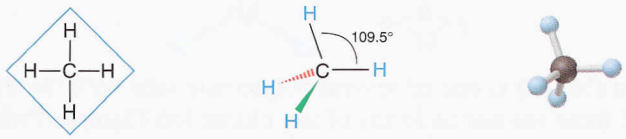
The actual bond angles deviate from the ideal because *the double bond, with its greater electron density, repels the two single bonds more strongly than they repel each other.*

Effect of Lone Pairs The molecular shape is defined only by the positions of the nuclei, so when one of the three electron groups is a lone pair (AX_2E), the shape is **bent,** or **V shaped,** not trigonal planar. Gaseous tin(II) chloride is an example, with the three electron groups in a trigonal plane and the lone pair at one of the triangle's corners. A lone pair can have a major effect on bond angle. Because a lone pair is held by only one nucleus, it is less confined and exerts stronger repulsions than a bonding pair. Thus, *a lone pair repels bonding pairs more strongly than bonding pairs repel each other.* This stronger repulsion *decreases* the angle between bonding pairs. Note the decrease from the ideal 120° angle in $SnCl_2$:



Molecular Shapes with Four Electron Groups (Tetrahedral Arrangement)

The shapes described so far have all been easy to depict in two dimensions, but four electron groups must use three dimensions to achieve maximal separation. This is a good time for you to recall that *Lewis structures do* ***not*** *depict shape.* Consider the shape of methane. The Lewis structure shown below (left) indicates four bonds pointing to the corners of a square, which suggests a 90° bond angle. However, in three dimensions, the four electron groups can move farther apart than 90° and point to the vertices of a tetrahedron, a polyhedron with four faces made of identical equilateral triangles. Methane has a bond angle of 109.5°. Perspective drawings, such as the one shown below (middle) for methane, indicate depth by using solid and dashed wedges for some of the bonds:

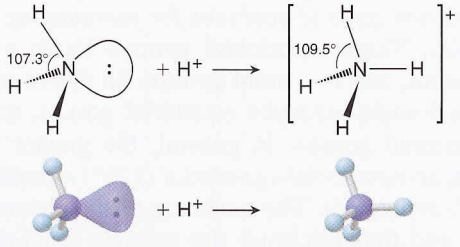


In a *perspective drawing,* the normal bond lines represent shared electron groups in the plane of the page (blue); the solid wedge is the bond between the atom in the plane of the page and a group lying toward you above the page (green); and the dashed wedge is the bond to a group lying away from you below the page (red). The ball-and-stick model (right) shows the tetrahedral shape clearly.

All molecules or ions with four electron groups around a central atom adopt the ***tetrahedral arrangement*** (Figure 10.5). When all four electron groups are bonding groups, as in the case of methane, the molecular shape is also *tetrahedral* (AX_4), a very common geometry in organic molecules. In Sample Problem 10.1, we drew the Lewis structure for the tetrahedral molecule dichlorodifluoromethane (CCl_2F_2), without regard to how the halogen atoms surround the carbon atom. Because Lewis structures are flat, it may seem as if we can write two different structures for CCl_2F_2, but these actually represent the same molecule, as Figure 10.6 makes clear.

When one of the four electron groups in the tetrahedral arrangement is a lone pair, the molecular shape is that of a **trigonal pyramid** (AX_3E), a tetrahedron with one vertex "missing." As we would expect from the stronger repulsions due to the lone pair, the measured bond angle is slightly less than the ideal 109.5°. In ammonia (NH_3), for example, the lone pair forces the N—H bonding pairs closer, and the H—N—H bond angle is 107.3°.

Picturing molecular shapes is a great way to visualize what happens during a reaction. For instance, when ammonia reacts with the proton from an acid, the lone pair on the N atom of trigonal pyramidal NH_3 forms a covalent bond to the H^+ and yields the ammonium ion (NH_4^+), one of many tetrahedral polyatomic ions. Note how the H—N—H bond angle expands from 107.3° in NH_3 to 109.5° in NH_4^+, as the lone pair becomes another bonding pair:



When the four electron groups around the central atom include two bonding and two nonbonding groups, the molecular shape is *bent, or V shaped* (AX_2E_2). [In the trigonal planar arrangement, the shape with two bonding groups and one lone pair (AX_2E) is also called bent, but its ideal bond angle is 120°, not 109.5°.] Water is the most important V-shaped molecule with the tetrahedral arrangement. We might expect the repulsions from its two lone pairs to have a *greater* effect

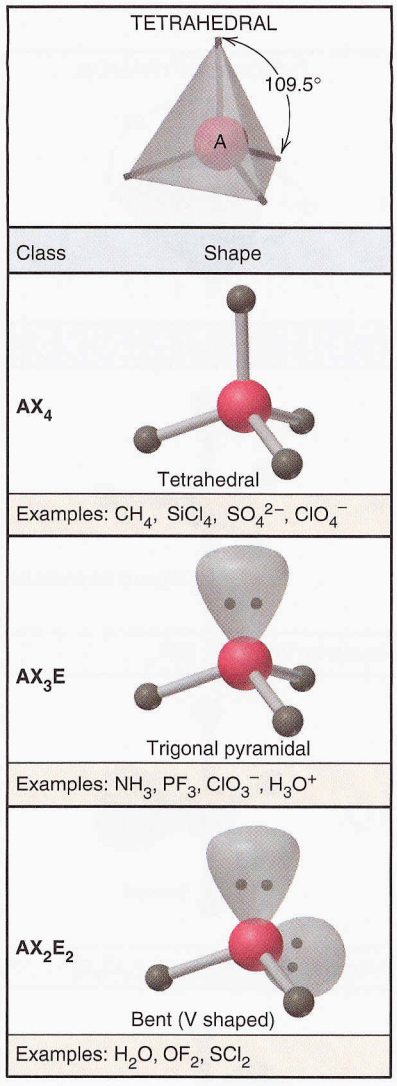


Figure 10.5 The three molecular shapes of the tetrahedral electron-group arrangement.

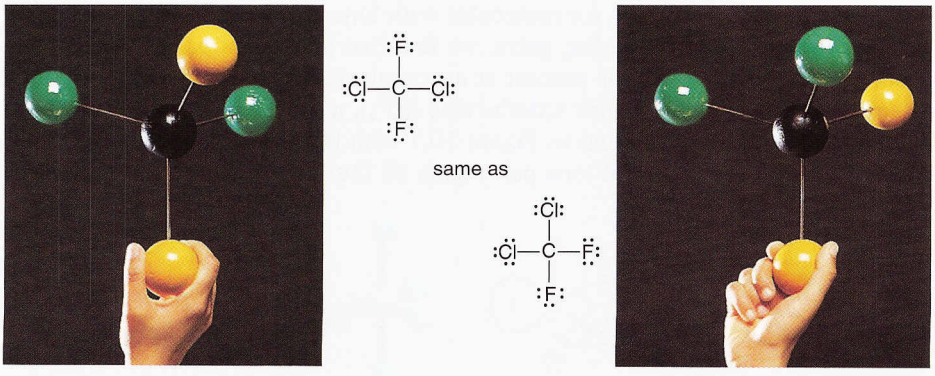

Figure 10.6 Lewis structures and molecular shapes. Lewis structures do not indicate geometry. For example, it may seem as if two different Lewis structures can be written for CCl_2F_2, but a twist of the model (Cl, *green;* F, *yellow*) shows that they represent the same molecule.

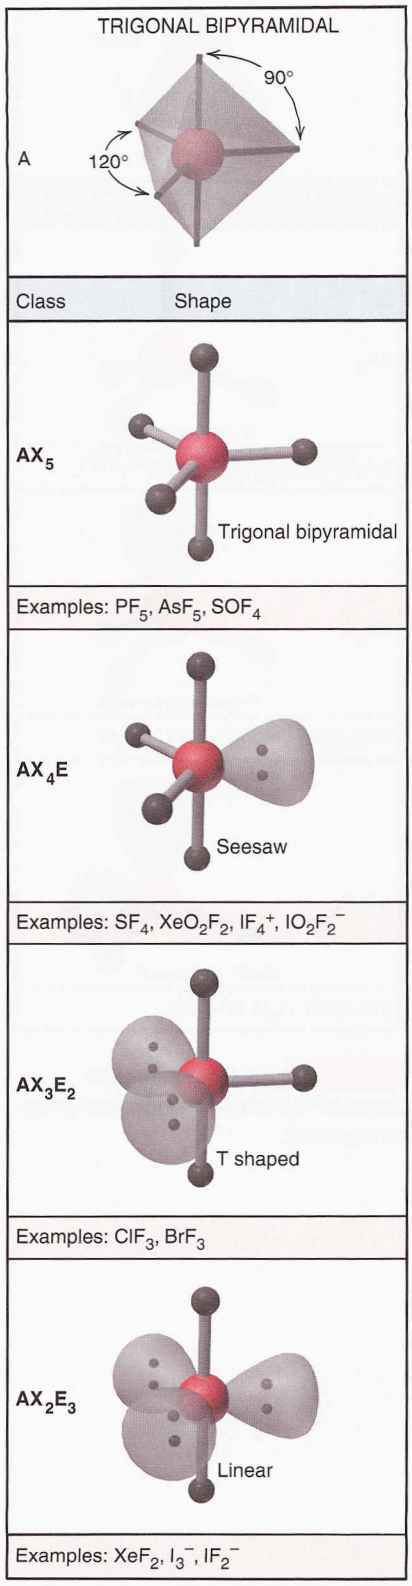

Figure 10.7 **The four molecular shapes of the trigonal bipyramidal electron-group arrangement.**

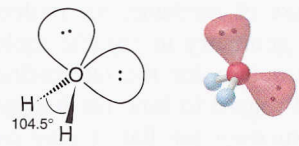
on the bond angle than the repulsions from the single lone pair in NH_3. Indeed, the H—O—H bond angle is 104.5°, even less than the H—N—H angle in NH_3:



Thus, for similar molecules within a given electron-group arrangement, electron-pair repulsions cause deviations from ideal bond angles in the following order:

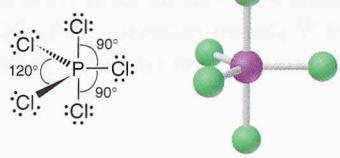
Lone pair–lone pair > lone pair–bonding pair > bonding pair–bonding pair **(10.2)**

Molecular Shapes with Five Electron Groups (Trigonal Bipyramidal Arrangement)

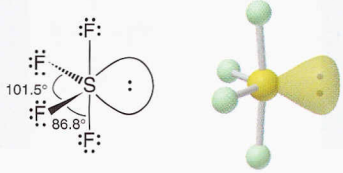
All molecules with five or six electron groups have a central atom from Period 3 or higher because only these atoms have the *d* orbitals available to expand the valence shell beyond eight electrons.

When five electron groups maximize their separation, they form the **trigonal bipyramidal arrangement.** In a trigonal bipyramid, two trigonal pyramids share a common base, as shown in Figure 10.7. Note that, in a molecule with this arrangement, *there are two types of positions for surrounding electron groups and two ideal bond angles.* Three **equatorial groups** lie in a trigonal plane that includes the central atom, and two **axial groups** lie above and below this plane. Therefore, a 120° bond angle separates equatorial groups, and a 90° angle separates axial from equatorial groups. In general, the greater the bond angle, the weaker the repulsions, so *equatorial-equatorial (120°) repulsions are weaker than axial-equatorial (90°) repulsions.* The tendency of the electron groups to occupy *equatorial* positions, and thus minimize the stronger axial-equatorial repulsions, governs the four shapes of the trigonal bipyramidal arrangement.

With all five positions occupied by bonded atoms, the molecule has the *trigonal bipyramidal* shape (AX_5), as in phosphorus pentachloride (PCl_5):

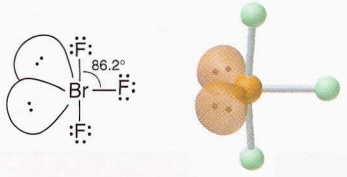


Three other shapes arise for molecules with lone pairs. Since lone pairs exert stronger repulsions than bonding pairs, we find that *lone pairs occupy equatorial positions.* With one lone pair present at an equatorial position, the molecule has a **seesaw shape** (AX_4E). Sulfur tetrafluoride (SF_4), a powerful fluorinating agent, has this shape, shown here and in Figure 10.7 with the "seesaw" tipped up on an end. Note how the equatorial lone pair repels all four bonding pairs to reduce the bond angles:

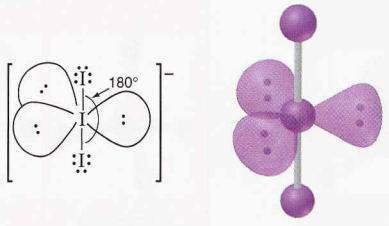


The tendency of lone pairs to occupy equatorial positions causes molecules with three bonding groups and two lone pairs to have a **T shape** (AX_3E_2). Bromine trifluoride (BrF_3), one of many compounds with fluorine bonded to a

larger halogen, has this shape. Note the predicted decrease from the ideal 90° F—Br—F bond angle:



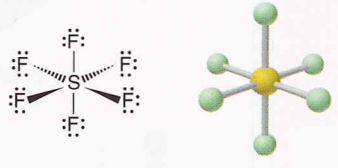
Molecules with three lone pairs in equatorial positions must have the two bonding groups in axial positions, which gives the molecule a *linear* shape (AX_2E_3) and a 180° axial-to-central-to-axial (X—A—X) bond angle. For example, the triiodide ion (I_3^-), which forms when I_2 dissolves in aqueous I^- solution, is linear:



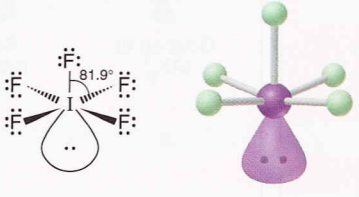
Molecular Shapes with Six Electron Groups (Octahedral Arrangement)

The last of the five major electron-group arrangements is the **octahedral arrangement.** An octahedron is a polyhedron with eight faces made of identical equilateral triangles and six identical vertices, as shown in Figure 10.8. In a molecule (or ion) with this arrangement, six electron groups surround the central atom and each points to one of the six vertices, which gives all the groups a 90° ideal bond angle. Three important molecular shapes occur with this arrangement.

With six bonding groups, the molecular shape is *octahedral* (AX_6). When the seesaw-shaped SF_4 reacts with additional F_2, the central S atom expands its valence shell further to form octahedral sulfur hexafluoride (SF_6):



Because all six electron groups have the same ideal bond angle, it makes no difference which position one lone pair occupies. Five bonded atoms and one lone pair define the **square pyramidal shape** (AX_5E), as in iodine pentafluoride (IF_5):



When a molecule has two lone pairs, however, they always lie at *opposite vertices* to avoid the stronger 90° lone pair–lone pair repulsions. This positioning gives the **square planar shape** (AX_4E_2), as in xenon tetrafluoride (XeF_4):

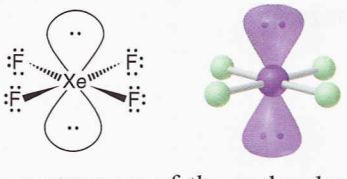


Figure 10.9 (next page) is a summary of the molecular shapes we've discussed.

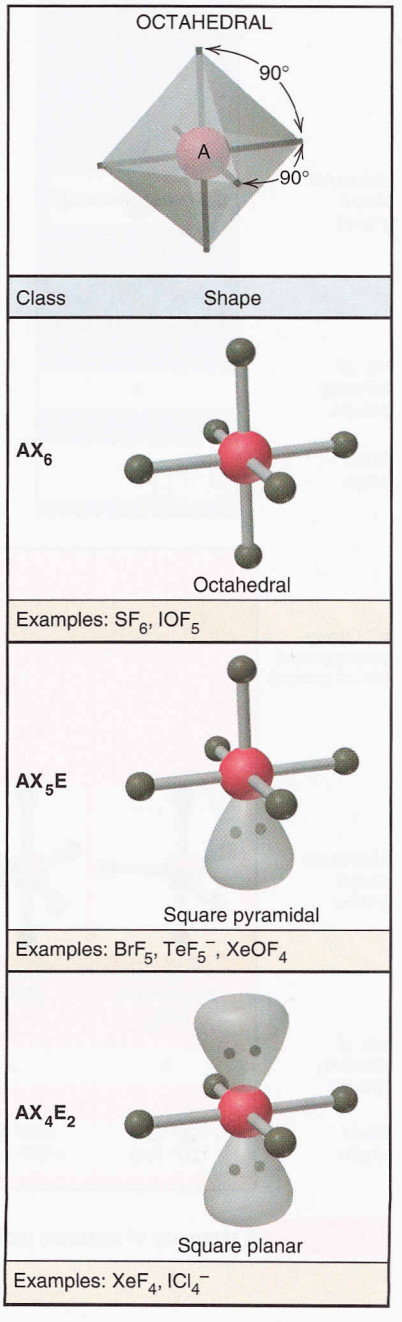

Figure 10.8 **The three molecular shapes of the octahedral electron-group arrangement.**

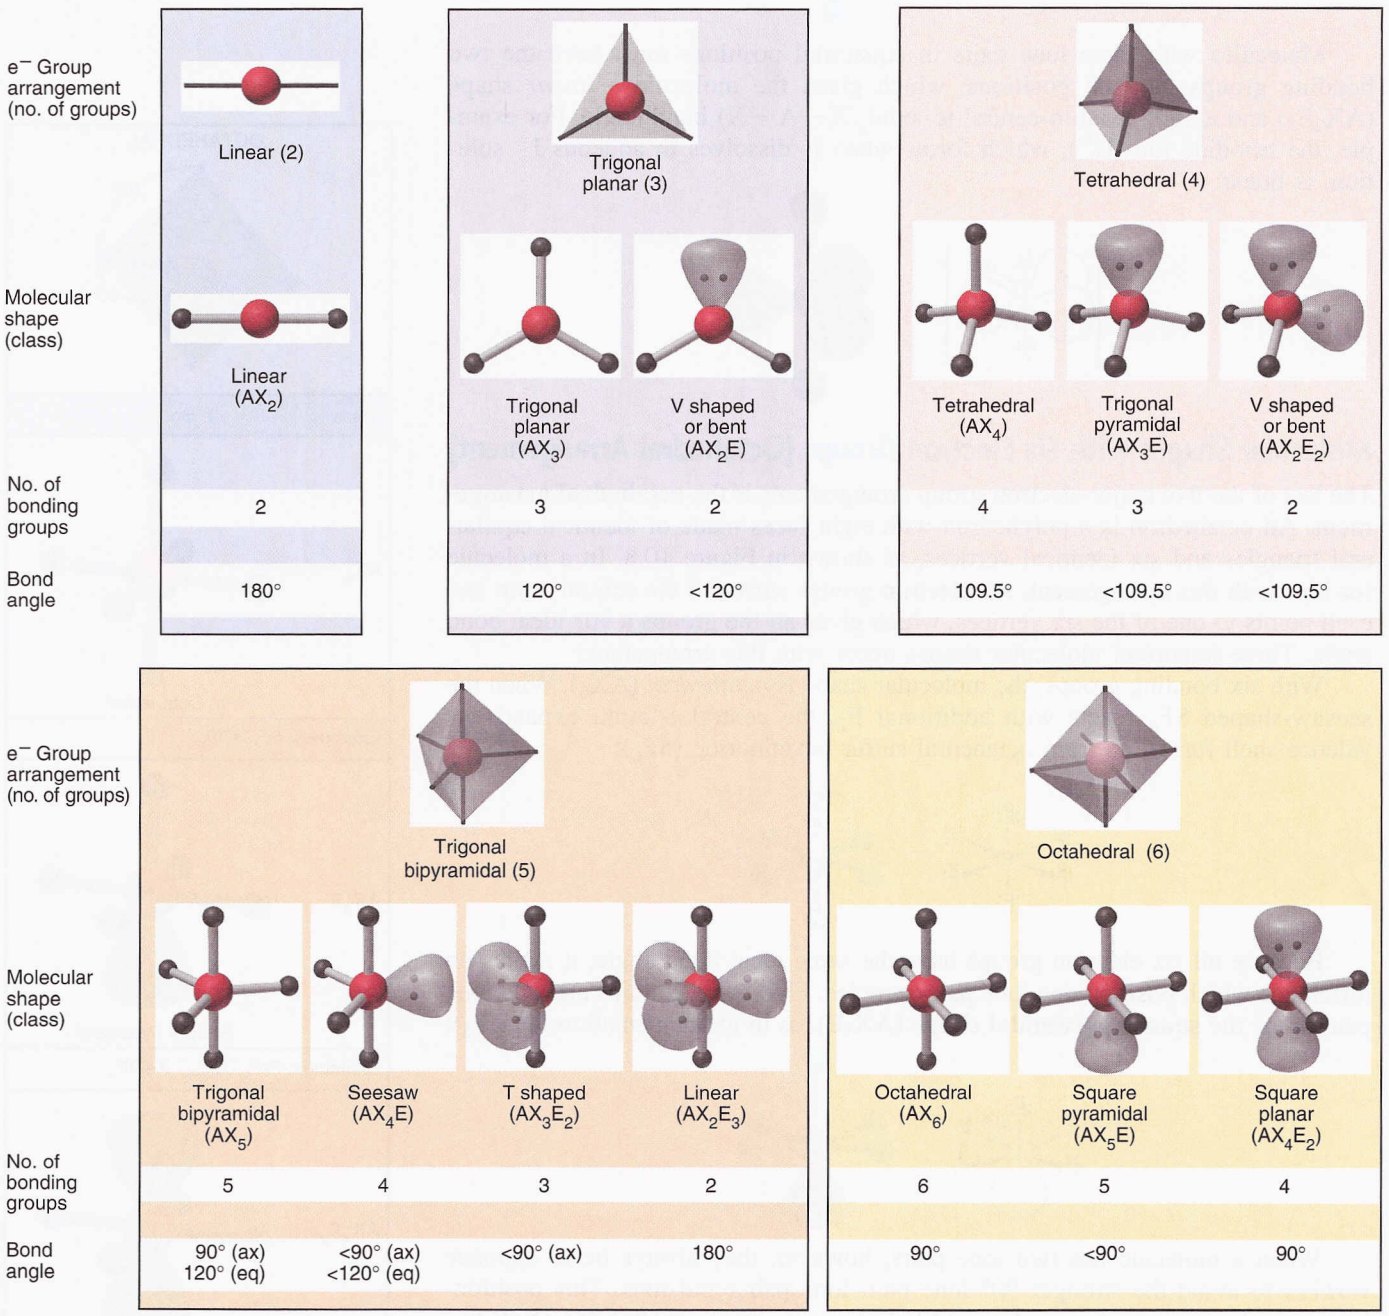

Figure 10.9 **A summary of common molecular shapes with two to six electron groups.**

Using VSEPR Theory to Determine Molecular Shape

Let's apply a stepwise method for using the VSEPR theory to determine a molecular shape from a molecular formula:

Step 1. Write the Lewis structure from the molecular formula (Figure 10.1, p. 366) to see the relative placement of atoms and the number of electron groups.

Step 2. Assign an electron-group arrangement by counting *all* electron groups around the central atom, bonding *plus* nonbonding.

Step 3. Predict the ideal bond angle from the electron-group arrangement and *the direction of any deviation* caused by lone pairs or double bonds.

Step 4. Draw and name the molecular shape by counting bonding groups and nonbonding groups separately.

Figure 10.10 summarizes these steps, and the next two sample problems apply them.

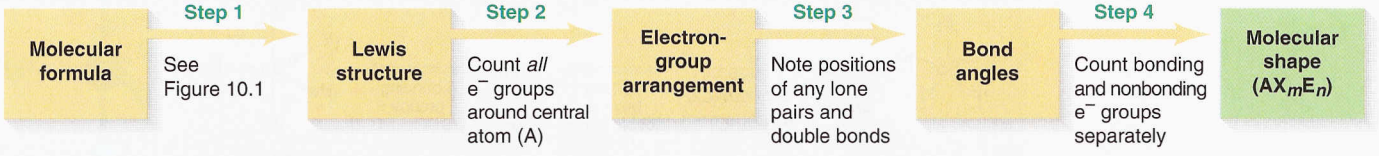

Figure 10.10 The steps in determining a molecular shape. Four steps are needed to convert a molecular formula to a molecular shape.

SAMPLE PROBLEM 10.6 Predicting Molecular Shapes with Two, Three, or Four Electron Groups

Problem Draw the molecular shapes and predict the bond angles (relative to the ideal angles) of **(a)** PF_3 and **(b)** $COCl_2$.

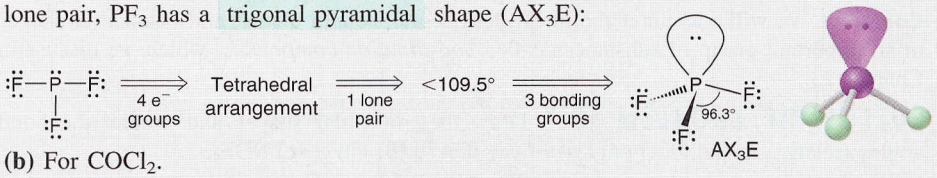
Solution **(a)** For PF_3.

Step 1. Write the Lewis structure from the formula (see below left).

Step 2. Assign the electron-group arrangement: Three bonding groups plus one lone pair give four electron groups around P and the *tetrahedral arrangement.*

Step 3. Predict the bond angle: For the tetrahedral electron-group arrangement, the ideal bond angle is 109.5°. There is one lone pair, so the actual bond angle should be less than 109.5°.

Step 4. Draw and name the molecular shape: With four electron groups, one of them a lone pair, PF_3 has a trigonal pyramidal shape (AX_3E):



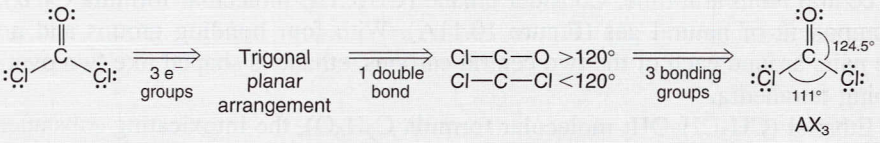
(b) For $COCl_2$.

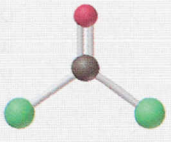
Step 1. Write the Lewis structure from the formula (see below left).

Step 2. Assign the electron-group arrangement: Two single bonds plus one double bond give three electron groups around C and the *trigonal planar arrangement.*

Step 3. Predict the bond angles: The ideal bond angle is 120°, but the double bond between C and O should compress the Cl—C—Cl angle to less than 120°.

Step 4. Draw and name the molecular shape: With three electron groups and no lone pairs, $COCl_2$ has a trigonal planar shape (AX_3):





Check We compare the answers with the general information in Figure 10.9.

Comment Be sure the Lewis structure is correct because it determines the other steps.

FOLLOW-UP PROBLEM 10.6 Draw the molecular shapes and predict the bond angles (relative to the ideal angles) of **(a)** CS_2; **(b)** $PbCl_2$; **(c)** CBr_4; **(d)** SF_2.

SAMPLE PROBLEM 10.7 Predicting Molecular Shapes with Five or Six Electron Groups

Problem Determine the molecular shapes and predict the bond angles (relative to the ideal angles) of **(a)** SbF_5 and **(b)** BrF_5.

Plan We proceed as in Sample Problem 10.6, keeping in mind the need to minimize the number of 90° repulsions.

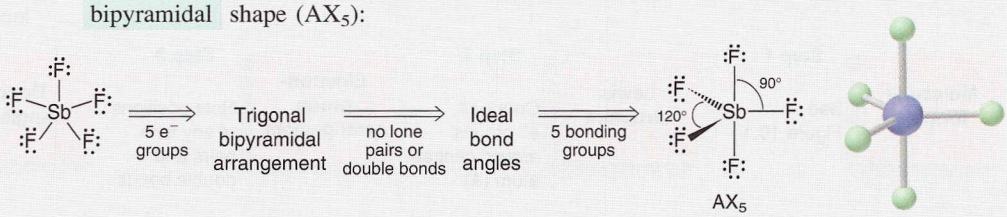
Solution **(a)** For SbF_5.

Step 1. Lewis structure (see below left).

Step 2. Electron-group arrangement: With five electron groups, this is the *trigonal bipyramidal* arrangement.

Step 3. Bond angles: All the groups and surrounding atoms are identical, so the bond angles are ideal: 120° between equatorial groups and 90° between axial and equatorial groups.

Step 4. Molecular shape: Five electron groups and no lone pairs give the trigonal bipyramidal shape (AX_5):



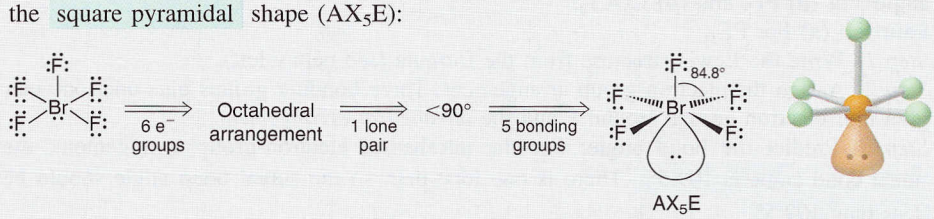
(b) For BrF_5.

Step 1. Lewis structure (see below left).

Step 2. Electron-group arrangement: Six electron groups give the *octahedral* arrangement.

Step 3. Bond angles: The lone pair should make all bond angles less than the ideal 90°.

Step 4. Molecular shape: With six electron groups and one of them a lone pair, BrF_5 has the square pyramidal shape (AX_5E):



Check We compare our answers with Figure 10.9.

Comment We will encounter the linear, tetrahedral, square planar, and octahedral shapes in an important group of substances called *coordination compounds,* which we discuss in Chapter 23.

FOLLOW-UP PROBLEM 10.7 Draw the molecular shapes and predict the bond angles (relative to the ideal angles) of **(a)** ICl_2^-; **(b)** ClF_3; **(c)** SOF_4.

Molecular Shapes with More Than One Central Atom

Many molecules, especially those in living systems, have more than one central atom. The shapes of these molecules are combinations of the molecular shapes for each central atom. For these molecules, we find the molecular shape around one central atom at a time. Consider ethane (CH_3CH_3; molecular formula C_2H_6), a component of natural gas (Figure 10.11A). With four bonding groups and no lone pairs around each of the two central carbons, ethane is shaped like two overlapping tetrahedra.

Ethanol (CH_3CH_2OH; molecular formula C_2H_6O), the intoxicating substance in beer and wine, has three central atoms (Figure 10.11B). The CH_3— group is tetrahedrally shaped, and the —CH_2— group has four bonding groups around its central C atom, so it is tetrahedrally shaped also. The O atom has four electron groups and two lone pairs around it, which gives the V shape (AX_2E_2).

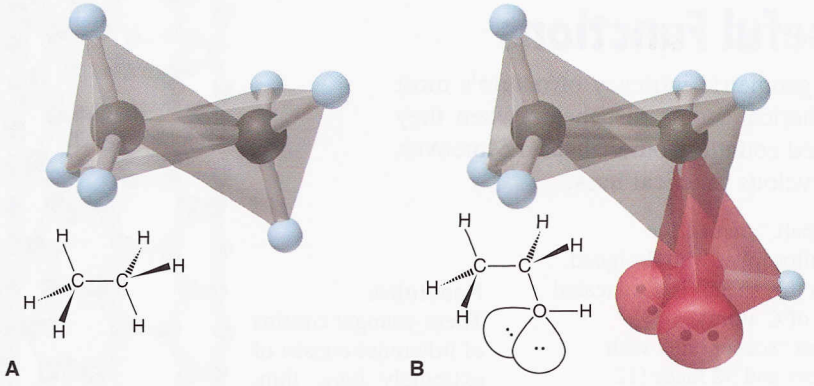


Figure 10.11 The tetrahedral centers of ethane and of ethanol. When a molecule has more than one central atom, the shape is a composite of the shape around each center. **A,** Ethane's shape can be viewed as two overlapping tetrahedra. **B,** Ethanol's shape can be viewed as three overlapping tetrahedral arrangements, with the shape around the O atom bent (V shaped) because of its two lone pairs.

SAMPLE PROBLEM 10.8 Predicting Molecular Shapes with More Than One Central Atom

Problem Determine the shape around each of the central atoms in acetone, $(CH_3)_2C{=}O$.

Plan There are three central atoms, all C, two of which are in CH_3- groups. We determine the shape around one central atom at a time.

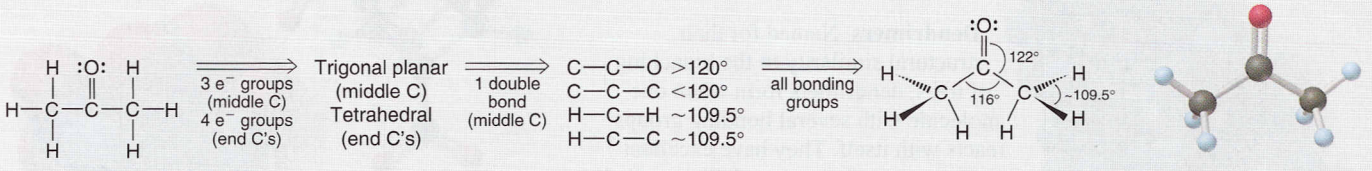
Solution

Step 1. Lewis structure (see below left).

Step 2. Electron-group arrangement: Each CH_3- group has four electron groups around its central C, so its electron-group arrangement is *tetrahedral.* The third C atom has three electron groups around it, so it has the *trigonal planar* arrangement.

Step 3. Bond angles: The H—C—H angle in the CH_3- groups should be near the ideal tetrahedral angle of 109.5°. The C=O double bond should compress the C—C—C angle to less than the ideal 120°.

Step 4. Shapes around central atoms: With four electron groups and no lone pairs, the shapes around the two C atoms in the CH_3- groups are tetrahedral (AX_4). With three electron groups and no lone pairs, the shape around the middle C atom is trigonal planar (AX_3):



FOLLOW-UP PROBLEM 10.8 Determine the shape around each central atom and predict any deviations from ideal bond angles in the following: **(a)** H_2SO_4; **(b)** propyne (C_3H_4; there is one C≡C bond); **(c)** S_2F_2.

In recent years, chemists have synthesized some organic molecules with remarkable—some would say beautiful—shapes. Some of their uses may still be speculative, but there is no question about their geometric elegance. A few of these molecules appear in the Gallery on the next page.

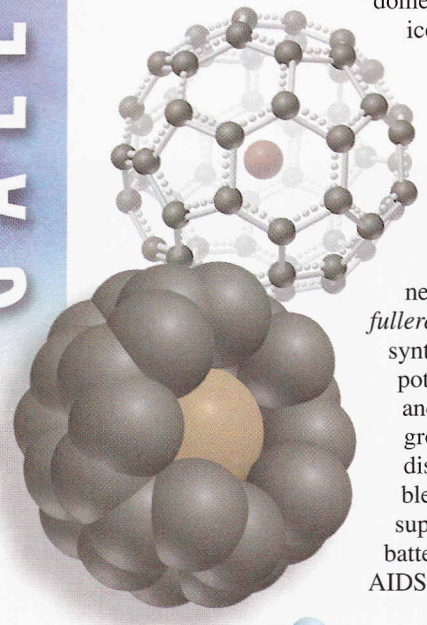
SECTION SUMMARY

The VSEPR theory proposes that each group of electrons (single bond, multiple bond, lone pair, or lone electron) around a central atom remains as far away from the others as possible. One of five electron-group arrangements results when two, three, four, five, or six electron groups surround a central atom. Each arrangement is associated with one or more molecular shapes. Ideal bond angles are prescribed by the regular geometric shapes; deviations from these angles occur when the surrounding atoms or electron groups are not identical. Lone pairs and double bonds exert greater repulsions than single bonds. Larger molecules have shapes that are composites of the shapes around each central atom.

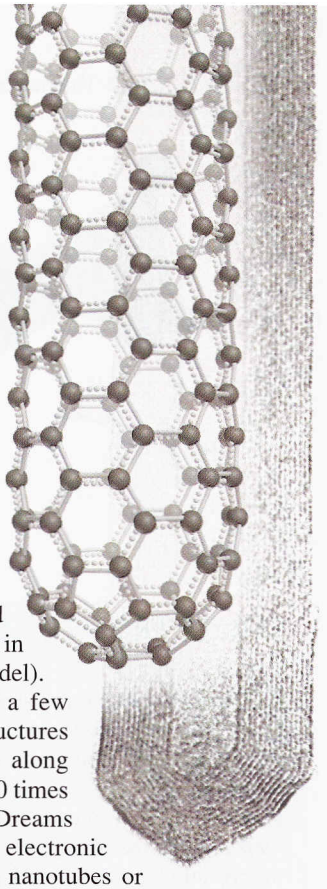
GALLERY

Molecular Beauty: Odd Shapes with Useful Functions

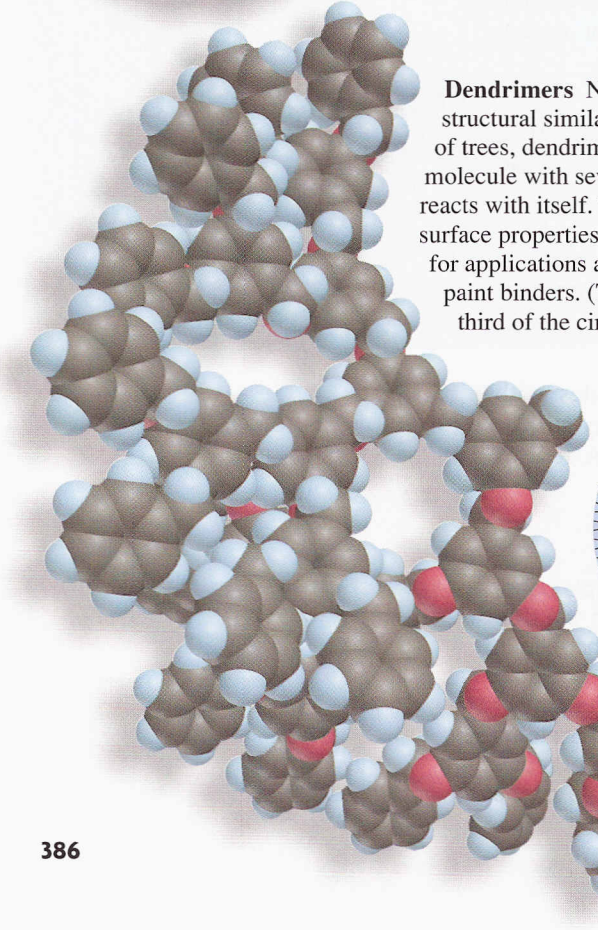
Chemists see a strange beauty in the geometric intricacy of nature's most minute objects. The simplicity of spherical atoms disappears when they combine to form pentagons, helices, and countless other shapes. Moreover, many "beautiful" molecules have marvelous practical uses.



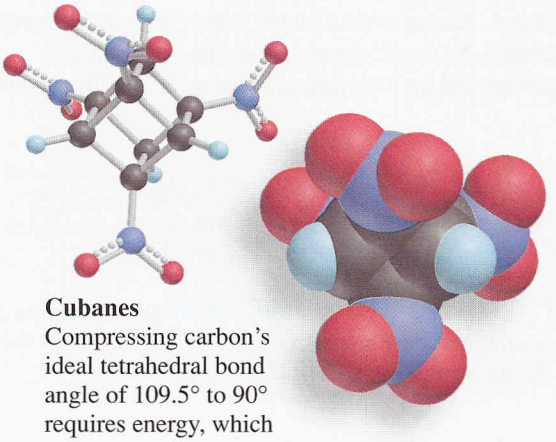
Fullerenes Buckminsterfullerene ("bucky ball," named for R. Buckminster Fuller, the architect and philosopher who designed domes based on this shape) is a truncated icosahedron of C atoms, a molecular "soccer ball" with 60 vertices and 32 faces (12 pentagons and 20 hexagons). This C_{60} structure, discovered in soot in 1985 and prepared in bulk in 1990, represents a third crystalline form of carbon (graphite and diamond are the other two). It is the parent of a new family of structures called *fullerenes* and has spawned a new field of synthesis. By inserting atoms, such as potassium, inside the ball (see models) and bonding countless types of chemical groups to the outside, researchers have discovered a whole new range of possible applications, including lubricants, superconductors, rocket fuels, lasers, batteries, magnetic films, cancer and AIDS drugs—the list grows daily!



Nanotubes These younger cousins of fullerenes consist of extremely long, thin, graphite-like cylinders with fullerene ends. They are often nested within one another (as in the photo behind the model). Despite thicknesses of a few nanometers, these structures are highly conductive along their length and about 40 times stronger than steel! Dreams abound of nanoscale electronic components made with nanotubes or atom-thick wires formed by inserting metal atoms within their interiors.



Dendrimers Named for their structural similarity to the branching of trees, dendrimers form when one molecule with several bonding groups reacts with itself. They have excellent surface properties and are being studied for applications as films, fibers, and paint binders. (The model shows one-third of the circular schematic.)



Cubanes Compressing carbon's ideal tetrahedral bond angle of 109.5° to 90° requires energy, which becomes stored in the bond. Thus, cyclobutane, a square of C atoms with two H atoms at each corner, is unstable above 500 K. Much more energy is stored in the bonds of cubane, a cube of C atoms with one H at each corner, synthesized in 1964. The bond-strain energy of cubane can yield enormous explosive power. Tetranitrocubane (shown here) is a very powerful explosive, and octanitrocubane, which was synthesized in 2000, is considered the most powerful non-nuclear explosive known. Other properties of cubanes, which are apparently unrelated to the bond energy, include attacking cancer cells and inactivating an enzyme involved in Parkinson's disease.

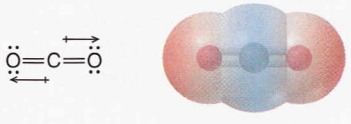
10.3 MOLECULAR SHAPE AND MOLECULAR POLARITY

Knowing the shape of a substance's molecules is a key to understanding its physical and chemical behavior. One of the most important and far-reaching effects of molecular shape is molecular polarity, which can influence melting and boiling points, solubility, chemical reactivity, and even biological function.

In Chapter 9, you learned that a covalent bond is *polar* when it joins atoms of different electronegativities because the atoms share the electrons unequally. In diatomic molecules, such as HF, where there is only one bond, the bond polarity causes the molecule itself to be polar. Molecules with a net imbalance of charge have a **molecular polarity.** In molecules with more than two atoms, *both shape and bond polarity determine molecular polarity.* In an electric field, polar molecules become oriented, on average, with their partial charges pointing toward the oppositely charged electric plates, as shown for HF in Figure 10.12. The **dipole moment (μ)** is the product of these partial charges and the distance between them. It is typically measured in *debye* (D) units; using the SI units of charge (coulomb, C) and length (meter, m), 1 D = 3.34×10^{-30} C·m. [The unit is named for Peter Debye (1884–1966), the Dutch American chemist and physicist who won the Nobel Prize in 1936 for his major contributions to our understanding of molecular structure and solution behavior.]

Bond Polarity, Bond Angle, and Dipole Moment

When determining molecular polarity, we must take shape into account because the presence of polar bonds does not *always* lead to a polar molecule. In carbon dioxide, for example, the large electronegativity difference between C (EN = 2.5) and O (EN = 3.5) makes each C=O bond quite polar. However, CO_2 is linear, so its bonds point 180° from each other. As a result, the two identical bond polarities are counterbalanced and give the molecule *no net dipole moment* (μ = 0 D). Note that the electron density model shows regions of high negative charge (*red*) distributed equally on either side of the central region of high positive charge (*blue*):



Water also has identical atoms bonded to the central atom, but it *does* have a significant dipole moment (μ = 1.85 D). In each O—H bond, electron density is pulled toward the more electronegative O atom. Here, the bond polarities are *not* counterbalanced, because the water molecule is V shaped (also see Figure 4.1, p. 135). Instead, the bond polarities are partially reinforced, and the O end of the molecule is more negative than the other end (the region between the H atoms), which the electron density model shows clearly:

(The molecular polarity of water has some amazing effects, from determining the composition of the oceans to supporting life itself, as you'll see in Chapter 12.)

In the two previous examples, molecular shape influences polarity. When different molecules have the same shape, the nature of the atoms surrounding the central atom can have a major effect on polarity. Consider carbon tetrachloride (CCl_4) and chloroform ($CHCl_3$), two tetrahedral molecules with very different polarities. In CCl_4, the surrounding atoms are all Cl atoms. Although each C—Cl bond is polar (ΔEN = 0.5), the molecule is nonpolar (μ = 0 D) because the

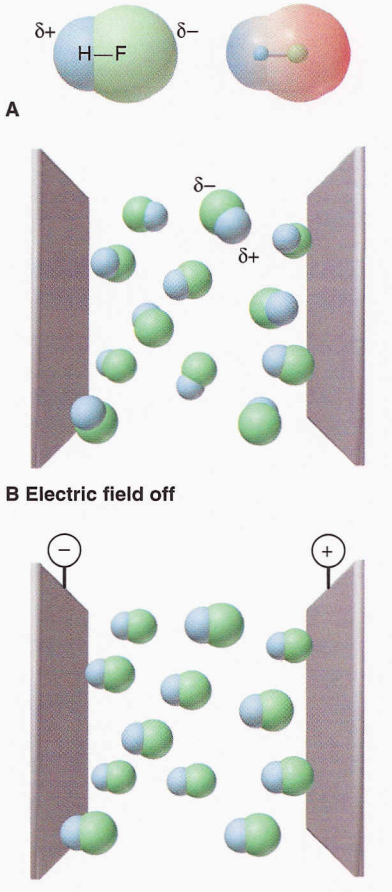


Figure 10.12 The orientation of polar molecules in an electric field. A, A space-filling model of HF (*left*) shows the partial charges of this polar molecule. The electron density model (*right*) shows high electron density (*red*) associated with the F end and low electron density (*blue*) with the H end. **B,** In the absence of an external electric field, HF molecules are oriented randomly. **C,** In the presence of the field, the molecules, on average, become oriented with their partial charges pointing toward the oppositely charged plates.

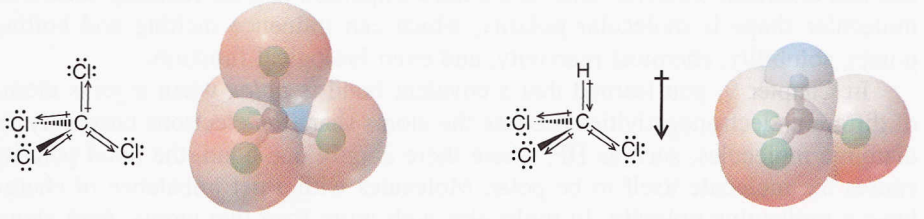
Animation: Influence of Shape on Polarity
Online Learning Center

individual bond polarities counterbalance each other. In $CHCl_3$, H substitutes for one Cl atom, disrupting the balance and giving chloroform a significant dipole moment (μ = 1.01 D):



SAMPLE PROBLEM 10.9 Predicting the Polarity of Molecules

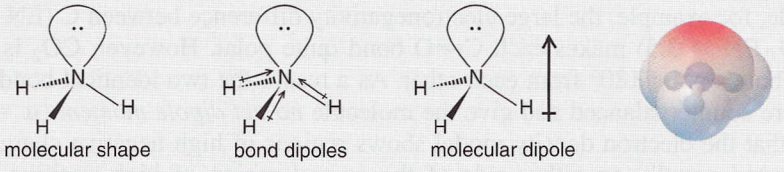
Problem From electronegativity (EN) values and their periodic trends (see Figure 9.19, p. 352), predict whether each of the following molecules is polar and show the direction of bond dipoles and the overall molecular dipole when applicable:

(a) Ammonia, NH_3 **(b)** Boron trifluoride, BF_3

(c) Carbonyl sulfide, COS (atom sequence SCO)

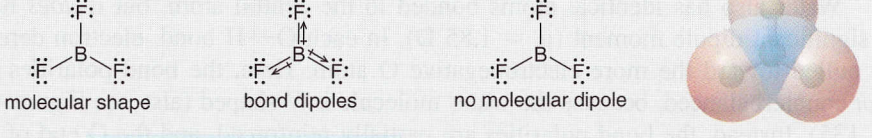
Plan First, we draw and name the molecular shape. Then, using relative EN values, we decide on the direction of each bond dipole. Finally, we see if the bond dipoles balance or reinforce each other in the molecule as a whole.

Solution **(a)** For NH_3. The molecular shape is trigonal pyramidal. From Figure 9.19, we see that N (EN = 3.0) is more electronegative than H (EN = 2.1), so the bond dipoles point toward N. The bond dipoles partially reinforce each other, and thus the molecular dipole points toward N:



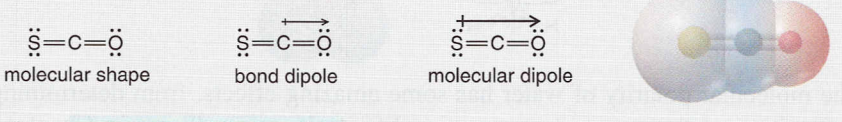
Therefore, ammonia is polar.

(b) For BF_3. The molecular shape is trigonal planar. Because F (EN = 4.0) is farther to the right in Period 2 than B (EN = 2.0), it is more electronegative; thus, each bond dipole points toward F. However, the bond angle is 120°, so the three bond dipoles counterbalance each other, and BF_3 has no molecular dipole:



Therefore, boron trifluoride is nonpolar.

(c) For COS. The molecular shape is linear. With C and S having the same EN, the C=S bond is nonpolar, but the C=O bond is quite polar (ΔEN = 1.0), so there is a net molecular dipole toward the O:



Therefore, carbonyl sulfide is polar.

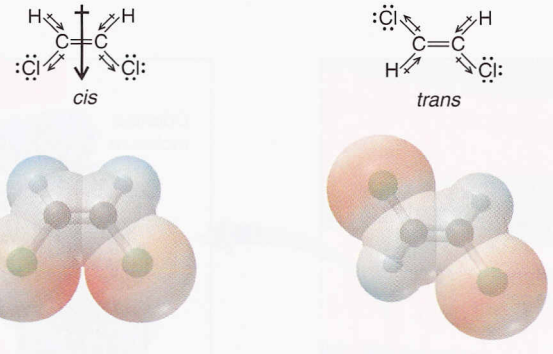
FOLLOW-UP PROBLEM 10.9 Show the bond dipoles and molecular dipole, if any, for **(a)** dichloromethane (CH_2Cl_2); **(b)** iodine oxide pentafluoride (IOF_5); **(c)** nitrogen tribromide (NBr_3).

The Effect of Molecular Polarity on Behavior

Animation: Polarity of Molecules
Online Learning Center

To get a sense of the influence of molecular polarity on physical behavior, consider what effect a molecular dipole might have when many polar molecules lie near each other, as they do in a liquid. How does a molecular property such as dipole moment affect a macroscopic property such as boiling point? A liquid boils when its molecules have enough energy to form bubbles of gas. To enter the bubble, the molecules in the liquid must overcome the weak attractive forces *between* them. A molecular dipole influences the strength of these attractions.

Consider the two dichloroethylenes shown below. These compounds have the *same* molecular formula ($C_2H_2Cl_2$), but they have *different* physical and chemical properties; they are constitutional isomer in particular, *cis*-1,2-dichloroethylene boils 13°C higher than *trans*-1,2-dichloroethylene. VSEPR theory predicts, and laboratory observation confirms, that all the nuclei lie in the same plane, with a trigonal planar shape around each C atom. The *trans* isomer has no dipole moment ($\mu = 0$ D) because the C—Cl bond polarities balance each other. In contrast, the *cis* isomer *is* polar ($\mu = 1.90$ D) because the bond dipoles partially reinforce each other, with the molecular dipole pointing between the Cl atoms. In the liquid state, the polar *cis* molecules attract each other more strongly than the nonpolar *trans* molecules, so more energy is needed to overcome these stronger forces. Therefore, the *cis* isomer has a higher boiling point. We extend these ideas in Chapter 12. The upcoming Chemical Connections essay discusses some fundamental effects of molecular shape and polarity on biological behavior.



SECTION SUMMARY

Bond polarity and molecular shape determine molecular polarity, which is measured as a dipole moment. When bond polarities counterbalance each other, the molecule is nonpolar; when they reinforce each other, the molecule is polar. Molecular shape and polarity can affect physical properties, such as boiling point, and they play a central role in many aspects of biological function.

Chapter Perspective

In this chapter, you saw how chemists use the simple idea of electrostatic repulsion between electron groups to account for the shapes of molecules and, ultimately, their properties. In the next chapter, you'll learn how chemists explain molecular shape and behavior through the nature of the orbitals that electrons occupy. The landscape of a molecule—its geometric contours and regions of charge—gives rise to all its other properties. In upcoming chapters, we'll explore the physical behavior of liquids and solids (Chapter 12), the properties of solutions (Chapter 13), and the behavior of the main-group elements (Chapter 14) and organic molecules (Chapter 15), all of which emerge from atomic properties and their resulting molecular properties.

Molecular Shape, Biological Receptors, and the Sense of Smell

In a very simple sense, a biological cell is a membrane-bound sack filled with molecular shapes interacting in an aqueous fluid. As a result of the magnificent internal organization of cells, many complex processes in an organism begin when a molecular "key" fits into a correspondingly shaped molecular "lock." The key can be a relatively small molecule circulating in a body fluid, whereas the lock is usually a large molecule, known as a *biological receptor,* that is often found embedded in a cell membrane. The receptor contains a precisely shaped cavity, or *receptor site,* that is exposed to the passing fluid. Thousands of molecules collide with this site, but when one with the correct shape (that is, the molecular key) lands on it, the receptor "grabs" it through intermolecular attractions, and the biological response begins.

Let's see how this fitting together of molecular shapes operates in the sense of smell (olfaction). A substance must have certain properties to have an odor. An odorous molecule travels through the air, so it must come from a gas or a volatile liquid or solid. To reach the receptor, it must be soluble, at least to a small extent, in the thin film of aqueous solution that lines the nasal passages. Most important, the odorous molecule, or a portion of it, must have a shape that fits into one of the olfactory receptor sites that cover the nerve endings deep within the nasal passage (Figure B10.1). When this happens, the resulting nerve impulses travel from these endings to the brain, which interprets the impulses as a specific odor.

In the 1950s, a stereochemical theory of odor (*stereo* means "three-dimensional") was introduced to explain the relationship between odor and molecular shape. Its basic premise is that a molecule's shape (and sometimes its polarity), but *not* its composition, determines its odor. The original theory proposed seven primary odors—camphor-like, musky, floral, minty, ethereal, pungent, and putrid—which correspond to seven different shapes of olfactory receptor sites. Figure B10.2 shows three of the seven receptor sites occupied by a molecule having that odor.

Several predictions of this original theory have been verified. If two substances fit the same receptors, they should have the same odor. The four very different molecules in Figure B10.3 all fit the bowl-shaped camphor-like receptor and all smell like moth repellent. If different portions of one molecule fit different receptors, the molecule should have a mixed odor. Portions of the

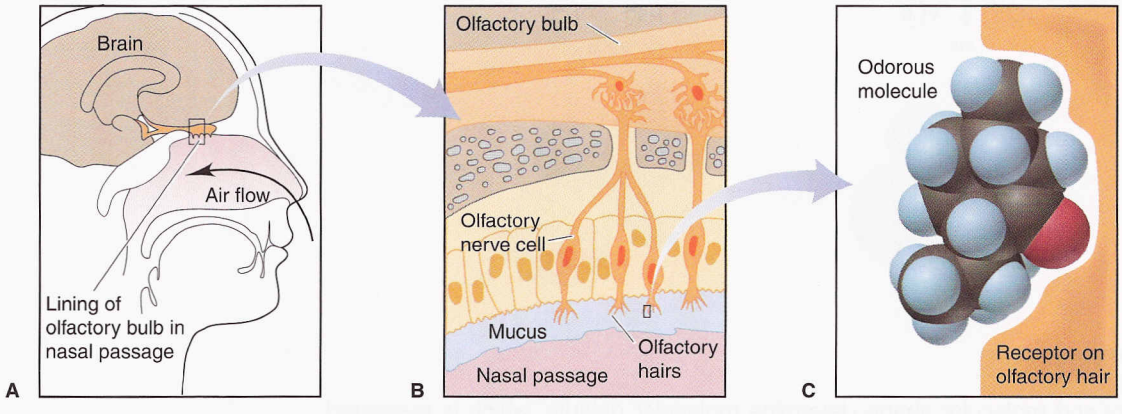


Figure B10.1 The location of olfactory receptors within the nose. A, The olfactory area lies at the top of the nasal passage very close to the brain. Air containing odorous molecules is sniffed in, warmed, moistened, and channeled toward this region. **B,** A blow-up of the region shows olfactory nerve cells with their hairlike endings protruding into the liquid-coated nasal passage. **C,** A greater blow-up shows a receptor site on one of the endings containing an odorous molecule that matches its shape. This particular molecule has a minty odor.

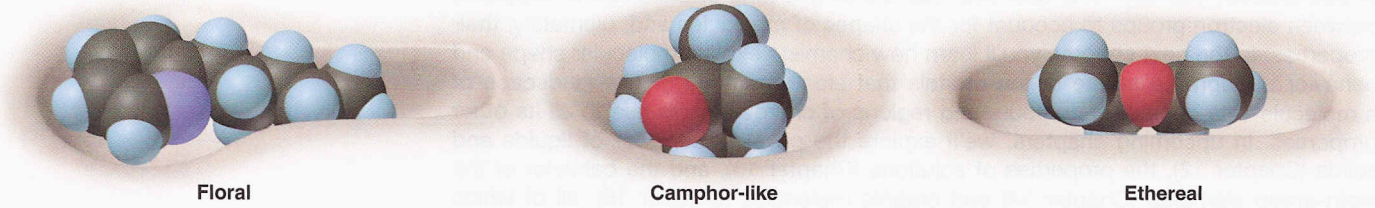

Figure B10.2 Shapes of some olfactory receptor sites. Three of the seven proposed olfactory receptors are shown with a molecule having that odor occupying the site.

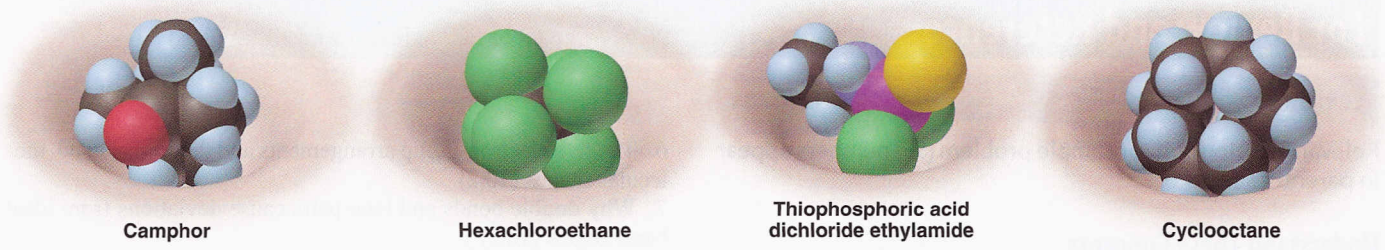

Figure B10.3 Different molecules with the same odor. The theory stating that odor is based on shape, not composition, is supported by these four different substances: all have a camphor-like (moth repellent) odor.

benzaldehyde molecule fit the camphor-like, floral, and minty receptors, which gives it an almond odor; other molecules that smell like almonds fit the same three receptors.

Recent evidence suggests, however, that the original model is far too simple. In many cases, the odor predicted from the shape turns out to be wrong when the substance is smelled. One reason for this discrepancy is that a molecule may have a very different shape in the gas phase than it does when it is in solution at the receptor. By the early 1990s, evidence had indicated that there are about 1000 different receptors and that various combinations of stimulation produce the more than 10,000 odors humans can distinguish. In fact, the 2004 Nobel Prize in medicine or physiology was awarded to Richard Axel and Linda B. Buck for this work. Thus, although a key premise of the theory is still accepted—odor depends on molecular shape—the nature of the dependence is complex and is the focus of active research in the food, cosmetics, and insecticide industries. The sense of smell is so vital for survival that these topics are important areas of study for biologists as well.

Many other biochemical processes are controlled by one molecule fitting into a receptor site on another. Enzymes are proteins that bind cellular reactants and speed their reaction (Figure B10.4). Nerve impulses are transmitted when small molecules released from one nerve fit into receptors on the next. Mind-altering drugs act by chemically disrupting the molecular fit at such nerve receptors in the brain. One type of immune response is triggered when a molecule on a bacterial surface binds to the receptors on "killer" cells in the bloodstream. Hormones regulate energy production and growth by fitting into and activating key receptors. Genes function when certain nucleic acid molecules fit into specific regions of other nucleic acids. Indeed, *no molecular property is more crucial to living systems than shape.*

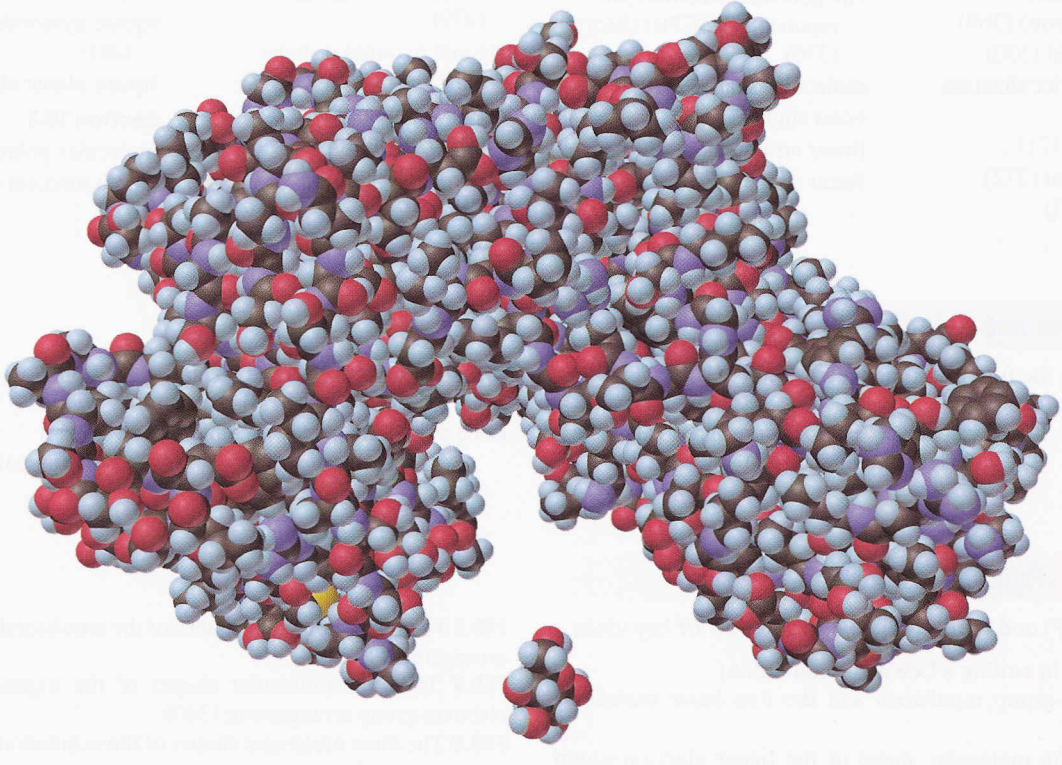

Figure B10.4 Molecular shape and enzyme action. A small sugar molecule (*bottom*) is about to move up and fit into the receptor site of an enzyme molecule and undergo reaction.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. How Lewis structures depict the atoms and their bonding and lone electron pairs in a molecule or ion (10.1)
2. How resonance and electron delocalization explain bond properties in many compounds with double bonds adjacent to single bonds (10.1)
3. The meaning of formal charge and how it is used to select the most important resonance structure; the difference between formal charge and oxidation number (10.1)
4. The octet rule and its three major exceptions—molecules with a central atom that has an electron deficiency, an odd number of electrons, or an expanded valence shell (10.1)
5. How electron-group repulsions lead to molecular shapes (10.2)
6. The five electron-group arrangements and their associated molecular shapes (10.2)
7. Why double bonds and lone pairs cause deviations from ideal bond angles (10.2)
8. How bond polarities and molecular shape combine to give a molecule polarity (10.3)

Master These Skills

1. Using a stepwise method for writing a Lewis structure from a molecular formula (SPs 10.1 to 10.3 and 10.5)
2. Writing resonance structures for molecules and ions (SP 10.4)
3. Calculating the formal charge of any atom in a molecule or ion (10.5)
4. Predicting molecular shapes from Lewis structures (SPs 10.6 to 10.8)
5. Using molecular shape and electronegativity values to predict the direction of a molecular dipole (SP 10.9)

Comprehensive Problems are based on material from any section or previous chapter.

Depicting Molecules and Ions with Lewis Structures

(Sample Problems 10.1 to 10.5)

Concept Review Questions

10.1 Which of these atoms *cannot* serve as a central atom in a Lewis structure: (a) O; (b) He; (c) F; (d) H; (e) P? Explain.

10.2 When is a resonance hybrid needed to adequately depict the bonding in a molecule? Using NO_2 as an example, explain how a resonance hybrid is consistent with the actual bond length, bond strength, and bond order.

10.3 In which of these bonding patterns does X obey the octet rule?

(a) —X— (b) :X— (c) X (d) ≡X: (e) —X= (f) —X= (g) X (h) :X:$^{2-}$

10.4 What is required for an atom to expand its valence shell? Which of the following atoms can expand its valence shell: F, S, H, Al, Se, Cl?

Skill-Building Exercises *(grouped in similar pairs)*

10.5 Draw a Lewis structure for (a) SiF_4; (b) $SeCl_2$; (c) COF_2 (C is central).

10.6 Draw a Lewis structure for (a) PH_4^+; (b) C_2F_4; (c) SbH_3.

10.7 Draw a Lewis structure for (a) PF_3; (b) H_2CO_3 (both H atoms are attached to O atoms); (c) CS_2.

10.8 Draw a Lewis structure for (a) CH_4S; (b) S_2Cl_2; (c) $CHCl_3$.

10.9 Draw Lewis structures of all the important resonance forms of (a) NO_2^+; (b) NO_2F (N is central).

10.10 Draw Lewis structures of all the important resonance forms of (a) HNO_3 ($HONO_2$); (b) $HAsO_4^{2-}$ ($HOAsO_3^{2-}$).

10.11 Draw Lewis structures of all the important resonance forms of (a) N_3^-; (b) NO_2^-.

10.12 Draw Lewis structures of all the important resonance forms of (a) HCO_2^- (H is attached to C); (b) $HBrO_4$ ($HOBrO_3$).

10.13 Draw a Lewis structure and calculate the formal charge of each atom in (a) IF_5; (b) AlH_4^-.

10.14 Draw a Lewis structure and calculate the formal charge of each atom in (a) COS (C is central); (b) NO.

10.15 Draw a Lewis structure and calculate the formal charge of each atom in (a) CN^-; (b) ClO^-.

10.16 Draw a Lewis structure and calculate the formal charge of each atom in (a) BF_4^-; (b) ClNO.

10.17 Draw a Lewis structure for the most important resonance form of each ion, showing formal charges and oxidation numbers of the atoms: (a) BrO_3^-; (b) SO_3^{2-}.

10.18 Draw a Lewis structure for the most important resonance form of each ion, showing formal charges and oxidation numbers of the atoms: (a) AsO_4^{3-}; (b) ClO_2^-.

10.19 These species do not obey the octet rule. Draw a Lewis structure for each, and state the type of octet-rule exception:
(a) BH_3 (b) AsF_4^- (c) $SeCl_4$

10.20 These species do not obey the octet rule. Draw a Lewis structure for each, and state the type of octet-rule exception:
(a) PF_6^- (b) ClO_3 (c) H_3PO_3

10.21 These species do not obey the octet rule. Draw a Lewis structure for each, and state the type of octet-rule exception:
(a) BrF_3 (b) ICl_2^- (c) BeF_2

10.22 These species do not obey the octet rule. Draw a Lewis structure for each, and state the type of octet-rule exception:
(a) O_3^- (b) XeF_2 (c) SbF_4^-

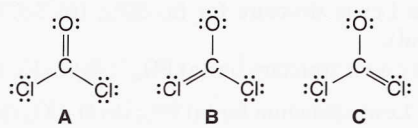
Problems in Context

10.23 Molten beryllium chloride reacts with chloride ion from molten NaCl to form the $BeCl_4^{2-}$ ion, in which the Be atom attains an octet. Show the net ionic reaction with Lewis structures.

10.24 Despite many attempts, the perbromate ion (BrO_4^-) was not prepared in the laboratory until about 1970. (Indeed, articles were published explaining theoretically why it could never be prepared!) Draw a Lewis structure for BrO_4^- in which all atoms have lowest formal charges.

10.25 Cryolite (Na_3AlF_6) is an indispensable component in the electrochemical manufacture of aluminum. Draw a Lewis structure for the AlF_6^{3-} ion.

10.26 Phosgene is a colorless, highly toxic gas employed against troops in World War I and used today as a key reactant in organic syntheses. Use formal charges to select the most important of the following resonance structures:



Valence-Shell Electron-Pair Repulsion (VSEPR) Theory and Molecular Shape

(Sample Problems 10.6 to 10.8)

Concept Review Questions

10.27 If you know the formula of a molecule or ion, what is the first step in predicting its shape?

10.28 In what situation is the name of the molecular shape the same as the name of the electron-group arrangement?

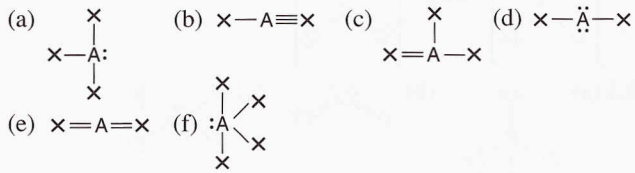
10.29 Which of the following numbers of electron groups can give rise to a bent (V-shaped) molecule: two, three, four, five, six? Draw an example for each case, showing the shape classification (AX_mE_n) and the ideal bond angle.

10.30 Name all the molecular shapes that have a tetrahedral electron-group arrangement.

10.31 Why aren't lone pairs considered along with surrounding bonding groups when describing the molecular shape?

10.32 Use wedge-bond perspective drawings (if necessary) to sketch the atom positions in a general molecule of formula (not shape class) AX_n that has each of the following shapes:
(a) V shaped (b) trigonal planar (c) trigonal bipyramidal
(d) T shaped (e) trigonal pyramidal (f) square pyramidal

10.33 What would you expect to be the electron-group arrangement around atom A in each of the following cases? For each arrangement, give the ideal bond angle and the direction of any expected deviation:



Skill-Building Exercises *(grouped in similar pairs)*

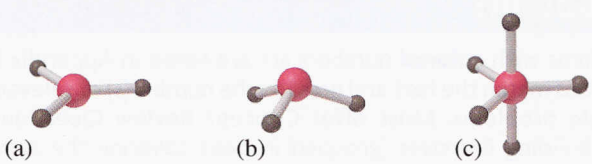
10.34 Determine the electron-group arrangement, molecular shape, and ideal bond angle(s) for each of the following:
(a) O_3 (b) H_3O^+ (c) NF_3

10.35 Determine the electron-group arrangement, molecular shape, and ideal bond angle(s) for each of the following:
(a) SO_4^{2-} (b) NO_2^- (c) PH_3

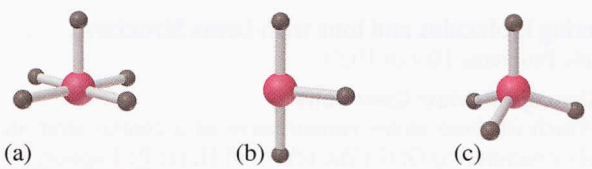
10.36 Determine the electron-group arrangement, molecular shape, and ideal bond angle(s) for each of the following:
(a) CO_3^{2-} (b) SO_2 (c) CF_4

10.37 Determine the electron-group arrangement, molecular shape, and ideal bond angle(s) for each of the following:
(a) SO_3 (b) N_2O (N is central) (c) CH_2Cl_2

10.38 Name the shape and give the AX_mE_n classification and ideal bond angle(s) for each of the following general molecules:



10.39 Name the shape and give the AX_mE_n classification and ideal bond angle(s) for each of the following general molecules:



10.40 Determine the shape, ideal bond angle(s), and the direction of any deviation from these angles for each of the following:
(a) ClO_2^- (b) PF_5 (c) SeF_4 (d) KrF_2

10.41 Determine the shape, ideal bond angle(s), and the direction of any deviation from these angles for each of the following:
(a) ClO_3^- (b) IF_4^- (c) $SeOF_2$ (d) TeF_5^-

10.42 Determine the shape around each central atom in each molecule, and explain any deviation from ideal bond angles:
(a) CH_3OH (b) N_2O_4 (O_2NNO_2)

10.43 Determine the shape around each central atom in each molecule, and explain any deviation from ideal bond angles:
(a) H_3PO_4 (no H—P bond) (b) $CH_3—O—CH_2CH_3$

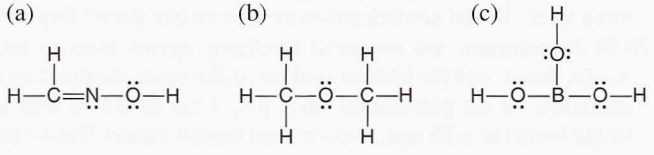
10.44 Determine the shape around each central atom in each molecule, and explain any deviation from ideal bond angles:
(a) CH_3COOH (b) H_2O_2

10.45 Determine the shape around each central atom in each molecule, and explain any deviation from ideal bond angles:
(a) H_2SO_3 (no H—S bond) (b) N_2O_3 ($ONNO_2$)

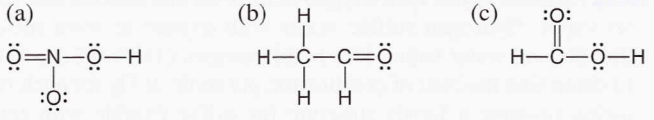
10.46 Arrange the following AF_n species in order of *increasing* F—A—F bond angles: BF_3, BeF_2, CF_4, NF_3, OF_2.

10.47 Arrange the following ACl_n species in order of *decreasing* Cl—A—Cl bond angles: SCl_2, OCl_2, PCl_3, $SiCl_4$, $SiCl_6^{2-}$.

10.48 State an ideal value for each of the bond angles in each molecule, and note where you expect deviations:
(a) (b) (c)



10.49 State an ideal value for each of the bond angles in each molecule, and note where you expect deviations:
(a) (b) (c)



Problems in Context

10.50 Because both tin and carbon are members of Group 4A(14), they form structurally similar compounds. However, tin exhibits a greater variety of structures because it forms several ionic species. Predict the shapes and ideal bond angles, including any deviations, for the following:
(a) $Sn(CH_3)_2$ (b) $SnCl_3^-$ (c) $Sn(CH_3)_4$
(d) SnF_5^- (e) SnF_6^{2-}

10.51 In the gas phase, phosphorus pentachloride exists as separate molecules. In the solid phase, however, the compound is composed of alternating PCl_4^+ and PCl_6^- ions. What change(s) in molecular shape occur(s) as PCl_5 solidifies? How does the Cl—P—Cl angle change?

Molecular Shape and Molecular Polarity

(Sample Problem 10.9)

Concept Review Questions

10.52 For molecules of general formula AX_n (where $n > 2$), how do you determine if a molecule is polar?

10.53 How can a molecule with polar covalent bonds fail to be a polar molecule? Give an example.

10.54 Explain in general why the shape of a biomolecule is important to its function.

Skill-Building Exercises *(grouped in similar pairs)*

10.55 Consider the molecules SCl_2, F_2, CS_2, CF_4, and BrCl.
(a) Which has bonds that are the most polar?
(b) Which have a molecular dipole moment?

10.56 Consider the molecules BF_3, PF_3, BrF_3, SF_4, and SF_6.
(a) Which has bonds that are the most polar?
(b) Which have a molecular dipole moment?

10.57 Which molecule in each pair has the greater dipole moment? Give the reason for your choice.
(a) SO_2 or SO_3 (b) ICl or IF
(c) SiF_4 or SF_4 (d) H_2O or H_2S

10.58 Which molecule in each pair has the greater dipole moment? Give the reason for your choice.
(a) ClO_2 or SO_2 (b) HBr or HCl
(c) $BeCl_2$ or SCl_2 (d) AsF_3 or AsF_5

Problems in Context

10.59 There are three different dichloroethylenes (molecular formula $C_2H_2Cl_2$), which we can designate X, Y, and Z. Compound X has no dipole moment, but compound Z does. Compounds X and Z each combine with hydrogen to give the same product:

$$C_2H_2Cl_2\,(\text{X or Z}) + H_2 \longrightarrow ClCH_2—CH_2Cl$$

What are the structures of X, Y, and Z? Would you expect compound Y to have a dipole moment?

10.60 Dinitrogen difluoride, N_2F_2, is the only stable, simple inorganic molecule with an N=N bond. The compound occurs in *cis* and *trans* forms.
(a) Draw the molecular shapes of the two forms of N_2F_2.
(b) Predict the polarity, if any, of each form.

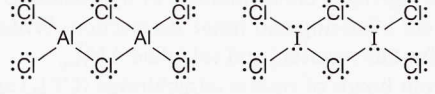
Comprehensive Problems

10.61 In addition to ammonia, nitrogen forms three other hydrides: hydrazine (N_2H_4), diazene (N_2H_2), and tetrazene (N_4H_4).
(a) Use Lewis structures to compare the strength, length, and order of nitrogen-nitrogen bonds in hydrazine, diazene, and N_2.
(b) Tetrazene (atom sequence H_2NNNNH_2) decomposes above 0°C to hydrazine and nitrogen gas. Draw a Lewis structure for tetrazene, and calculate ΔH^0_{rxn} for this decomposition.

10.62 Draw a Lewis structure for each species: (a) PF_5; (b) CCl_4; (c) H_3O^+; (d) ICl_3; (e) BeH_2; (f) PH_2^-; (g) $GeBr_4$; (h) CH_3^-; (i) BCl_3; (j) BrF_4^+; (k) XeO_3; (l) TeF_4.

10.63 Determine the molecular shape of each of the species in Problem 10.62.

10.64 Both aluminum and iodine form chlorides, Al_2Cl_6 and I_2Cl_6, with "bridging" Cl atoms. The Lewis structures are



(a) What is the formal charge on each atom? (b) Which of these molecules has a planar shape? Explain.

10.65 Nitrosyl fluoride (NOF) has an atom sequence in which all atoms have formal charges of zero. Write the Lewis structure consistent with this fact.

10.66 The VSEPR model was developed in the 1950s, before any xenon compounds had been prepared. Thus, in the early 1960s, these compounds provided an excellent test of the model's predictive power. What would you have predicted for the shapes of XeF_2, XeF_4, and XeF_6?

10.67 Boron trifluoride is an important reactant in organic syntheses but is a very reactive gas at room temperature and thus difficult to handle. Boron's ability to accept another pair of electrons and attain an octet is used to prepare an easily stored liquid form: a compound of BF_3 and diethyl ether ($CH_3—CH_2—O—CH_2—CH_3$). Draw Lewis structures for BF_3, diethyl ether, and the product, and indicate how the molecular shapes around B and O change during the reaction.

10.68 The actual bond angle in NO_2 is 134.3°, and in NO_2^- it is 115.4°, although the ideal bond angle is 120° in both. Explain.

10.69 "Inert" xenon actually forms several compounds, especially with the highly electronegative elements oxygen and fluorine. The simple fluorides XeF_2, XeF_4, and XeF_6 are all formed by direct reaction of the elements. As you might expect from the size of the xenon atom, the Xe—F bond is not a strong one. Calculate the Xe—F bond energy in XeF_6, given that the heat of formation is −402 kJ/mol.

10.70 Propylene oxide is used to make many products, including plastics such as polyurethane. One method for synthesizing it involves oxidizing propene with hydrogen peroxide:

(a) What is the molecular shape and ideal bond angle around each carbon atom in propylene oxide?

(b) Predict any deviation from the ideal for the actual bond angle (assume the three atoms in the ring form an equilateral triangle).

10.71 Chloral, $Cl_3C—CH=O$, reacts with water to form the sedative and hypnotic agent chloral hydrate, $Cl_3C—CH(OH)_2$. Draw Lewis structures for these substances, and describe the change in molecular shape, if any, that occurs around each of the carbon atoms during the reaction.

10.72 Dichlorine heptaoxide, Cl_2O_7, can be viewed as two ClO_4 groups sharing an O atom. Draw a Lewis structure for Cl_2O_7 with the lowest formal charges, and predict any deviation from the ideal for the Cl—O—Cl bond angle.

10.73 Like several other bonds, carbon-oxygen bonds have lengths and strengths that depend on the bond order. Draw Lewis structures for the following species, and arrange them in order of increasing carbon-oxygen bond length and then by increasing carbon-oxygen bond strength: (a) CO; (b) CO_3^{2-}; (c) H_2CO; (d) CH_4O; (e) HCO_3^- (H attached to O).

10.74 In the 1980s, there was an international agreement to destroy all stockpiles of mustard gas, $ClCH_2CH_2SCH_2CH_2Cl$. When this substance contacts the moisture in eyes, nasal passages, and skin, the —OH groups of water replace the Cl atoms and create high local concentrations of hydrochloric acid, which cause severe blistering and tissue destruction. Write a balanced equation for this reaction, and calculate ΔH^0_{rxn}.

10.75 The four bonds of carbon tetrachloride (CCl_4) are polar, but the molecule is nonpolar because the bond polarity is canceled by the symmetric tetrahedral shape. When other atoms substitute for some of the Cl atoms, the symmetry is broken and the molecule becomes polar. Use Figure 9.19 (p. 352) to rank the following molecules from the least polar to the most polar: CH_2Br_2, CF_2Cl_2, CH_2F_2, CH_2Cl_2, CBr_4, CF_2Br_2.

10.76 Ethanol (CH_3CH_2OH) is being used as a gasoline additive or alternative in many parts of the world.

(a) Use bond energies to find the ΔH^0_{comb} of gaseous ethanol. (Assume H_2O forms as a gas.)

(b) In its standard state at 25°C, ethanol is a liquid. Its vaporization requires 40.5 kJ/mol. Correct the value from part (a) to find the heat of combustion of liquid ethanol.

(c) How does the value from part (b) compare with the value you calculate from standard heats of formation (Appendix B)?

(d) "Greener" methods produce ethanol from corn and other plant material, but the main industrial method involves hydrating ethylene from petroleum. Use Lewis structures and bond energies to calculate ΔH^0_{rxn} for the formation of gaseous ethanol from ethylene gas with water vapor.

10.77 In the following compounds, the C atoms form a single ring. Draw a Lewis structure for each compound, identify cases for which resonance exists, and determine the carbon-carbon bond order(s): (a) C_3H_4; (b) C_3H_6; (c) C_4H_6; (d) C_4H_4; (e) C_6H_6.

10.78 An oxide of nitrogen is 25.9% N by mass, has a molar mass of 108 g/mol, and contains no nitrogen-nitrogen or oxygen-oxygen bonds. Draw its Lewis structure, and name it.

10.79 An experiment requires 50.0 mL of 0.040 *M* NaOH for the titration of 1.00 mmol of acid. Mass analysis of the acid shows 2.24% hydrogen, 26.7% carbon, and 71.1% oxygen. Draw the Lewis structure of the acid.

10.80 A gaseous compound has a composition by mass of 24.8% carbon, 2.08% hydrogen, and 73.1% chlorine. At STP, the gas has a density of 4.3 g/L. Draw a Lewis structure that satisfies these facts. Would another structure also satisfy them? Explain.

10.81 Perchlorates are powerful oxidizing agents used in fireworks, flares, and the booster rockets of the space shuttle. Lewis structures for the perchlorate ion (ClO_4^-) can be drawn with all single bonds or with one, two, or three double bonds. Draw each of these possible resonance forms, use formal charges to determine the most important, and calculate its average bond order.

10.82 Methane reacts with oxygen to form carbon dioxide and water vapor. Hydrogen sulfide reacts with oxygen to form sulfur dioxide and water vapor. Use bond energies (Table 9.2, p. 341) to determine the heat of combustion per mole of O_2 for each reaction (assume a Lewis structure for sulfur dioxide with zero formal charge; BE of S=O is 552 kJ/mol).

10.83 Use Lewis structures to determine which *two* of the following are unstable: (a) SF_2; (b) SF_3; (c) SF_4; (d) SF_5; (e) SF_6.

10.84 A major short-lived, neutral species in flames is OH.

(a) What is unusual about the electronic structure of OH?

(b) Use the standard heat of formation of OH(*g*) and bond energies to calculate the O—H bond energy in OH(*g*) (ΔH^0_f of OH(*g*) = 39.0 kJ/mol).

(c) From the average value for the O—H bond energy in Table 9.2 (p. 341) and your value for the O—H bond energy in OH(*g*), find the energy needed to break the first O—H bond in water.

10.85 Pure HN_3 (atom sequence HNNN) is a very explosive compound. In aqueous solution, it is a weak acid (comparable to acetic acid) that yields the azide ion, N_3^-. Draw resonance structures to explain why the nitrogen-nitrogen bond lengths are equal in N_3^- but unequal in HN_3.

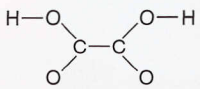
10.86 Except for nitrogen, the elements of Group 5A(15) all form pentafluorides, and most form pentachlorides. The chlorine atoms of PCl_5 can be replaced with fluorine atoms one at a time to give, successively, PCl_4F, PCl_3F_2, . . . , PF_5.

(a) Given the sizes of F and Cl, would you expect the first two F substitutions to be at axial or equatorial positions? Explain.

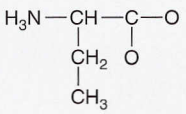
(b) Which of the five fluorine-containing molecules have no dipole moment?

10.87 Dinitrogen monoxide (N_2O), used as the anesthetic "laughing gas" in dental surgery, supports combustion in a manner similar to oxygen, with the nitrogen atoms forming N_2. Draw three resonance structures for N_2O (one N is central), and use formal charges to decide the relative importance of each. What correlation can you suggest between the most important structure and the observation that N_2O supports combustion?

10.88 Oxalic acid ($H_2C_2O_4$) is found in toxic concentrations in rhubarb leaves. The acid forms two ions, $HC_2O_4^-$ and $C_2O_4^{2-}$, by the sequential loss of H^+ ions. Draw Lewis structures for the three species, and comment on the relative lengths and strengths of their carbon-oxygen bonds. The connections among the atoms are shown below with single bonds only.



10.89 Some scientists speculate that many organic molecules required for life on the young Earth arrived on meteorites. The Murchison meteorite that landed in Australia in 1969 contained 92 different amino acids, including 21 found in Earth organisms. A skeleton structure (single bonds only) of one of these extraterrestrial amino acids is



Draw a Lewis structure, and identify any atoms with a nonzero formal charge.

10.90 Hydrazine (N_2H_4) is used as a rocket fuel because it reacts very exothermically with oxygen to form nitrogen gas and water vapor. The heat released and the increase in number of moles of gas provide thrust. Calculate the heat of reaction.

10.91 When gaseous sulfur trioxide is dissolved in concentrated sulfuric acid, disulfuric acid forms:

$$SO_3(g) + H_2SO_4(l) \longrightarrow H_2S_2O_7(l)$$

Use bond energies (Table 9.2, p. 341) to determine ΔH^0_{rxn}. (The S atoms in $H_2S_2O_7$ are bonded through an O atom. Assume Lewis structures with zero formal charges; BE of S=O is 552 kJ/mol.)

10.92 In addition to propyne (see Follow-up Problem 10.8), there are two other structures with molecular formula C_3H_4. Draw a Lewis structure for each, determine the shape around each carbon, and predict any deviations from ideal bond angles.

10.93 A molecule of formula AY_3 is found experimentally to be polar. Which molecular shapes are possible and which impossible for AY_3?

10.94 In contrast to the cyanate ion (NCO^-), which is stable and found in many compounds, the fulminate ion (CNO^-), with its different atom sequence, is unstable and forms compounds with heavy metal ions, such as Ag^+ and Hg^{2+}, that are explosive. Like the cyanate ion, the fulminate ion has three resonance structures. Which is the most important contributor to the resonance hybrid? Suggest a reason for the instability of fulminate.

10.95 Hydrogen cyanide (and organic nitriles, which contain the cyano group) can be catalytically reduced with hydrogen to form amines. Use Lewis structures and bond energies to determine ΔH^0_{rxn} for

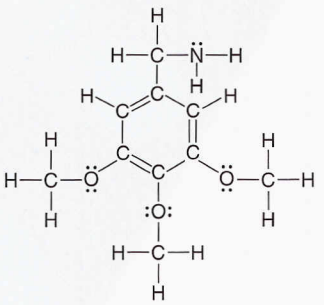
$$HCN(g) + 2H_2(g) \longrightarrow CH_3NH_2(g)$$

10.96 Ethylene, C_2H_4, and tetrafluoroethylene, C_2F_4, are used to make the polymers polyethylene and polytetrafluoroethylene (Teflon), respectively.

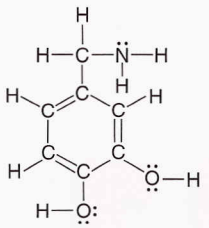
(a) Draw the Lewis structures for C_2H_4 and C_2F_4, and give the ideal H—C—H and F—C—F bond angles.

(b) The actual H—C—H and F—C—F bond angles are 117.4° and 112.4°, respectively. Explain these deviations.

10.97 Lewis structures of mescaline, a hallucinogenic compound in peyote cactus, and dopamine, a neurotransmitter in the mammalian brain, appear below. Suggest a reason for mescaline's ability to disrupt nerve impulses.



mescaline



dopamine

10.98 Using bond lengths in Table 9.3 (p. 342) and assuming ideal geometry, calculate each of the following distances:

(a) Between H atoms in C_2H_2

(b) Between F atoms in SF_6 (two answers)

(c) Between equatorial F atoms in PF_5

10.99 Phosphorus pentachloride, a key industrial compound with annual world production of about 2×10^7 kg, is used to make other compounds. It reacts with sulfur dioxide to produce phosphorus oxychloride ($POCl_3$) and thionyl chloride ($SOCl_2$). Draw a Lewis structure and name the molecular shape of each product.

Bonding theory visualized How do molecular shapes emerge from interacting atomic orbitals? One theory proposes that new types of orbitals arise during bonding, such as these hybrid orbitals of the sulfur in SF_6. In this chapter, we explore two models that use quantum mechanics to rationalize the shapes of molecules and the properties of their covalent bonds.

MO Descriptions of Benzene and Ozone

All scientific models have limitations because they are simplifications of reality. The VSEPR model accounts for molecular shapes by assuming that electron groups minimize their repulsions, and thus occupy as much space as possible around a central atom. But it does *not* explain how the shapes arise from interactions of atomic orbitals. After all, the orbitals we examined in Chapter 7 aren't oriented toward the corners of a tetrahedron or a trigonal bipyramid, to mention just two of the common molecular shapes. Moreover, knowing the shape doesn't help us explain the magnetic and spectral properties of molecules; only an understanding of their orbitals and energy levels can do that.

IN THIS CHAPTER . . . We use quantum mechanics, with which we explained the properties of atoms, to discuss two theories of bonding in molecules. Valence bond (VB) theory rationalizes observed molecular shapes through interactions of atomic orbitals that create new "hybrid" orbitals. We apply VB theory to sigma and pi bonding, the two types of covalent bonds. Molecular orbital (MO) theory explains molecular energy levels and properties using orbitals associated with the whole molecule. Simple diatomic and polyatomic molecules are covered. Each theory complements the other, so don't be concerned if we need more than one model to explain a complex phenomenon like bonding. In every science, one model often accounts for some aspect of a topic better than another, and several models are called into service to explain a wider range of phenomena.

Concepts & Skills to Review

before you study this chapter

- atomic orbital shapes (Section 7.4)
- the exclusion principle (Section 8.2)
- Hund's rule (Section 8.3)
- writing Lewis structures (Section 10.1)
- resonance in covalent bonding (Section 10.1)
- molecular shapes (Section 10.2)
- molecular polarity (Section 10.3)

11.1 VALENCE BOND (VB) THEORY AND ORBITAL HYBRIDIZATION

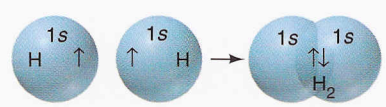
What *is* a covalent bond, and what characteristic gives it strength? And how can we explain *molecular* shapes from the interactions of *atomic* orbitals? The most useful approach for answering these questions is **valence bond (VB) theory.**

The Central Themes of VB Theory

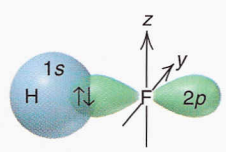
The basic principle of VB theory is that *a covalent bond forms when orbitals of two atoms overlap and the overlap region, which is between the nuclei, is occupied by a pair of electrons.* ("Orbital overlap" is another way of saying that the two wave functions are *in phase,* so the amplitude increases between the nuclei.) The central themes of VB theory derive from this principle:

1. *Opposing spins of the electron pair.* As the exclusion principle (Section 8.2) prescribes, the space formed by the overlapping orbitals *has a maximum capacity of two electrons that must have opposite spins.* When a molecule of H_2 forms, for instance, the two 1*s* electrons of two H atoms occupy the overlapping 1*s* orbitals and have opposite spins (Figure 11.1A).

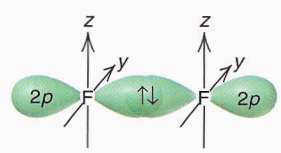
2. *Maximum overlap of bonding orbitals.* The bond strength depends on the attraction of the nuclei for the shared electrons, so *the greater the orbital overlap, the stronger (more stable) the bond.* The extent of overlap depends on the shapes and directions of the orbitals. An *s* orbital is spherical, but *p* and *d* orbitals have more electron density in one direction than in another. Thus, whenever possible, a bond involving *p* or *d* orbitals will be oriented in the direction that maximizes overlap. In the HF bond, for example, the 1*s* orbital of H overlaps the half-filled 2*p* orbital of F *along the long axis* of that orbital (Figure 11.1B). Any other direction would result in less overlap and, thus, a weaker bond. Similarly, in the F—F bond of F_2, the two half-filled 2*p* orbitals interact end to end, that is, *along the long axes* of the orbitals, to maximize overlap (Figure 11.1C).



A Hydrogen, H_2



B Hydrogen fluoride, HF



C Fluorine, F_2

Figure 11.1 Orbital overlap and spin pairing in three diatomic molecules. A, In the H_2 molecule, the two overlapping 1*s* orbitals are occupied by the two 1*s* electrons with opposite spins. (The electrons, shown as arrows, spend the most time between the nuclei but move throughout the overlapping orbitals.) **B,** To maximize overlap in HF, half-filled H 1*s* and F 2*p* orbitals overlap along the long axis of the 2*p* orbital involved in bonding. (The $2p_x$ orbital is shown bonding; the other two 2*p* orbitals of F are not shown.) **C,** In F_2, the half-filled $2p_x$ orbital on one F points end to end toward the similar orbital on the other F to maximize overlap.

3. *Hybridization of atomic orbitals.* To account for the bonding in simple diatomic molecules like HF, we picture the direct overlap of *s* and *p* orbitals of isolated atoms. But how can we account for the shapes of so many molecules and polyatomic ions through the overlap of spherical *s* orbitals, dumbbell-shaped *p* orbitals, and cloverleaf-shaped *d* orbitals?

Consider a methane molecule. It has four H atoms bonded to a central C atom. An isolated ground-state C atom ([He] $2s^2 2p^2$) has four valence electrons: two in the 2*s* orbital and one each in two of the three 2*p* orbitals. We might easily see how the two half-filled *p* orbitals of C could overlap with the 1*s* orbitals of two H atoms to form *two* C—H bonds with a 90° H—C—H bond angle. But methane is not CH_2, and it's not easy to see how the orbitals overlap to form the *four* C—H bonds with the 109.5° bond angle that occurs in methane.

To explain such facts, Linus Pauling proposed that *the valence atomic orbitals in the molecule are* ***different*** *from those in the isolated atoms.* Indeed, quantum-mechanical calculations show that if we "mix" specific combinations of orbitals mathematically, we obtain *new atomic orbitals.* The spatial orientations of these new orbitals lead to more stable bonds and are consistent with observed molecular shapes. The process of orbital mixing is called **hybridization,** and the new atomic orbitals are called **hybrid orbitals.** Two key points about the number and type of hybrid orbitals are that

Animation: Molecular Shapes and Orbital Hybridization
Online Learning Center

- The *number* of hybrid orbitals obtained *equals* the number of atomic orbitals mixed.
- The *type* of hybrid orbitals obtained *varies* with the types of atomic orbitals mixed.

You can imagine hybridization as a process in which atomic orbitals mix, hybrid orbitals form, and electrons enter them with spins parallel (Hund's rule) to create stable bonds. In truth, though, hybridization is a mathematically derived result from quantum mechanics that accounts for the molecular shapes we observe.

Types of Hybrid Orbitals

We postulate the presence of a certain type of hybrid orbital *after* we observe the molecular shape. As we discuss the five common types of hybridization, notice that the spatial orientation of each type of hybrid orbital corresponds with one of the five common electron-group arrangements predicted by VSEPR theory.

sp* Hybridization** When two electron groups surround the central atom, we observe a linear shape, which means that the bonding orbitals must have a linear orientation. VB theory explains this by proposing that mixing two *nonequivalent* orbitals of a central atom, one *s* and one *p*, gives rise to two *equivalent* ***sp **hybrid orbitals** that lie 180° apart, as shown in Figure 11.2A. Note the shape of the hybrid orbital: with one large and one small lobe, it differs markedly from the shapes of the atomic orbitals that were mixed. The orientations of hybrid orbitals extend electron density in the bonding direction and minimize repulsions between the electrons that occupy them. Thus, *both shape and orientation maximize overlap with the orbital of the other atom in the bond.*

In gaseous $BeCl_2$, for example, the Be atom is said to be *sp* hybridized. The rest of Figure 11.2 depicts the hybridization of Be in $BeCl_2$ in terms of a traditional orbital diagram of the valence level (part B), a similar diagram with orbital contours (C), and the bond formation with Cl (D). The 2*s* and one of the three 2*p* orbitals of Be mix and form two *sp* orbitals. These overlap 3*p* orbitals of two Cl atoms, and the four valence electrons—two from Be and one from each Cl—occupy the overlapped orbitals in pairs with opposite spins. The two unhybridized 2*p* orbitals of Be lie perpendicular to each other and to the bond axes. Thus, through hybridization, the paired 2*s* electrons in the isolated Be atom are distributed into two *sp* orbitals, which form two Be—Cl bonds.

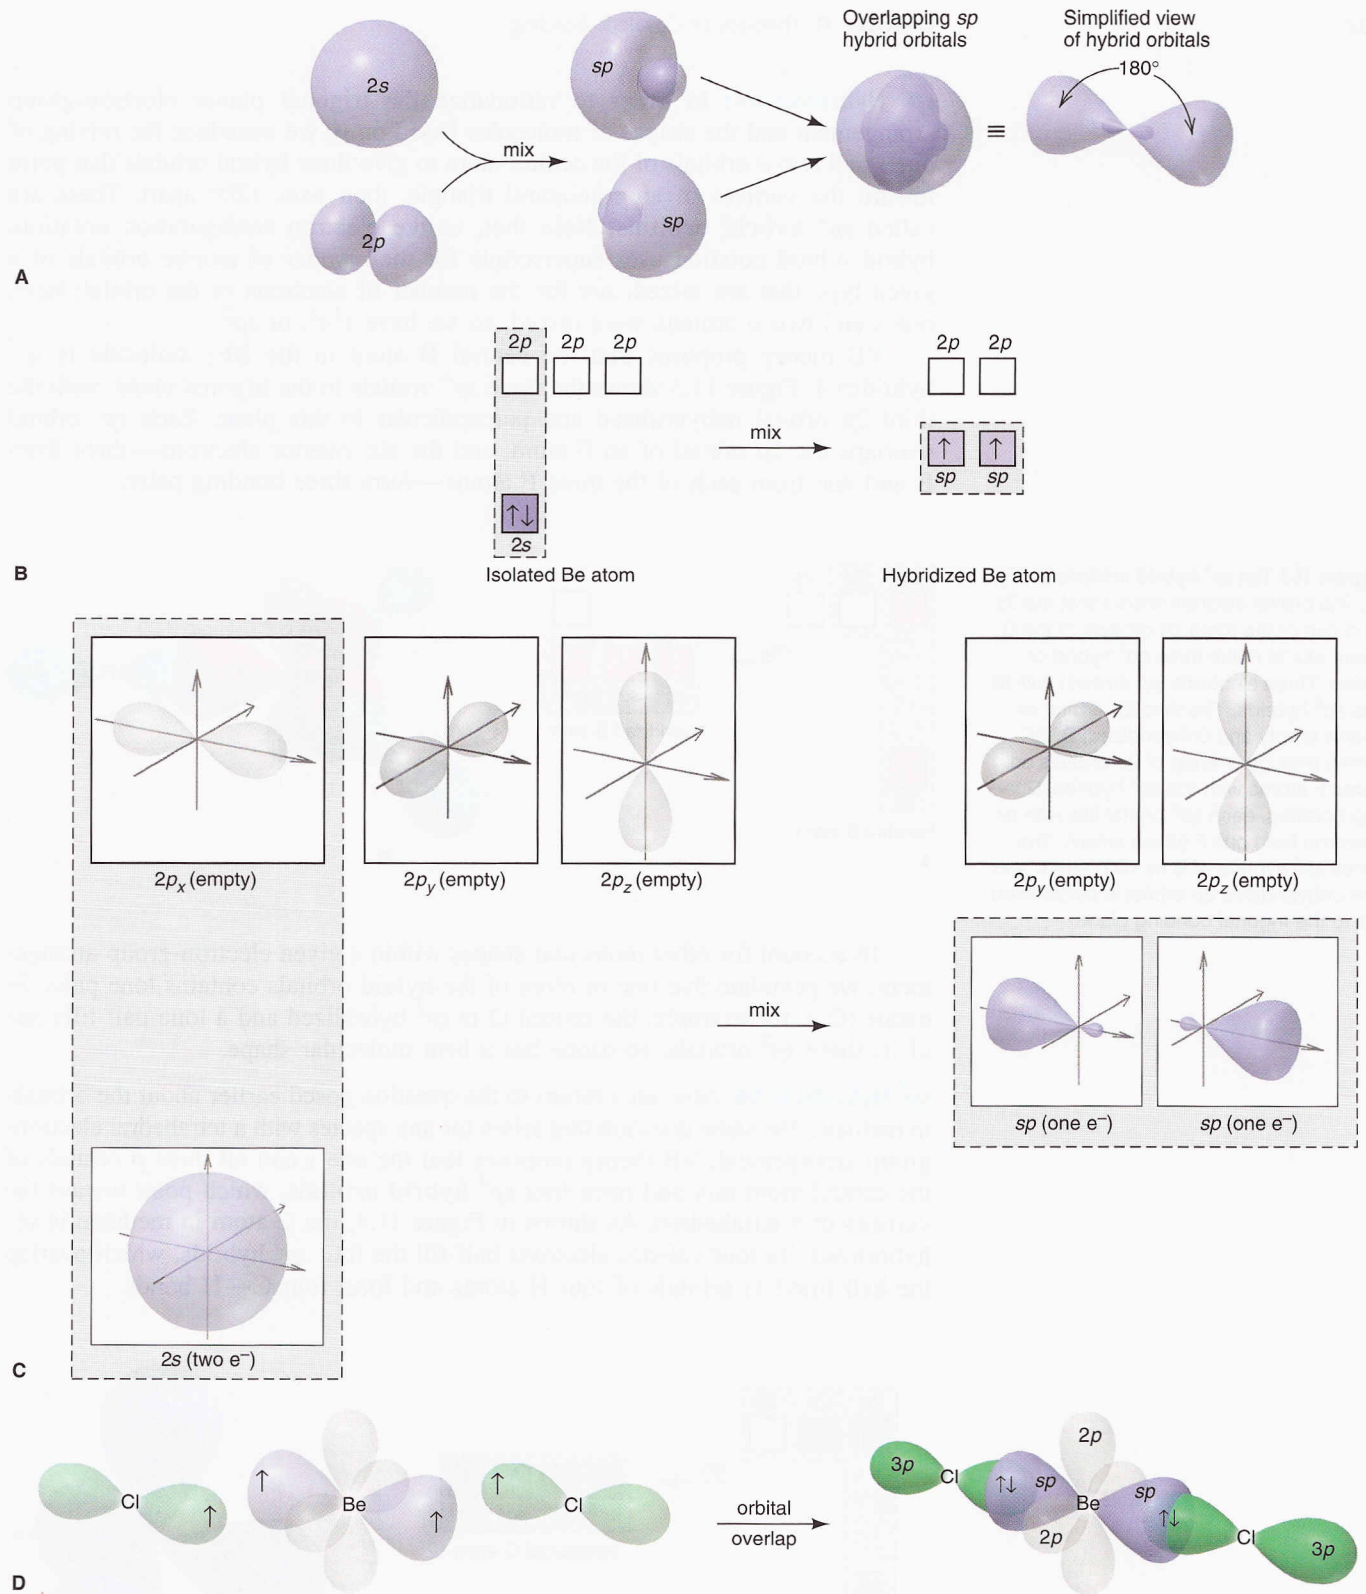


Figure 11.2 **The *sp* hybrid orbitals in gaseous $BeCl_2$. A,** One 2*s* and one 2*p* atomic orbital mix to form two *sp* hybrid orbitals (shown above and below one another and slightly to the side for ease of viewing). Note the large and small lobes of the hybrid orbitals. In the molecule, the two *sp* orbitals of Be are oriented in opposite directions. For clarity, the simplified hybrid orbitals will be used throughout the text, usually without the small lobe. **B,** The orbital diagram for hybridization in Be is drawn vertically and shows that the 2*s* and one of the three 2*p* orbitals form two *sp* hybrid orbitals, and the two other 2*p* orbitals remain unhybridized. Electrons half-fill the *sp* hybrid orbitals. During bonding, each *sp* orbital fills by sharing an electron from Cl (not shown). **C,** The orbital diagram is shown with orbital contours instead of electron arrows. **D,** $BeCl_2$ forms by overlap of the two *sp* hybrids with the 3*p* orbitals of two Cl atoms; the two unhybridized Be 2*p* orbitals lie perpendicular to the *sp* hybrids. (For clarity, only the 3*p* orbital involved in bonding is shown for each Cl.)

sp^2 Hybridization In order to rationalize the trigonal planar electron-group arrangement and the shapes of molecules based on it, we introduce the mixing of one *s* and two *p* orbitals of the central atom to give three hybrid orbitals that point toward the vertices of an equilateral triangle, their axes 120° apart. These are called ***sp^2* hybrid orbitals.** Note that, unlike electron configuration notation, hybrid orbital notation uses superscripts for the *number* of atomic orbitals of a given type that are mixed, *not* for the number of electrons in the orbital: here, one *s* and two *p* orbitals were mixed, so we have s^1p^2, or sp^2.

VB theory proposes that the central B atom in the BF_3 molecule is sp^2 hybridized. Figure 11.3 shows the three sp^2 orbitals in the trigonal plane, with the third 2*p* orbital unhybridized and perpendicular to this plane. Each sp^2 orbital overlaps the 2*p* orbital of an F atom, and the six valence electrons—three from B and one from each of the three F atoms—form three bonding pairs.

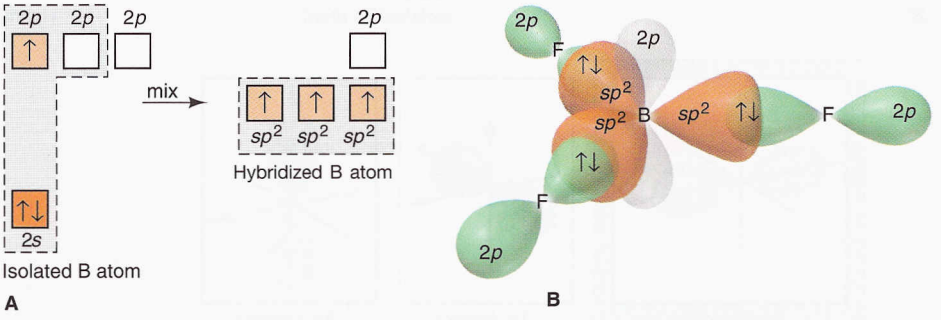

Figure 11.3 The sp^2 hybrid orbitals in BF_3. **A,** The orbital diagram shows that the 2*s* and two of the three 2*p* orbitals of the B atom mix to make three sp^2 hybrid orbitals. Three electrons (*up arrows*) half-fill the sp^2 hybrids. The third 2*p* orbital remains empty and unhybridized. **B,** BF_3 forms through overlap of 2*p* orbitals on three F atoms with the sp^2 hybrids. During bonding, each sp^2 orbital fills with an electron from one F (*down arrow*). The three sp^2 hybrids of B lie 120° apart, and the unhybridized 2*p* orbital is perpendicular to the trigonal bonding plane.

To account for other molecular shapes within a given electron-group arrangement, we postulate that one or more of the hybrid orbitals contains lone pairs. In ozone (O_3), for example, the central O is sp^2 hybridized and a lone pair fills one of its three sp^2 orbitals, so ozone has a bent molecular shape.

sp^3 Hybridization Now let's return to the question posed earlier about the orbitals in methane, the same question that arises for any species with a tetrahedral electron-group arrangement. VB theory proposes that the one *s* and all three *p* orbitals of the central atom mix and form four ***sp^3* hybrid orbitals,** which point toward the vertices of a tetrahedron. As shown in Figure 11.4, the C atom in methane is sp^3 hybridized. Its four valence electrons half-fill the four sp^3 hybrids, which overlap the half-filled 1*s* orbitals of four H atoms and form four C—H bonds.

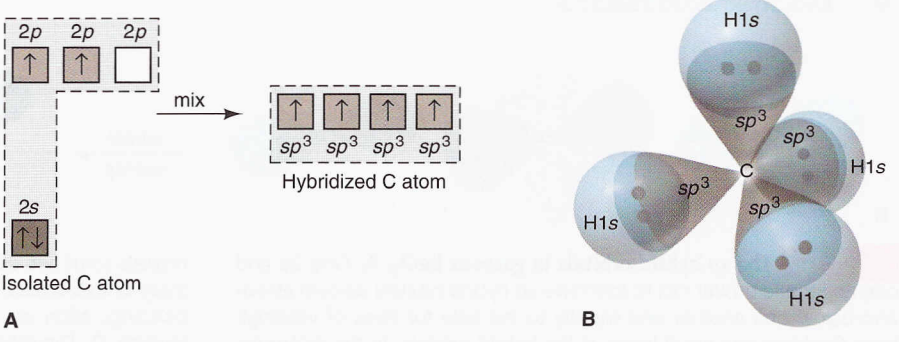

Figure 11.4 The sp^3 hybrid orbitals in CH_4. **A,** The 2*s* and all three 2*p* orbitals of C are mixed to form four sp^3 hybrids. Carbon's four valence electrons half-fill the sp^3 hybrids. **B,** In methane, the four sp^3 orbitals of C point toward the corners of a tetrahedron and overlap the 1*s* orbitals of four H atoms. Each sp^3 orbital fills by addition of an electron from one H (electrons are shown as dots).

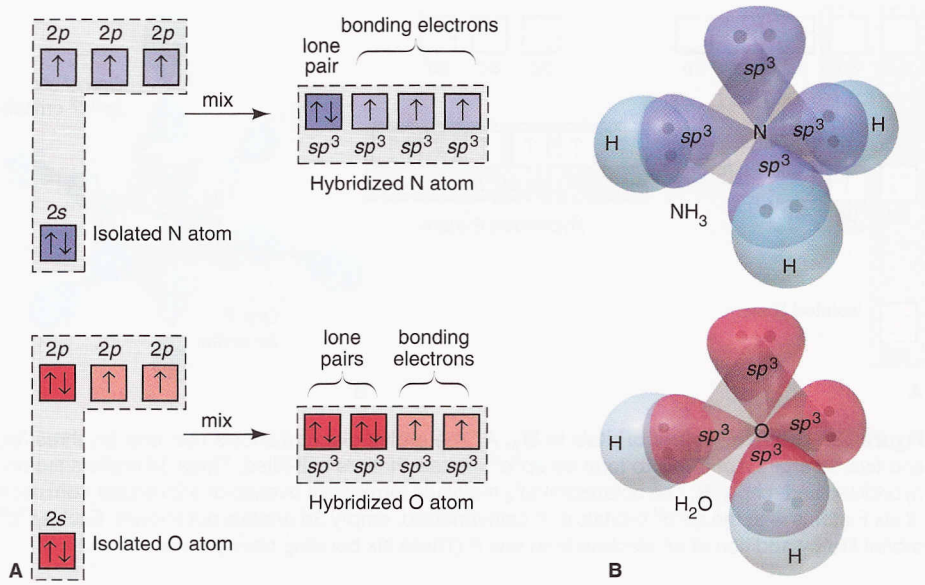

Figure 11.5 The sp^3 hybrid orbitals in NH_3 and H_2O. A, The orbital diagrams show sp^3 hybridization, as in CH_4. In NH_3 (*top*), one sp^3 orbital is filled with a lone pair. In H_2O (*bottom*), two sp^3 orbitals are filled with lone pairs. **B,** Contour diagrams show the tetrahedral orientation of the sp^3 orbitals and the overlap of the bonded H atoms. Each half-filled sp^3 orbital fills by addition of an electron from one H. (Shared pairs and lone pairs are shown as dots.)

Figure 11.5 shows the bonding in molecules of the other shapes with the tetrahedral arrangement. The trigonal pyramidal shape of NH_3 arises when a lone pair fills one of the four sp^3 orbitals of N, and the bent shape of H_2O arises when lone pairs fill two of the sp^3 orbitals of O.

sp^3d Hybridization The shapes of molecules with trigonal bipyramidal or octahedral electron-group arrangements are rationalized with VB theory through similar arguments. The only new point is that such molecules have central atoms from Period 3 or higher, so atomic *d* orbitals, as well as *s* and *p* orbitals, are mixed to form the hybrid orbitals.

To rationalize the trigonal bipyramidal shape of the PCl_5 molecule, for example, the VB model proposes that the one 3*s*, the three 3*p*, and one of the five 3*d* orbitals of the central P atom mix and form five ***sp^3d* hybrid orbitals,** which point to the vertices of a trigonal bipyramid. Each hybrid orbital overlaps a 3*p* orbital of a Cl atom, and the five valence electrons of P, together with one from each of the five Cl atoms, pair up to form five P—Cl bonds, as shown in Figure 11.6. Other shapes in this electron-group arrangement have lone pairs in one or more of the central atom's sp^3d orbitals.

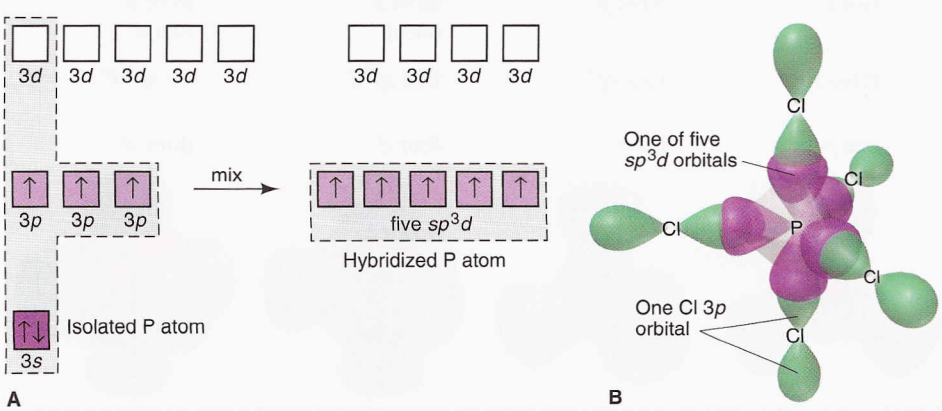

Figure 11.6 The sp^3d hybrid orbitals in PCl_5. A, The orbital diagram shows that one 3*s*, three 3*p*, and one of the five 3*d* orbitals of P mix to form five sp^3d orbitals that are half-filled. Four 3*d* orbitals are unhybridized and empty. **B,** The trigonal bipyramidal PCl_5 molecule forms by the overlap of a 3*p* orbital from each of the five Cl atoms with the sp^3d hybrid orbitals of P (unhybridized, empty 3*d* orbitals not shown). Each sp^3d orbital fills by addition of an electron from one Cl. (These five bonding pairs are not shown.)

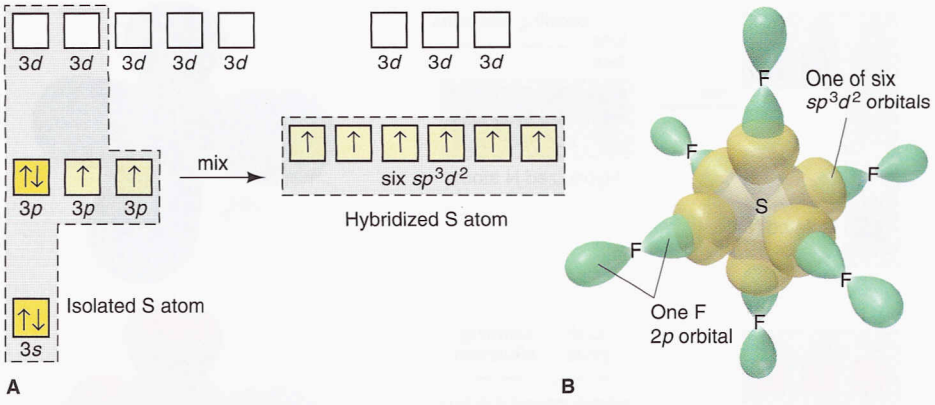

Figure 11.7 The sp^3d^2 hybrid orbitals in SF_6. A, The orbital diagram shows that one 3*s*, three 3*p*, and two 3*d* orbitals of S mix to form six sp^3d^2 orbitals that are half-filled. Three 3*d* orbitals are unhybridized and empty. **B,** The octahedral SF_6 molecule forms from overlap of a 2*p* orbital from each of six F atoms with the sp^3d^2 orbitals of S (unhybridized, empty 3*d* orbitals not shown). Each sp^3d^2 orbital fills by addition of an electron from one F. (These six bonding pairs are not shown.)

sp^3d^2 Hybridization To rationalize the shape of SF_6, the VB model proposes that the one 3*s*, the three 3*p*, and two of the five 3*d* orbitals of the central S atom mix and form six ***sp^3d^2* hybrid orbitals,** which point to the vertices of an octahedron. Each hybrid orbital overlaps a 2*p* orbital of an F atom, and the six valence electrons of S, together with one from each of the six F atoms, pair up to form six S—F bonds (Figure 11.7). Square pyramidal and square planar molecules have lone pairs in one and two of the central atom's sp^3d^2 orbitals, respectively.

Table 11.1 summarizes the numbers and types of atomic orbitals that are mixed to obtain the five types of hybrid orbitals. Once again, note the similarities between the orientations of the hybrid orbitals proposed by VB theory and the shapes predicted by VSEPR theory (see Figure 10.2, p. 376). Figure 11.8 shows the three conceptual steps from molecular formula to postulating the hybrid orbitals in the molecule, and Sample Problem 11.1 details the end of that process.

Table 11.1 Composition and Orientation of Hybrid Orbitals

	Linear	Trigonal Planar	Tetrahedral	Trigonal Bipyramidal	Octahedral
Atomic orbitals mixed	one *s* one *p*	one *s* two *p*	one *s* three *p*	one *s* three *p* one *d*	one *s* three *p* two *d*
Hybrid orbitals formed	two *sp*	three sp^2	four sp^3	five sp^3d	six sp^3d^2
Unhybridized orbitals remaining	two *p*	one *p*	none	four *d*	three *d*
Orientation					

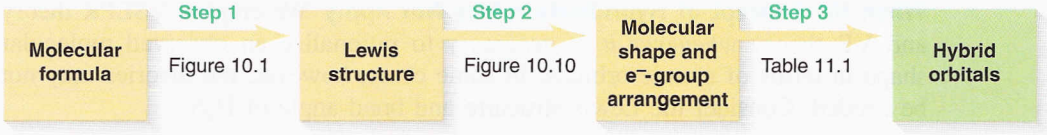

Figure 11.8 **The conceptual steps from molecular formula to the hybrid orbitals used in bonding.**
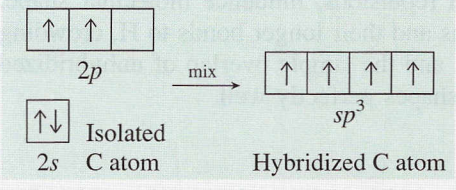
(See Figures 10.1, page 366, and 10.10, page 383.)

SAMPLE PROBLEM 11.1 Postulating Hybrid Orbitals in a Molecule

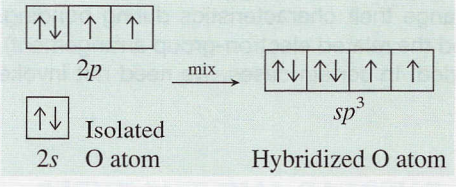
Problem Use partial orbital diagrams to describe how mixing of the atomic orbitals of the central atom leads to the hybrid orbitals in each of the following:
(a) Methanol, CH_3OH **(b)** Sulfur tetrafluoride, SF_4

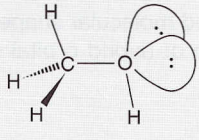
Plan From the Lewis structure, we determine the number and arrangement of electron groups around the central atoms, along with the molecular shape. From that, we postulate the type of hybrid orbitals involved. Then, we write the partial orbital diagram for each central atom before and after the orbitals are hybridized.

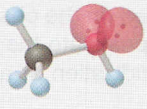
Solution **(a)** For CH_3OH. The electron-group arrangement is tetrahedral around both C and O atoms. Therefore, each central atom is sp^3 hybridized. The C atom has four half-filled sp^3 orbitals:



The O atom has two half-filled sp^3 orbitals and two filled with lone pairs:

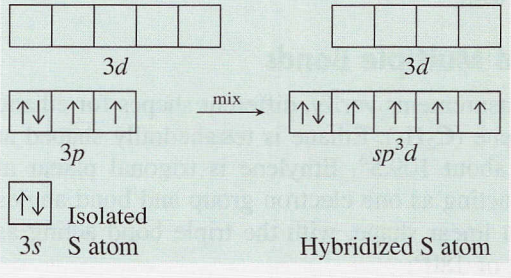


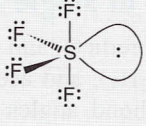


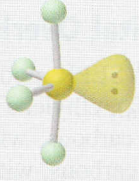


During bonding, each half-filled C or O orbital becomes filled, with the second electron in each case coming from an H atom.

(b) For SF_4. The molecular shape is seesaw, which is based on the trigonal bipyramidal electron-group arrangement. Thus, the central S atom is surrounded by five electron groups, which implies sp^3d hybridization. One $3s$ orbital, three $3p$ orbitals, and one $3d$ orbital are mixed. One hybrid orbital is filled with a lone pair, and four are half-filled. Four unhybridized $3d$ orbitals remain empty:







During bonding, each half-filled S orbital becomes filled, with the second electrons coming from F atoms.

FOLLOW-UP PROBLEM 11.1 Use partial orbital diagrams to show how the atomic orbitals of the central atoms mix to form hybrid orbitals in **(a)** beryllium fluoride, BeF_2; **(b)** silicon tetrachloride, $SiCl_4$; **(c)** xenon tetrafluoride, XeF_4.

When the Concept of Hybridization May Not Apply We employ VSEPR theory and VB theory *whenever it is necessary* to rationalize an observed molecular shape in terms of atomic orbitals. In some cases, however, the theories may not be needed. Consider the Lewis structure and bond angle of H_2S:

Based on VSEPR theory, we would predict that, as in H_2O, the four electron groups around H_2S point to the vertices of a tetrahedron, and the two lone pairs compress the H—S—H bond angle somewhat below the ideal 109.5°. Based on VB theory, we would propose that the 3*s* and 3*p* orbitals of the central S atom mix and form four sp^3 hybrids, two of which are filled with lone pairs, while the other two overlap 1*s* orbitals of two H atoms and are filled with bonding pairs.

The problem is that observation does *not* support these arguments. In fact, the H_2S molecule has a bond angle of 92°, close to the 90° angle expected between *unhybridized,* perpendicular, atomic *p* orbitals. Similar angles occur in the hydrides of other Group 6A(16) elements and also in the hydrides of larger Group 5A(15) elements. It makes no sense to apply a theory when the facts don't warrant it. In the case of H_2S and these other hydrides, neither VSEPR theory nor the concept of hybridization applies. It's important to remember that real factors, such as bond length, atomic size, and electron-electron repulsions, influence molecular shape. Apparently, with these larger central atoms and their longer bonds to H, crowding and electron-electron repulsions decrease, and the simple overlap of unhybridized atomic orbitals rationalizes the observed shapes perfectly well.

SECTION SUMMARY

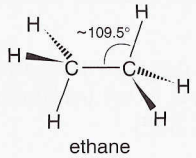
VB theory explains that a covalent bond forms when two atomic orbitals overlap. The bond holds two electrons with paired (opposite) spins. Orbital hybridization allows us to explain how atomic orbitals mix and change their characteristics during bonding. Based on the observed molecular shape (and the related electron-group arrangement), we postulate the type of hybrid orbital needed. In certain cases, we need not invoke hybridization at all.

11.2 THE MODE OF ORBITAL OVERLAP AND THE TYPES OF COVALENT BONDS

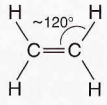
In this section, we focus on the *mode* by which orbitals overlap—end to end or side to side—to see the detailed makeup of covalent bonds. These two modes give rise to the two types of covalent bonds—*sigma* bonds and *pi* bonds. We'll use valence bond theory to describe the two types here, but they are essential features of molecular orbital theory as well.

Orbital Overlap in Single and Multiple Bonds

The VSEPR model predicts, and measurements verify, different shapes for ethane (C_2H_6), ethylene (C_2H_4), and acetylene (C_2H_2). Ethane is tetrahedrally shaped at both carbons, with bond angles of about 109.5°. Ethylene is trigonal planar at both carbons, with the double bond acting as one electron group and bond angles near the ideal 120°. Acetylene has a linear shape, with the triple bond acting as one electron group and bond angles of 180°:



ethane



ethylene

acetylene

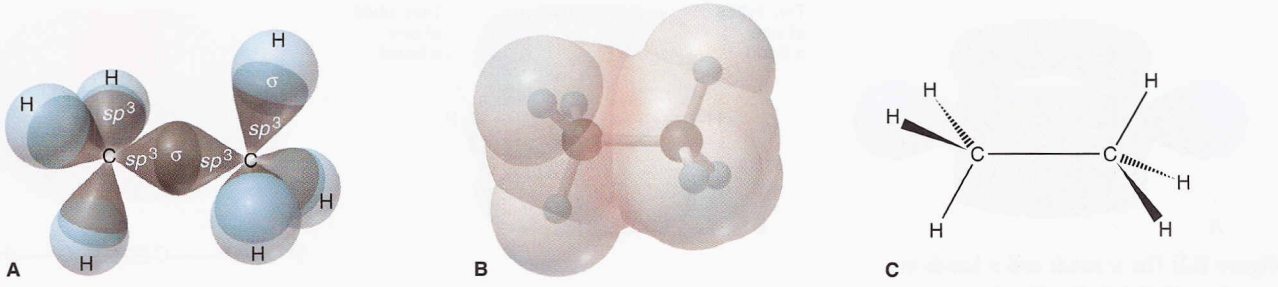


Figure 11.9 The σ bonds in ethane (C_2H_6). **A,** Two sp^3 hybridized C atoms and six H atoms in ethane form one C—C σ bond and six C—H σ bonds. **B,** Electron density is distributed relatively evenly among the σ bonds. **C,** Bond-line drawing.

A close look at the bonds shows two modes of orbital overlap, which correspond to the two types of covalent bonds:

1. *End-to-end overlap and sigma (σ) bonding.* Both C atoms of ethane are sp^3 hybridized (Figure 11.9). The C—C bond involves overlap of one sp^3 orbital from each C, and each of the six C—H bonds involves overlap of a C sp^3 orbital with an H 1*s* orbital. The bonds in ethane are like all the others described so far in this chapter. Look closely at the C—C bond, for example. It involves the overlap of the end of one orbital with the end of the other. The bond resulting from such *end-to-end* overlap is called a **sigma (σ) bond.** It has its *highest electron density along the bond axis* (an imaginary line joining the nuclei) and is shaped like an ellipse rotated about its long axis (the shape resembles a football). All single bonds, formed by any combination of overlapping hybrid, *s*, or *p* orbitals, have their electron density concentrated along the bond axis, and thus are σ bonds.

2. *Side-to-side overlap and pi (π) bonding.* A close look at Figure 11.10 reveals the double nature of the carbon-carbon bond in ethylene. Here, each C atom is sp^2 hybridized. Each C atom's four valence electrons half-fill its three sp^2 orbitals and its unhybridized 2*p* orbital, which lies perpendicular to the sp^2 plane. Two sp^2 orbitals of each C form C—H σ bonds by overlapping the 1*s* orbitals of two H atoms. The third sp^2 orbital forms a C—C σ bond with an sp^2 orbital of the other C because their orientation allows end-to-end overlap. With the σ-bonded C atoms near each other, their half-filled unhybridized 2*p* orbitals are close enough to overlap *side to side.* Such overlap forms another type of covalent bond called a **pi (π) bond.** It has *two regions of electron density,* one above and one below the σ-bond axis. *One π bond holds two electrons that occupy both regions of the bond. A double bond always consists of one σ bond and one π bond.* As shown in Figure 11.10C, the double bond increases electron density between the C atoms.

Now we can answer a question brought up in our discussion of VSEPR theory in Chapter 10: why do the two electron pairs in a double bond act as one electron group; that is, why don't they push each other apart? The answer is that each electron pair occupies a distinct orbital, a specific region of electron density, so repulsions are reduced.

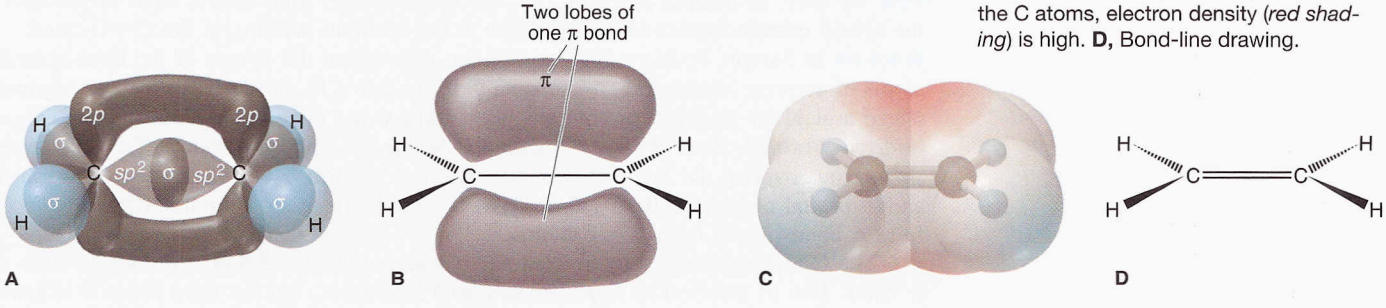

Figure 11.10 The σ and π bonds in ethylene (C_2H_4). **A,** Two sp^2 hybridized C atoms form one C—C σ bond and four C—H σ bonds. Half-filled unhybridized 2*p* orbitals lie perpendicular to the σ-bond axis and overlap side to side. **B,** The two overlapping regions comprise *one* π bond, which is occupied by two electrons. The σ bonds are shown as a line and wedges. **C,** With four electrons (one σ bond and one π bond) between the C atoms, electron density (*red shading*) is high. **D,** Bond-line drawing.

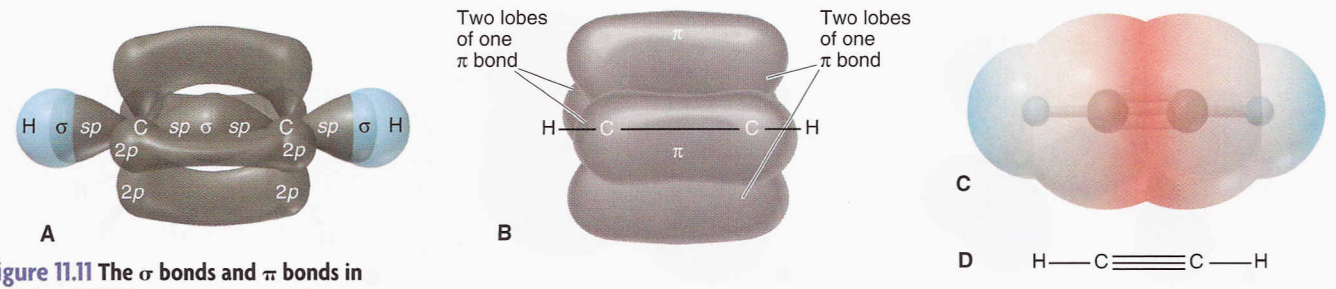

Figure 11.11 The σ bonds and π bonds in acetylene (C_2H_2). **A,** The C—C σ bond in acetylene forms when an *sp* orbital of each C overlaps. Two C—H σ bonds form from overlap of the other *sp* orbital of each C and an *s* orbital of an H. Two unhybridized 2*p* orbitals on each C are shown overlapping. **B,** Side-to-side overlap of pairs of 2*p* orbitals results in two π bonds, one with its lobes above and below the C—C σ bond (shown as a line), and the other with its lobes in front of and behind the σ bond. **C,** The two π bonds give the molecule cylindrical symmetry. Six electrons—one σ bond and two π bonds—create greater electron density between the C atoms than in ethylene. **D,** Bond-line drawing.

A triple bond, such as the C≡C bond in acetylene, *consists of one σ and two π bonds* (Figure 11.11). To maximize overlap in a linear shape, one *s* and one *p* orbital in *each* C atom form two *sp* hybrids, and two 2*p* orbitals remain unhybridized. The four valence electrons half-fill all four orbitals. Each C uses one of its *sp* orbitals to form a σ bond with an H atom and uses the other to form the C—C σ bond. Side-to-side overlap of one pair of 2*p* orbitals gives one π bond, with electron density above and below the σ bond. Side-to-side overlap of the other pair of 2*p* orbitals gives the other π bond, 90° away from the first, with electron density in front and back of the σ bond. The result is a *cylindrically symmetrical* H—C≡C—H molecule. Note the greater electron density between the C atoms created by the six bonding electrons. Figure 11.12 shows electron density relief maps of the carbon-carbon bonds in these compounds; note the increasing electron density between the nuclei from single to double to triple bond.

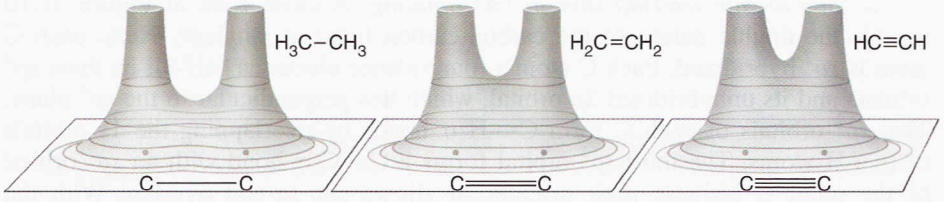

Figure 11.12 Electron density and bond order. Relief maps of the carbon-carbon bonding region in ethane, ethylene, and acetylene show a large increase in electron density as the bond order increases.

The extent of overlap influences bond strength. Because side-to-side overlap is not as extensive as end-to-end overlap, we might expect a π bond to be weaker than a σ bond, and thus a double bond should be less than twice as strong as a single bond. This expectation *is* borne out for carbon-carbon bonds. However, many factors, such as lone-pair repulsions, bond polarities, and other electrostatic contributions, affect overlap and the relative strength of σ and π bonds between other pairs of atoms. Thus, as a rough approximation, a double bond is about twice as strong as a single bond, and a triple bond is about three times as strong.

SAMPLE PROBLEM 11.2 Describing the Types of Bonds in Molecules

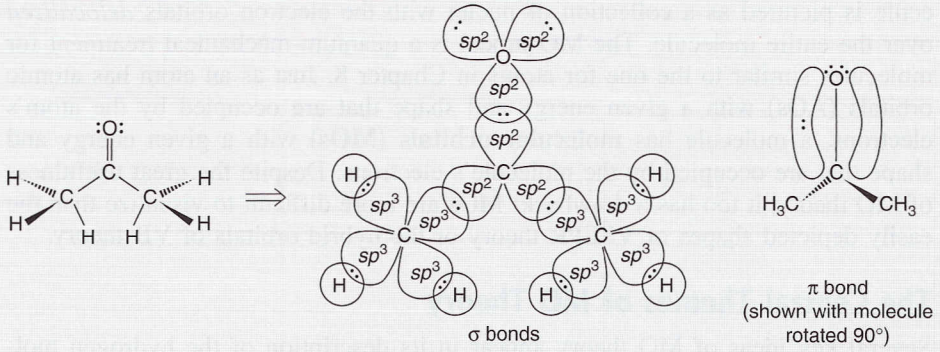
Problem Describe the types of bonds and orbitals in acetone, $(CH_3)_2CO$.

Plan We note, in Sample Problem 11.1, the shape around each central atom to postulate the hybrid orbitals used, and pay attention to the multiple bonding of the C=O bond.

Solution In Sample Problem 10.8, p. 385, we determined the shapes of the three central atoms of acetone: tetrahedral around each C of the two CH_3 (methyl) groups and trigonal planar around the middle C atom. Thus, the middle C has three sp^2 orbitals and one unhybridized *p* orbital. Each of the two methyl C atoms has four sp^3 orbitals. Three of these sp^3 orbitals overlap the 1*s* orbitals of the H atoms to form σ bonds; the fourth overlaps an sp^2 orbital of the middle C atom. Thus, two of the three sp^2 orbitals of the middle C form σ bonds to the other two C atoms.

The O atom is also sp^2 hybridized and has an unhybridized *p* orbital that can form a π bond. Two of the O atom's sp^2 orbitals hold lone pairs, and the third forms a σ bond

with the third sp^2 orbital of the middle C atom. The unhybridized, half-filled p orbitals of C and O form a π bond. The σ and π bonds constitute the C=O bond:



Comment How can we tell if a terminal atom, such as the O atom in acetone, is hybridized? After all, it could use two perpendicular p orbitals for the σ and π bonds with C and leave the other p and the s orbital to hold the two lone pairs. But, having each lone pair in an sp^2 orbital oriented away from the C=O bond, rather than in an s orbital, lowers repulsions. Moreover, in some compounds, the O of a C=O group is bonded to another atom, and those bond angles suggest that the O is sp^2 hybridized.

FOLLOW-UP PROBLEM 11.2 Describe the types of bonds and orbitals in **(a)** hydrogen cyanide, HCN, and **(b)** carbon dioxide, CO_2.

Orbital Overlap and Molecular Rotation

The type of bond influences the ability of one part of a molecule to rotate relative to another part. A *σ bond allows free rotation* of the parts of the molecule with respect to each other because the extent of overlap is not affected. If you could hold one CH_3 group of the ethane molecule, the other CH_3 group could spin like a pinwheel without affecting the C—C σ-bond overlap (see Figure 11.9).

However, p orbitals must be parallel to engage in side-to-side overlap, so *a π bond restricts rotation* around it. Rotating one CH_2 group in ethylene with respect to the other must decrease the side-to-side overlap and break the π bond. You can see why distinct *cis* and *trans* structures can exist for molecules with double bonds, such as 1,2-dichloroethylene (Section 10.3). As Figure 11.13 shows, the π bond allows two *different* arrangements of atoms around the two C atoms, which can have a major effect on molecular polarity (see p. 389). (Rotation around a triple bond is not meaningful: because each triple-bonded C atom is attached to only one other group, there can be no difference in their relative positions.)

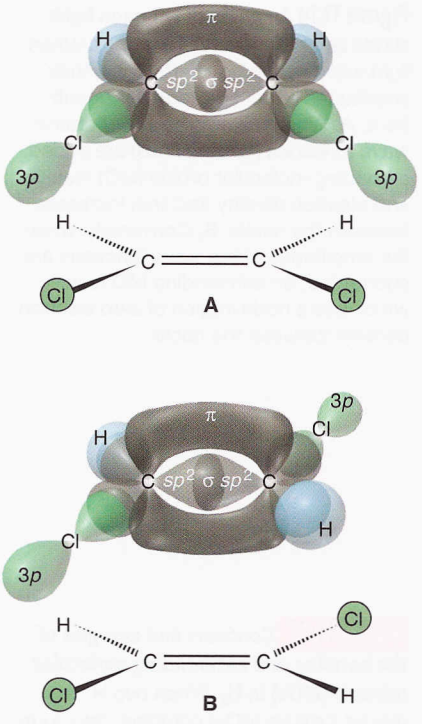


Figure 11.13 Restricted rotation of π-bonded molecules. A, *Cis*- and **B,** *trans*-1,2-dichloroethylene occur as distinct molecules because the π bond between the C atoms restricts rotation and maintains two different relative positions of the H and Cl atoms.

SECTION SUMMARY

End-to-end overlap of atomic orbitals forms a σ bond and allows free rotation of the parts of the molecule. Side-to-side overlap forms a π bond, which restricts rotation. A multiple bond consists of a σ bond and either one π bond (double bond) or two π bonds (triple bond). Multiple bonds have greater electron density than single bonds.

11.3 MOLECULAR ORBITAL (MO) THEORY AND ELECTRON DELOCALIZATION

Scientists choose the model that best helps them answer a particular question. If the question concerns molecular shape, chemists choose the VSEPR model, followed by hybrid-orbital analysis with VB theory. But VB theory does not adequately explain magnetic and spectral properties, and it understates the importance of electron delocalization. In order to deal with these phenomena, which involve molecular energy levels, chemists choose **molecular orbital (MO) theory.**

In VB theory, a molecule is pictured as a group of atoms bound together through *localized* overlap of valence-shell atomic orbitals. In MO theory, a molecule is pictured as a collection of nuclei with the electron orbitals *delocalized* over the entire molecule. The MO model is a quantum-mechanical treatment for molecules similar to the one for atoms in Chapter 8. Just as an atom has atomic orbitals (AOs) with a given energy and shape that are occupied by the atom's electrons, a molecule has **molecular orbitals (MOs)** with a given energy and shape that are occupied by the molecule's electrons. Despite the great usefulness of MO theory, it too has a drawback: MOs are more difficult to visualize than the easily depicted shapes of VSEPR theory or the hybrid orbitals of VB theory.

The Central Themes of MO Theory

Several key ideas of MO theory appear in its description of the hydrogen molecule and other simple species. These ideas include the formation of MOs, their energy and shape, and how they fill with electrons.

Formation of Molecular Orbitals Because electron motion is so complex, we use approximations to solve the Schrödinger equation for an atom with more than one electron. Similar complications arise even with H_2, the simplest molecule, so we use approximations to solve for the properties of MOs. The most common approximation mathematically *combines* (adds or subtracts) the atomic orbitals (atomic wave functions) of nearby atoms to form MOs (molecular wave functions).

When two H nuclei lie near each other, as in H_2, their AOs overlap. The two ways of combining the AOs are as follows:

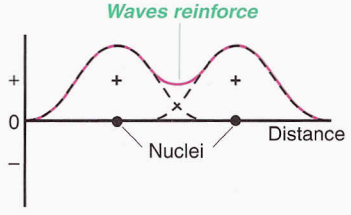
- *Adding the wave functions together.* This combination forms a **bonding MO,** which has *a region of high electron density between the nuclei.* Additive overlap is analogous to light waves reinforcing each other, making the resulting amplitude higher and the light brighter. For electron waves, the overlap *increases* the probability that the electrons are between the nuclei (Figure 11.14A).
- *Subtracting the wave functions from each other.* This combination forms an **antibonding MO,** which has *a region of zero electron density (a node) between the nuclei* (Figure 11.14B). Subtractive overlap is analogous to light waves canceling each other, so that the light disappears. With electron waves, the probability that the electrons lie between the nuclei *decreases* to zero.

The two possible combinations for hydrogen atoms H_A and H_B are

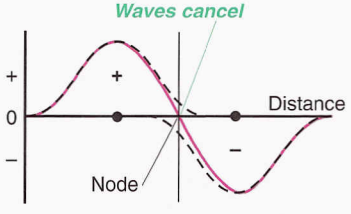
AO of H_A + AO of H_B = bonding MO of H_2 (more e^- density between nuclei)
AO of H_A − AO of H_B = antibonding MO of H_2 (less e^- density between nuclei)

Notice that *the number of AOs combined always equals the number of MOs formed:* two H atomic orbitals combine to form two H_2 molecular orbitals.

Energy and Shape of H_2 Molecular Orbitals *The bonding MO is lower in energy and the antibonding MO higher in energy than the AOs that combined to form them.* Let's examine Figure 11.15 to see why this is so.



A Amplitudes of wave functions added



B Amplitudes of wave functions subtracted

Figure 11.14 An analogy between light waves and atomic wave functions. When light waves undergo interference, their amplitudes either add together or subtract. **A,** When the amplitudes of atomic wave functions *(dashed lines)* are added, a bonding molecular orbital (MO) results, and electron density *(red line)* increases between the nuclei. **B,** Conversely, when the amplitudes of the wave functions are subtracted, an antibonding MO results, which has a node (region of zero electron density) between the nuclei.

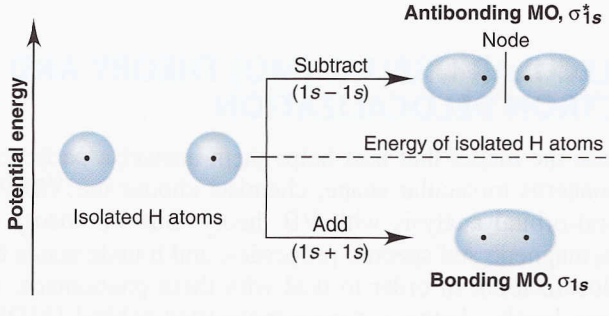


Figure 11.15 Contours and energies of the bonding and antibonding molecular orbitals (MOs) in H_2. When two H 1*s* atomic orbitals (AOs) combine, they form two H_2 MOs. The bonding MO (σ_{1s}) forms from addition of the AOs and is lower in energy than those AOs because most of its electron density lies *between* the nuclei (shown as dots). The antibonding MO (σ^*_{1s}) forms from subtraction of the AOs and is higher in energy because there is a *node* between the nuclei and most of the electron density lies outside the internuclear region.

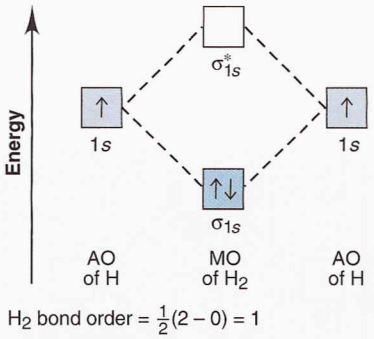
The bonding MO in H_2 is spread mostly *between* the nuclei, with the nuclei attracted to the intervening electrons. An electron in this MO can delocalize its charge over a much larger volume than is possible in an individual AO in H. Because the electron-electron repulsions are reduced, the bonding MO is *lower* in energy than the isolated AOs. Therefore, when electrons occupy this orbital, the molecule is *more stable* than the separate atoms. In contrast, the antibonding MO has a node between the nuclei and most of its electron density *outside* the internuclear region. The electrons do not shield one nucleus from the other, which increases the nucleus-nucleus repulsion and makes the antibonding MO *higher* in energy than the isolated AOs. Therefore, when the antibonding orbital is occupied, the molecule is *less stable* than when this orbital is empty.

Both the bonding and antibonding MOs of H_2 are **sigma (σ) MOs** because they are cylindrically symmetrical about an imaginary line that runs through the two nuclei. The bonding MO is denoted by σ_{1s}, that is, a σ MO formed by combination of 1*s* AOs. Antibonding orbitals are denoted with a superscript star, so the one derived from the 1*s* AOs is σ^*_{1s} (spoken "sigma, one ess, star").

To interact effectively and form MOs, *atomic orbitals must have similar energy and orientation.* The 1*s* orbitals on two H atoms have identical energy and orientation, so they interact strongly. This point will be important when we consider molecules composed of atoms with many sublevels.



H_2 bond order = $\frac{1}{2}(2 - 0) = 1$

Figure 11.16 The MO diagram for H_2. The positions of the boxes indicate the relative energies and the arrows show the electron occupancy of the MOs and the AOs from which they formed. Two electrons, one from each H atom, fill the lower energy σ_{1s} MO, while the higher energy σ^*_{1s} MO remains empty. Orbital occupancy is also shown by color (darker = full, paler = half-filled, no color = empty).

Filling Molecular Orbitals with Electrons Electrons fill MOs just as they fill AOs:

- Orbitals are filled in order of increasing energy (aufbau principle).
- An orbital has a maximum capacity of two electrons with opposite spins (exclusion principle).
- Orbitals of equal energy are half-filled, with spins parallel, before any is filled (Hund's rule).

A **molecular orbital (MO) diagram** shows the relative energy and number of electrons in each MO, as well as the AOs from which they formed. Figure 11.16 is the MO diagram for H_2.

MO theory redefines bond order. In a Lewis structure, bond order is the number of electron pairs per linkage. The **MO bond order** is the number of electrons in bonding MOs minus the number in antibonding MOs, divided by two:

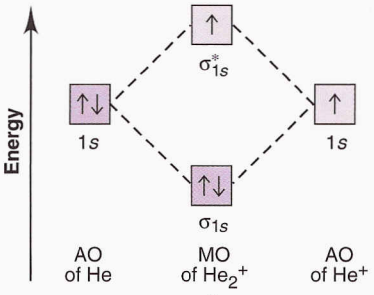
$$\text{Bond order} = \tfrac{1}{2}[(\text{no. of } e^- \text{ in bonding MO}) - (\text{no. of } e^- \text{ in antibonding MO})] \quad (11.1)$$

Thus, for H_2, the bond order is $\frac{1}{2}(2 - 0) = 1$. A bond order greater than zero indicates that the molecular species is stable relative to the separate atoms, whereas a bond order of zero implies no net stability and, thus, no likelihood that the species will form. In general, *the higher the bond order, the stronger the bond.*

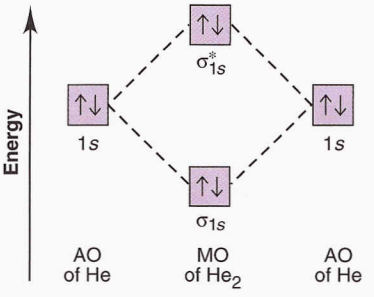
Another similarity of MO theory to the quantum-mechanical model for atoms is that we can write electron configurations for a molecule. The symbol of each occupied MO is shown in parentheses, and the number of electrons in it is written outside as a superscript. Thus, the electron configuration of H_2 is $(\sigma_{1s})^2$.

One of the early triumphs of MO theory was its ability to *predict* the existence of He_2^+, the dihelium molecule-ion, which is composed of two He nuclei and three electrons. Let's use MO theory to see why He_2^+ exists and, at the same time, why He_2 does not. In He_2^+, the 1*s* atomic orbitals form the molecular orbitals, so the MO diagram, shown in Figure 11.17A, is similar to that for H_2. The three electrons enter the MOs to give a pair in the σ_{1s} MO and a lone electron in the σ^*_{1s} MO. The bond order is $\frac{1}{2}(2 - 1) = \frac{1}{2}$. Thus, He_2^+ has a relatively weak bond, but it should exist. Indeed, this molecular ionic species has been observed frequently when He atoms collide with He^+ ions. Its electron configuration is $(\sigma_{1s})^2(\sigma^*_{1s})^1$.

On the other hand, He_2 has four electrons to place in its σ_{1s} and σ^*_{1s} MOs. As Figure 11.17B shows, both the bonding and antibonding orbitals are filled. The



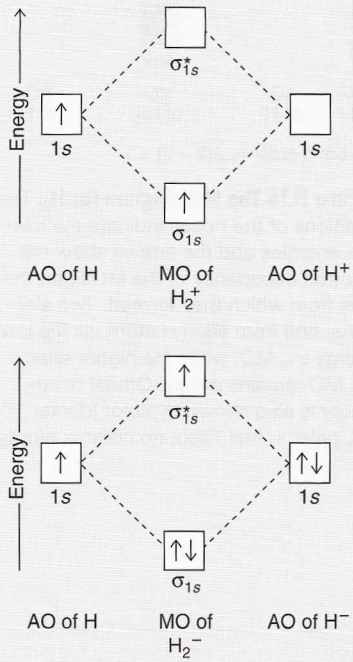
A He_2^+ bond order = $\frac{1}{2}$



B He_2 bond order = 0

Figure 11.17 MO diagrams for He_2^+ and He_2. A, In He_2^+, three electrons enter MOs in order of increasing energy to give a filled σ_{1s} MO and a half-filled σ^*_{1s} MO. The bond order of $\frac{1}{2}$ implies that He_2^+ exists. **B,** In He_2, the four electrons fill both the σ_{1s} and the σ^*_{1s} MOs, so there is no net stabilization (bond order = 0).

stabilization arising from the electron pair in the bonding MO is canceled by the destabilization due to the electron pair in the antibonding MO. From its zero bond order [$\frac{1}{2}(2 - 2) = 0$], we predict, and experiment has so far confirmed, that a covalent He_2 molecule does not exist.



SAMPLE PROBLEM 11.3 Predicting Stability of Species Using MO Diagrams

Problem Use MO diagrams to predict whether H_2^+ and H_2^- exist. Determine their bond orders and electron configurations.

Plan In these species, the 1*s* orbitals form MOs, so the MO diagrams are similar to that for H_2. We determine the number of electrons in each species and distribute the electrons in pairs to the bonding and antibonding MOs in order of increasing energy. We obtain the bond order with Equation 11.1 and write the electron configuration as described in the text.

Solution For H_2^+. H_2 has two e^-, so H_2^+ has only one, as shown in the margin (top diagram). The bond order is $\frac{1}{2}(1 - 0) = \frac{1}{2}$, so we predict that H_2^+ does exist. The electron configuration is $(\sigma_{1s})^1$.

For H_2^-. Since H_2 has two e^-, H_2^- has three, as shown in the margin (bottom diagram). The bond order is $\frac{1}{2}(2 - 1) = \frac{1}{2}$, so we predict that H_2^- does exist. The electron configuration is $(\sigma_{1s})^2(\sigma^*_{1s})^1$.

Check The number of electrons in the MOs equals the number of electrons in the AOs, as it should.

Comment Both these species have been detected spectroscopically: H_2^+ occurs in the hydrogen-containing material around stars; H_2^- has been formed in the laboratory.

FOLLOW-UP PROBLEM 11.3 Use an MO diagram to predict whether two hydride ions (H^-) will form H_2^{2-}. Calculate the bond order of H_2^{2-} and write its electron configuration.

Homonuclear Diatomic Molecules of the Period 2 Elements

Homonuclear diatomic molecules are those composed of two identical atoms. You're already familiar with several from Period 2—N_2, O_2, and F_2—as the elemental forms under standard conditions. Others in Period 2—Li_2, Be_2, B_2, C_2, and Ne_2—are observed, if at all, only in high-temperature gas-phase experiments. Molecular orbital descriptions of these species provide some interesting tests of the model. Let's look first at the molecules from the *s* block, Groups 1A(1) and 2A(2), and then at those from the *p* block, Groups 3A(13) through 8A(18).

Bonding in the *s*-Block Homonuclear Diatomic Molecules

Both Li and Be occur as metals under normal conditions, but let's see what MO theory predicts for their stability as the diatomic gases dilithium (Li_2) and diberyllium (Be_2).

These atoms have both inner (1*s*) and outer (2*s*) electrons, but the 1*s* orbitals interact negligibly. In general, *only outer (valence) orbitals interact enough to form molecular orbitals*. Like the MOs formed from 1*s* AOs, those formed from 2*s* AOs are σ orbitals, cylindrically symmetrical around the internuclear axis. Bonding (σ_{2s}) and antibonding (σ^*_{2s}) MOs form, and the two valence electrons fill the bonding MO, with opposing spins (Figure 11.18A). Dilithium has two electrons in bonding MOs and none in antibonding MOs; therefore, its bond order is $\frac{1}{2}(2 - 0) = 1$. In fact, Li_2 *has* been observed, and the MO electron configuration is $(\sigma_{2s})^2$.

With its two additional electrons, the MO diagram for Be_2 has filled σ_{2s} and σ^*_{2s} MOs (Figure 11.18B). This is similar to the case of He_2. The bond order is $\frac{1}{2}(2 - 2) = 0$. In keeping with a zero bond order, the ground state of Be_2 has never been observed.

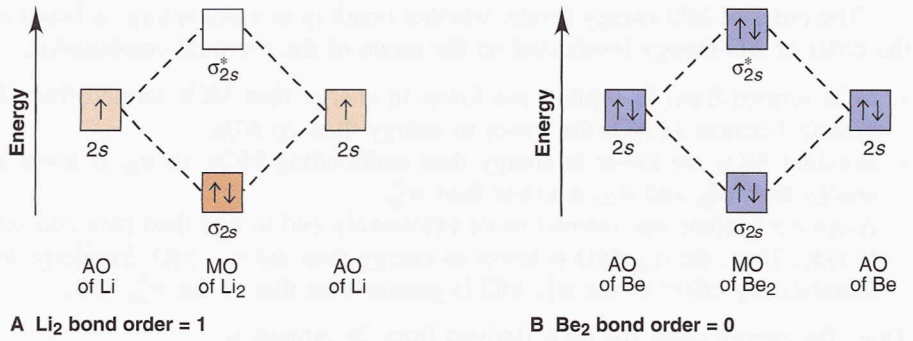


Figure 11.18 Bonding in *s*-block homonuclear diatomic molecules. Only outer (valence) AOs interact enough to form MOs. **A,** Li_2. The two valence electrons from two Li atoms fill the bonding (σ_{2s}) MO, and the antibonding (σ^*_{2s}) remains empty. With a bond order of 1, Li_2 does form. **B,** Be_2. The four valence electrons from two Be atoms fill both MOs to give no net stabilization. Ground-state Be_2 has a zero bond order and has never been observed.

Molecular Orbitals from Atomic *p*-Orbital Combinations As we move to the *p* block, atomic 2*p* orbitals become involved, so we first consider the shapes and energies of the MOs that result from their combinations. Recall that *p* orbitals can overlap with each other in two different modes, as shown in Figure 11.19. End-to-end combination gives a pair of σ MOs, the σ_{2p} and σ^*_{2p}. Side-to-side combination gives a pair of **pi (π) MOs,** π_{2p} and π^*_{2p}. Similar to MOs formed from *s* orbitals, bonding MOs from *p*-orbital combinations have their greatest electron density *between* the nuclei, whereas antibonding MOs from *p*-orbital combinations have a node between the nuclei and most of their electron density *outside* the internuclear region.

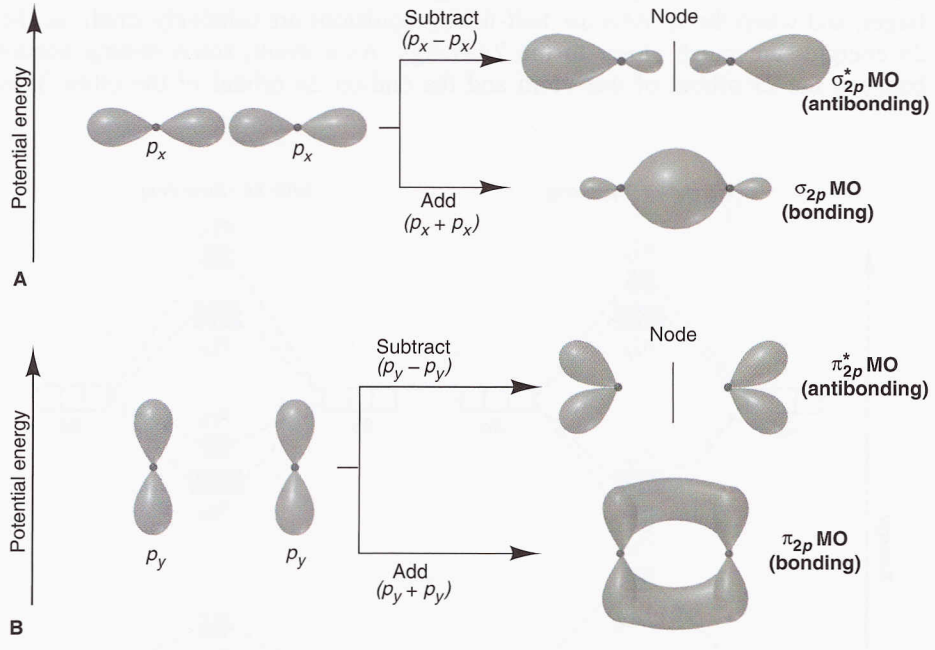

Figure 11.19 Contours and energies of σ and π MOs from combinations of 2*p* atomic orbitals. **A,** The *p* orbitals lying along the line between the atoms (usually designated p_x) undergo end-to-end overlap and form σ_{2p} and σ^*_{2p} MOs. Note the greater electron density between the nuclei for the bonding orbital and the node between the nuclei for the antibonding orbital. **B,** The *p* orbitals that lie perpendicular to the internuclear axis (p_y and p_z) undergo side-to-side overlap to form two π MOs. The p_z interactions are the same as those shown here for the p_y orbitals, so a total of four π MOs form. A π_{2p} is a bonding MO with its greatest density above and below the internuclear axis; a π^*_{2p} is an antibonding MO with a node between the nuclei and its electron density outside the internuclear region.

The order of MO energy levels, whether bonding or antibonding, is based on the order of AO energy levels *and* on the mode of the *p*-orbital combination:

- MOs formed from 2*s* orbitals are lower in energy than MOs formed from 2*p* orbitals because 2*s* AOs are lower in energy than 2*p* AOs.
- Bonding MOs are lower in energy than antibonding MOs, so σ_{2p} is lower in energy than σ^*_{2p} and π_{2p} is lower than π^*_{2p}.
- Atomic *p* orbitals can interact more extensively end to end than they can side to side. Thus, the σ_{2p} MO is lower in energy than the π_{2p} MO. Similarly, the destabilizing effect of the σ^*_{2p} MO is greater than that of the π^*_{2p} MO.

Thus, the energy order for MOs derived from 2*p* orbitals is

$$\sigma_{2p} < \pi_{2p} < \pi^*_{2p} < \sigma^*_{2p}$$

There are three mutually perpendicular 2*p* orbitals in each atom. When the six *p* orbitals in two atoms combine, the two orbitals that interact end to end form a σ and a σ^* MO, and the two pairs of orbitals that interact side to side form two π MOs of the same energy and two π^* MOs of the same energy. Combining these orientations with the energy order gives the *expected* MO diagram for the *p*-block Period 2 homonuclear diatomic molecules (Figure 11.20A).

One other factor influences the MO energy order. Recall that only AOs of similar energy interact to form MOs. The order in Figure 11.20A assumes that the *s* and *p* AOs are so different in energy that they do not interact with each other: the orbitals do not *mix*. This is true for O, F, and Ne. These atoms are small, so relatively strong repulsions occur as the 2*p* electrons pair up; these repulsions raise the energy of the 2*p* orbitals high enough above the energy of the 2*s* orbitals to minimize orbital mixing. In contrast, B, C, and N atoms are larger, and when the 2*p* AOs are half-filled, repulsions are relatively small; so the 2*p* energies are much closer to the 2*s* energy. As a result, some mixing occurs between the 2*s* orbital of one atom and the end-on 2*p* orbital of the other. This

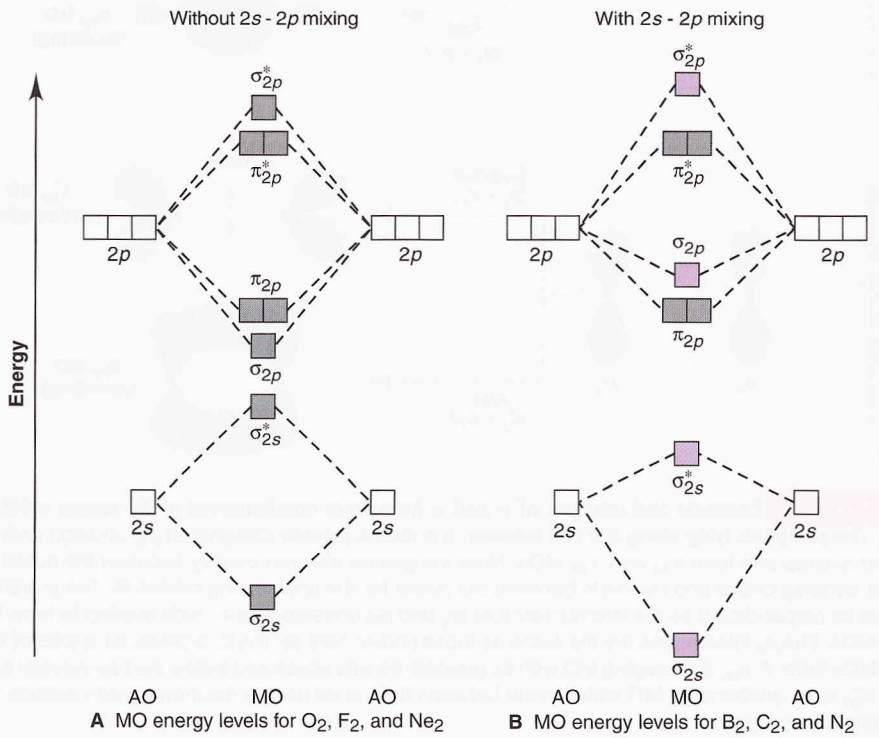

Figure 11.20 Relative MO energy levels for Period 2 homonuclear diatomic molecules. A, MO energy levels for O_2, F_2, and Ne_2. The six 2*p* orbitals of the two atoms form six MOs that are higher in energy than the two MOs formed from the two 2*s* orbitals. The AOs forming π orbitals give rise to two bonding MOs (π_{2p}) of equal energy and two antibonding MOs (π^*_{2p}) of equal energy. This sequence of energy levels arises from minimal 2*s*-2*p* orbital mixing. **B,** MO energy levels for B_2, C_2, and N_2. Because of significant 2*s*-2*p* orbital mixing, the energies of σ MOs formed from 2*p* orbitals increase and those formed from 2*s* orbitals decrease. The major effect of this orbital mixing on the MO sequence is that the σ_{2p} is higher in energy than the π_{2p}. (For clarity, those MOs affected by mixing are shown in purple.)

orbital mixing *lowers* the energy of the σ_{2s} and σ^*_{2s} MOs and raises the energy of the σ_{2p} and σ^*_{2p} MOs; the π MOs are not affected. The MO diagram for B_2 through N_2 (Figure 11.20B) reflects this AO mixing. The only change that affects this discussion is the *reverse in energy order* of the σ_{2p} and π_{2p} MOs.

Bonding in the *p*-Block Homonuclear Diatomic Molecules Figure 11.21 shows the MOs, their electron occupancy, and some properties of B_2 through Ne_2. Note how *a higher bond order correlates with a greater bond energy and shorter bond length*. Also note how orbital occupancy correlates with magnetic properties. Recall from Chapter 8 that the spins of unpaired electrons in an atom (or ion) cause the substance to be *paramagnetic*, attracted to an external magnetic field. If all the electron spins are paired, the substance is *diamagnetic*, unaffected (or weakly repelled) by the magnetic field. The same observations apply to molecules. These properties are not addressed directly in VSEPR or VB theory.

The B_2 molecule has six outer electrons to place in its MOs. Four of these fill the σ_{2s} and σ^*_{2s} MOs. The remaining two electrons occupy the two π_{2p} MOs, one in each orbital, in keeping with Hund's rule. With four electrons in bonding MOs and two electrons in antibonding MOs, the bond order of B_2 is $\frac{1}{2}(4 - 2) = 1$. As expected from its MO diagram, B_2 is paramagnetic.

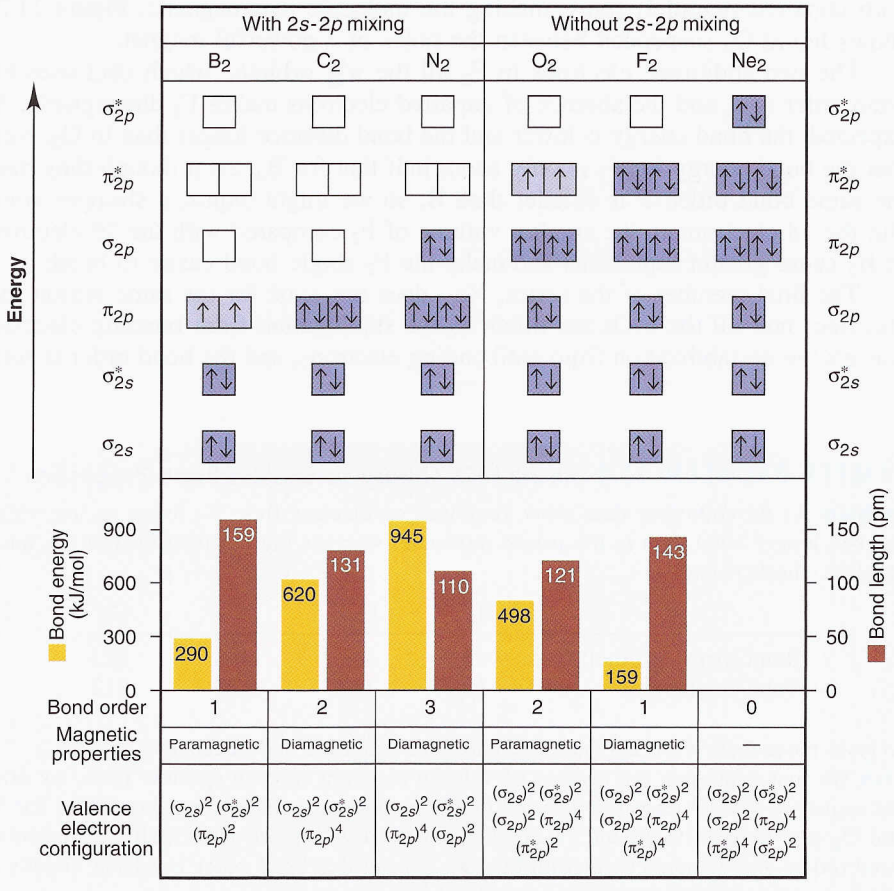

Figure 11.21 MO occupancy and molecular properties for B_2 through Ne_2. The sequence of MOs and their electron populations are shown for the homonuclear diatomic molecules in the *p* block of Period 2 [Groups 3A(13) to 8A(18)]. The bond energy, bond length, bond order, magnetic properties, and outer (valence) electron configuration appear below the orbital diagrams. Note the correlation between bond order and bond energy, both of which are inversely related to bond length.

The two additional electrons present in C_2 fill the two π_{2p} MOs. Since C_2 has two more bonding electrons than B_2, it has a bond order of 2 and the expected stronger, shorter bond. All the electrons are paired, and, as the model predicts, C_2 is diamagnetic.

In N_2, the two additional electrons fill the σ_{2p} MO. The resulting bond order is 3, which is consistent with the triple bond in the Lewis structure. As the model predicts, the bond energy is higher and the bond length shorter than for C_2, and N_2 is diamagnetic.

With O_2, we really see the power of MO theory compared to theories based on localized orbitals. For years, it seemed impossible to reconcile bonding theories with the bond strength and magnetic behavior of O_2. On the one hand, the data show a double-bonded molecule that is paramagnetic. On the other hand, we can write two possible Lewis structures for O_2, but neither gives such a molecule. One has a double bond and all electrons paired, the other a single bond and two electrons unpaired:

MO theory resolves this paradox beautifully. As Figure 11.21 shows, the bond order of O_2 is 2: eight electrons occupy bonding MOs and four occupy antibonding MOs [$\frac{1}{2}(8 - 4) = 2$]. Note the lower bond energy and greater bond length relative to N_2. The *two* electrons with highest energy occupy the *two* π^*_{2p} MOs with unpaired (parallel) spins, making the molecule paramagnetic. Figure 11.22 shows liquid O_2 suspended between the poles of a powerful magnet.

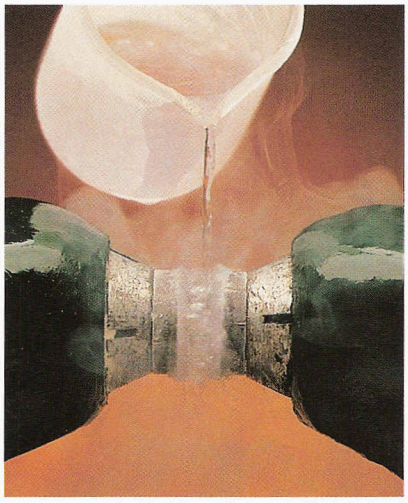

Figure 11.22 The paramagnetic properties of O_2. Liquid O_2 is attracted to the poles of a magnet because it is paramagnetic, as MO theory predicts. A diamagnetic substance would fall between the poles.

The two additional electrons in F_2 fill the π^*_{2p} orbitals, which decreases the bond order to 1, and the absence of unpaired electrons makes F_2 diamagnetic. As expected, the bond energy is lower and the bond distance longer than in O_2. Note that the bond energy for F_2 is only about half that for B_2, even though they have the same bond order. F is smaller than B, so we might expect a stronger bond. But the 18 electrons in the smaller volume of F_2 compared with the 10 electrons in B_2 cause greater repulsions and make the F_2 single bond easier to break.

The final member of the series, Ne_2, does not exist for the same reason that He_2 does not: all the MOs are filled, so the stabilization from bonding electrons cancels the destabilization from antibonding electrons, and the bond order is zero.

SAMPLE PROBLEM 11.4 Using MO Theory to Explain Bond Properties

Problem As the following data show, removing an electron from N_2 forms an ion with a weaker, longer bond than in the parent molecule, whereas the ion formed from O_2 has a stronger, shorter bond:

	N_2	N_2^+	O_2	O_2^+
Bond energy (kJ/mol)	945	841	498	623
Bond length (pm)	110	112	121	112

Explain these facts with diagrams that show the sequence and occupancy of MOs.

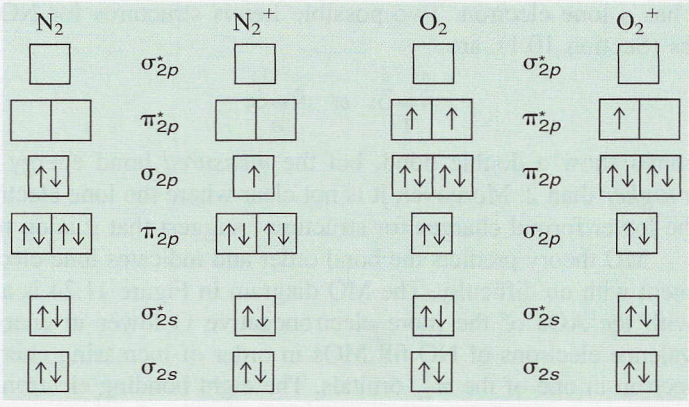
Plan We first determine the number of valence electrons in each species. Then, we draw the sequence of MO energy levels for the four species, recalling that they differ for N_2 and O_2 (see Figures 11.20 and 11.21), and fill them with electrons. Finally, we calculate bond orders and compare them with the data. Recall that bond order is related directly to bond energy and inversely to bond length.

Solution Determining the valence electrons:

N has 5 valence e^-, so N_2 has 10 and N_2^+ has 9

O has 6 valence e^-, so O_2 has 12 and O_2^+ has 11

Drawing and filling the MO diagrams:



Calculating bond orders:

$$\tfrac{1}{2}(8-2)=3 \qquad \tfrac{1}{2}(7-2)=2.5 \qquad \tfrac{1}{2}(8-4)=2 \qquad \tfrac{1}{2}(8-3)=2.5$$

When N_2 forms N_2^+, a *bonding* electron is removed, so the bond order decreases. Thus, N_2^+ has a weaker, longer bond than N_2. When O_2 forms O_2^+, an *antibonding* electron is removed, so the bond order increases. Thus, O_2^+ has a stronger, shorter bond than O_2.

Check The answer makes sense in terms of the relationships among bond order, bond energy, and bond length. Check that the total number of bonding and antibonding electrons equals the number of valence electrons calculated.

FOLLOW-UP PROBLEM 11.4 Determine the bond orders for the following species: F_2^{2-}, F_2^-, F_2, F_2^+, F_2^{2+}. List the species in order of increasing bond energy and in order of increasing bond length.

MO Description of Some Heteronuclear Diatomic Molecules

Heteronuclear diatomic molecules, those composed of two *different* atoms, have asymmetric MO diagrams because the atomic orbitals of the two atoms have unequal energies. Atoms with greater effective nuclear charge (Z_{eff}) draw their electrons closer to the nucleus and thus have atomic orbitals of lower energy (Section 8.2). Greater Z_{eff} also gives these atoms higher electronegativity values. Let's apply MO theory to the bonding in HF and NO.

Bonding in HF To form the MOs in HF, we combine appropriate AOs from isolated H and F atoms. The high effective nuclear charge of F holds all its electrons more tightly than the H nucleus holds its electron. As a result, *all* occupied atomic orbitals of F have lower energy than the 1*s* orbital of H. Therefore, the H 1*s* orbital interacts only with the F 2*p* orbitals, and only one of the three 2*p* orbitals, say the $2p_z$, leads to end-on overlap. This results in a σ MO and a σ* MO. The two other *p* orbitals of F ($2p_x$ and $2p_y$) are not involved in bonding and are called **nonbonding MOs;** they have the same energy as the isolated AOs (Figure 11.23).

Because the occupied bonding MO is closer in energy to the AOs of F, we say that the F 2*p* orbital contributes more to the bonding in HF than the H 1*s* orbital does. Generally, in polar covalent molecules, *bonding MOs are closer in energy to the AOs of the more electronegative atom.* In effect, fluorine's greater electronegativity lowers the energy of the bonding MO and draws the bonding electrons closer to its nucleus.

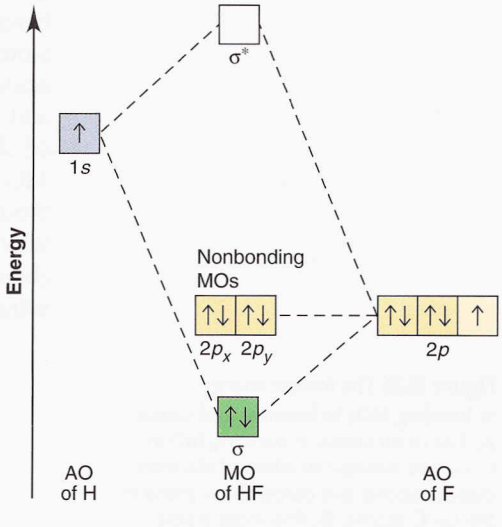


Figure 11.23 The MO diagram for HF. For a polar covalent molecule, the MO diagram is asymmetric because the more electronegative atom has AOs of lower energy. In HF, the bonding MO is closer in energy to the 2*p* orbital of F. Electrons that are not involved in bonding occupy nonbonding MOs. (The 2*s* AO of F is not shown.)

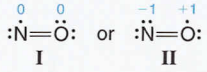
Bonding in NO Nitrogen monoxide (nitric oxide) is a highly reactive molecule because it has a lone electron. Two possible Lewis structures for NO, with formal charges (Section 10.1), are



Both structures show a double bond, but the *measured* bond energy suggests a bond order *higher* than 2. Moreover, it is not clear where the lone electron resides, although the lower formal charges for structure I suggest that it is on the N atom.

MO theory predicts the bond order and indicates lone-electron placement with no difficulty. The MO diagram in Figure 11.24 is asymmetric, with the AOs of the more electronegative O lower in energy. The 11 valence electrons of NO fill MOs in order of increasing energy, leaving the lone electron in one of the π^*_{2p} orbitals. The eight bonding electrons and three antibonding electrons give a bond order of $\frac{1}{2}(8 - 3) = 2.5$, more in keeping with experiment than either Lewis structure. The bonding electrons lie in MOs closer in energy to the AOs of the O atom. The lone electron occupies an antibonding orbital. Because this orbital receives a greater contribution from the $2p$ orbitals of N, the lone electron resides closer to the N atom.

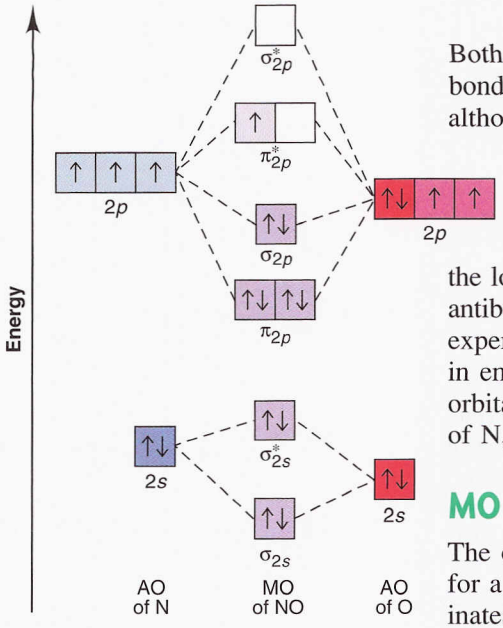


Figure 11.24 The MO diagram for NO. Eleven electrons occupy the MOs in nitric oxide. Note that the lone electron occupies an antibonding MO whose energy is closer to that of the AO of the (less electronegative) N atom.

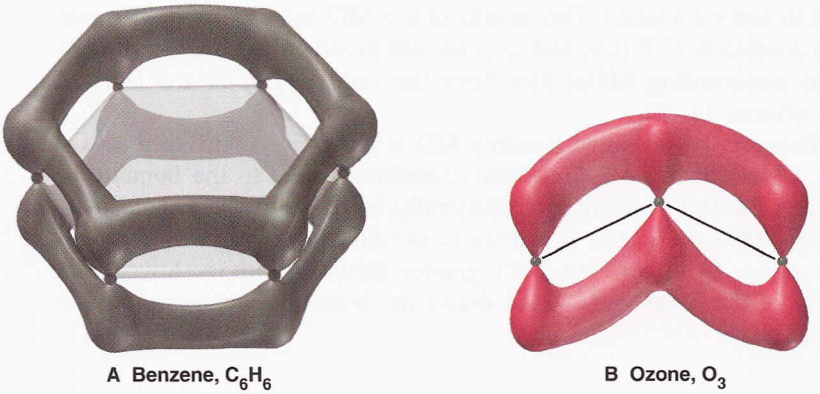
MO Descriptions of Benzene and Ozone

The orbital shapes and MO diagrams for polyatomic molecules are too complex for a detailed treatment here. However, let's briefly discuss how the model eliminates the need for resonance forms and helps explain the effects of the absorption of energy. Recall that we cannot draw a single Lewis structure that adequately depicts bonding in molecules such as ozone and benzene because the adjacent single and double bonds actually have identical properties. Instead, we draw more than one structure and mentally combine them into a resonance hybrid. The VB model also relies on resonance because it depicts *localized* electron-pair bonds.

In contrast, MO theory pictures a structure of delocalized σ and π bonding and antibonding MOs. Figure 11.25 shows the lowest energy π-bonding MOs in benzene and ozone. Each holds one pair of electrons. The extended electron densities allow delocalization of this π-bonding electron pair over the entire molecule, thus eliminating the need for separate resonance forms. In benzene, the upper and lower hexagonal lobes of this π-bonding MO lie above and below the σ plane of all six carbon nuclei. In ozone, the two lobes of the lowest energy π-bonding MO extend over and under all three oxygen nuclei. Another advantage of MO theory is that it can explain excited states and spectra of molecules: for instance, why O_3 decomposes when it absorbs ultraviolet radiation in the stratosphere (bonding electrons are excited and enter empty antibonding orbitals), and why the ultraviolet spectrum of benzene has its characteristic absorption bands.



A Benzene, C_6H_6 B Ozone, O_3

Figure 11.25 The lowest energy π-bonding MOs in benzene and ozone. **A,** The most stable π-bonding MO in C_6H_6 has hexagonal lobes of electron density above and below the σ plane of the six C atoms. **B,** The most stable π-bonding MO in O_3 extends above and below the σ plane (shown as bond lines) of the three O atoms.

SECTION SUMMARY

MO theory treats a molecule as a collection of nuclei with molecular orbitals delocalized over the entire structure. Atomic orbitals of comparable energy can be added and subtracted to obtain bonding and antibonding MOs, respectively. Bonding MOs have most of their electron density between the nuclei and are lower in energy than the atomic orbitals; most of the electron density of antibonding MOs does not lie between the nuclei, so these MOs are higher in energy. MOs are filled in order of their energy with paired electrons having opposing spins. MO diagrams show energy levels and orbital occupancy. The diagrams for homonuclear diatomic molecules of Period 2 explain observed bond energy, bond length, and magnetic behavior. In heteronuclear diatomic molecules, the more electronegative atom contributes more to the bonding MOs. MO theory eliminates the need for resonance forms to depict larger molecules.

Chapter Perspective

In this chapter, you've seen that the two most important orbital-based models of covalent bonding, each with its own benefits and limitations, complement each other. Next, you'll see how the electron distribution in the bonds of molecules gives rise to the physical behavior of liquids and solids. MO theory will come into play for a deeper understanding of metallic solids. Then, following Chapter 12 are three chapters that apply many concepts you've learned from Chapter 7 onward to the behavior of solutions and inorganic, organic, and biochemical substances.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The main ideas of valence bond theory—orbital overlap, opposing electron spins, and hybridization—as a means of rationalizing molecular shapes (11.1)
2. How orbitals mix to form hybrid orbitals with different spatial orientations (11.1)
3. The distinction between end-to-end and side-to-side overlap and the origin of sigma (σ) and pi (π) bonds in simple molecules (11.2)
4. How two modes of orbital overlap lead to single, double, and triple bonds (11.2)
5. Why π bonding restricts rotation around double bonds (11.2)
6. The distinction between the localized bonding of VB theory and the delocalized bonding of MO theory (11.3)
7. How addition or subtraction of AOs forms bonding or antibonding MOs (11.3)
8. The shapes of MOs formed from combinations of two *s* orbitals and combinations of two *p* orbitals (11.3)
9. How MO bond order predicts the stability of molecular species (11.3)
10. How MO theory explains the bonding and properties of homonuclear and heteronuclear diatomic molecules of Period 2 (11.3)

Master These Skills

1. Using molecular shape to postulate the hybrid orbitals used by a central atom (SP 11.1)
2. Describing the types of orbitals and bonds in a molecule (SP 11.2)
3. Drawing MO diagrams, writing electron configurations, and calculating bond orders of molecular species (SP 11.3)
4. Explaining bond properties with MO theory (SP 11.4)

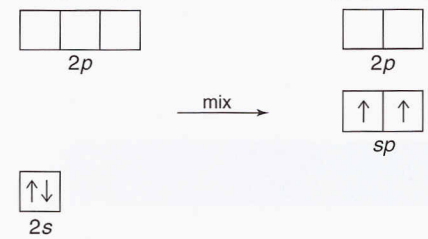
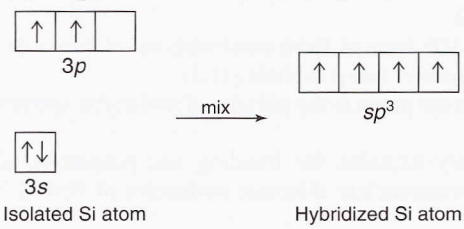
Brief Solutions to Follow-up Problems

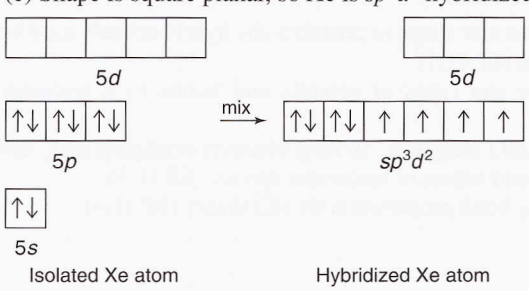
11.1 (a) Shape is linear, so Be is *sp* hybridized.



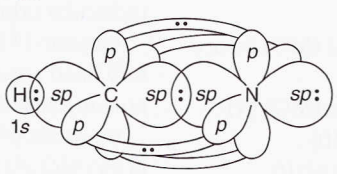
(b) Shape is tetrahedral, so Si is sp^3 hybridized.



(c) Shape is square planar, so Xe is sp^3d^2 hybridized.

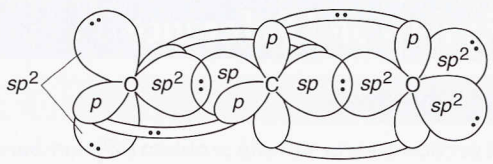


11.2 (a) H—C≡N:



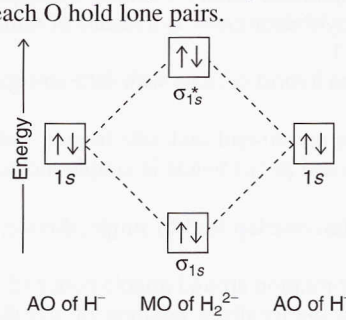
HCN is linear, so C is *sp* hybridized. N is also *sp* hybridized. One *sp* of C overlaps the 1*s* of H to form a σ bond. The other *sp* of C overlaps one *sp* of N to form a σ bond. The other *sp* of N holds a lone pair. Two unhybridized *p* orbitals of N and two of C overlap to form two π bonds.

(b) Ö=C=Ö



CO_2 is linear, so C is *sp* hybridized. Both O atoms are sp^2 hybridized. Each *sp* of C overlaps one sp^2 of an O to form two σ bonds. Each of the two unhybridized *p* orbitals of C forms a π bond with the unhybridized *p* of one of the two O atoms. Two sp^2 of each O hold lone pairs.

11.3



Does not exist: BO $= \frac{1}{2}(2 - 2) = 0$; $(\sigma_{1s})^2(\sigma^*_{1s})^2$

11.4 Bond orders: $F_2^{2-} = 0$; $F_2^- = \frac{1}{2}$; $F_2 = 1$; $F_2^+ = 1\frac{1}{2}$; $F_2^{2+} = 2$

Bond energy: $F_2^{2-} < F_2^- < F_2 < F_2^+ < F_2^{2+}$

Bond length: $F_2^{2+} < F_2^+ < F_2 < F_2^-$; F_2^{2-} does not exist

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Valence Bond (VB) Theory and Orbital Hybridization

(Sample Problem 11.1)

Concept Review Questions

11.1 What type of central-atom orbital hybridization corresponds to each electron-group arrangement: (a) trigonal planar; (b) octahedral; (c) linear; (d) tetrahedral; (e) trigonal bipyramidal?

11.2 What is the orbital hybridization of a central atom that has one lone pair and bonds to: (a) two other atoms; (b) three other atoms; (c) four other atoms; (d) five other atoms?

11.3 How do carbon and silicon differ with regard to the *types* of orbitals available for hybridization? Explain.

11.4 How many hybrid orbitals form when four atomic orbitals of a central atom mix? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

11.5 Give the number and type of hybrid orbital that forms when each set of atomic orbitals mixes:
(a) two *d*, one *s*, and three *p* (b) three *p* and one *s*

11.6 Give the number and type of hybrid orbital that forms when each set of atomic orbitals mixes:
(a) one *p* and one *s* (b) three *p*, one *d*, and one *s*

11.7 What is the hybridization of nitrogen in each of the following: (a) NO; (b) NO_2; (c) NO_2^-?

11.8 What is the hybridization of carbon in each of the following: (a) CO_3^{2-}; (b) $C_2O_4^{2-}$; (c) NCO^-?

11.9 What is the hybridization of chlorine in each of the following: (a) ClO_2; (b) ClO_3^-; (c) ClO_4^-?

11.10 What is the hybridization of bromine in each of the following: (a) BrF_3; (b) BrO_2^-; (c) BrF_5?

11.11 Which types of atomic orbitals of the central atom mix to form hybrid orbitals in (a) $SiClH_3$; (b) CS_2?

11.12 Which types of atomic orbitals of the central atom mix to form hybrid orbitals in (a) Cl_2O; (b) $BrCl_3$?

11.13 Which types of atomic orbitals of the central atom mix to form hybrid orbitals in (a) SCl_3F; (b) NF_3?

11.14 Which types of atomic orbitals of the central atom mix to form hybrid orbitals in (a) PF_5; (b) SO_3^{2-}?

11.15 Use partial orbital diagrams to show how the atomic orbitals of the central atom lead to hybrid orbitals in (a) $GeCl_4$; (b) BCl_3; (c) CH_3^+.

11.16 Use partial orbital diagrams to show how the atomic orbitals of the central atom lead to hybrid orbitals in (a) BF_4^-; (b) PO_4^{3-}; (c) SO_3.

11.17 Use partial orbital diagrams to show how the atomic orbitals of the central atom lead to hybrid orbitals in (a) $SeCl_2$; (b) H_3O^+; (c) IF_4^-.

11.18 Use partial orbital diagrams to show how the atomic orbitals of the central atom lead to hybrid orbitals in (a) $AsCl_3$; (b) $SnCl_2$; (c) PF_6^-.

Problems in Context

11.19 Methyl isocyanate, $CH_3—\ddot{N}=C=\ddot{O}:$, is an intermediate in the manufacture of many pesticides. It received notoriety in 1984 when a leak from a manufacturing plant resulted in the death of more than 2000 people in Bhopal, India. What are the hybridizations of the N atom and the two C atoms in methyl isocyanate? Sketch the molecular shape.

The Mode of Orbital Overlap and the Types of Covalent Bonds

(Sample Problem 11.2)

Concept Review Questions

11.20 Are these statements true or false? Correct any that are false.
(a) Two σ bonds comprise a double bond.
(b) A triple bond consists of one π bond and two σ bonds.
(c) Bonds formed from atomic *s* orbitals are always σ bonds.
(d) A π bond restricts rotation about the σ-bond axis.
(e) A π bond consists of two pairs of electrons.
(f) End-to-end overlap results in a bond with electron density above and below the bond axis.

Skill-Building Exercises *(grouped in similar pairs)*

11.21 Describe the hybrid orbitals used by the central atom and the type(s) of bonds formed in (a) NO_3^-; (b) CS_2; (c) CH_2O.

11.22 Describe the hybrid orbitals used by the central atom and the type(s) of bonds formed in (a) O_3; (b) I_3^-; (c) $COCl_2$ (C is central).

11.23 Describe the hybrid orbitals used by the central atom(s) and the type(s) of bonds formed in (a) FNO; (b) C_2F_4; (c) $(CN)_2$.

11.24 Describe the hybrid orbitals used by the central atom(s) and the type(s) of bonds formed in (a) BrF_3; (b) $CH_3C{\equiv}CH$; (c) SO_2.

Problems in Context

11.25 2-Butene ($CH_3CH=CHCH_3$) is a starting material in the manufacture of lubricating oils and many other compounds. Draw two different structures for 2-butene, indicating the σ and π bonds in each.

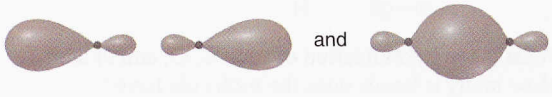
Molecular Orbital (MO) Theory and Electron Delocalization

(Sample Problems 11.3 and 11.4)

Concept Review Questions

11.26 Two *p* orbitals from one atom and two *p* orbitals from another atom are combined to form molecular orbitals for the joined atoms. How many MOs will result from this combination? Explain.

11.27 Certain atomic orbitals on two atoms were combined to form the following MOs. Name the atomic orbitals used and the MOs formed, and explain which MO has higher energy:



11.28 How do the bonding and antibonding MOs formed from a given pair of AOs compare to each other with respect to (a) energy; (b) presence of nodes; (c) internuclear electron density?

11.29 Antibonding MOs always have at least one node. Can a bonding MO have a node? If so, draw an example.

Skill-Building Exercises *(grouped in similar pairs)*

11.30 How many electrons does it take to fill (a) a σ bonding MO; (b) a π antibonding MO; (c) the MOs formed from combination of the 1*s* orbitals of two atoms?

11.31 How many electrons does it take to fill (a) the MOs formed from combination of the 2*p* orbitals of two atoms; (b) a σ^*_{2p} MO; (c) the MOs formed from combination of the 2*s* orbitals of two atoms?

11.32 Show the shapes of bonding and antibonding MOs formed by combination of (a) an *s* orbital and a *p* orbital; (b) two *p* orbitals (end to end).

11.33 Show the shapes of bonding and antibonding MOs formed by combination of (a) two *s* orbitals; (b) two *p* orbitals (side to side).

11.34 Use MO diagrams and the bond orders you obtain from them to answer: (a) Is Be_2^+ stable? (b) Is Be_2^+ diamagnetic? (c) What is the outer (valence) electron configuration of Be_2^+?

11.35 Use MO diagrams and the bond orders you obtain from them to answer: (a) Is O_2^- stable? (b) Is O_2^- paramagnetic? (c) What is the outer (valence) electron configuration of O_2^-?

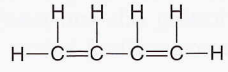
11.36 Use MO diagrams to place C_2^-, C_2, and C_2^+ in order of (a) increasing bond energy; (b) increasing bond length.

11.37 Use MO diagrams to place B_2^+, B_2, and B_2^- in order of (a) decreasing bond energy; (b) decreasing bond length.

Comprehensive Problems

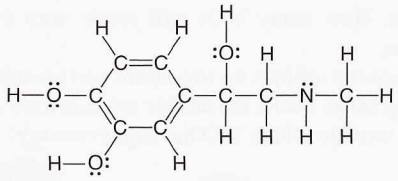
11.38 Predict the shape, state the hybridization of the central atom, and give the ideal bond angle(s) and any expected deviations for
(a) BrO_3^- (b) $AsCl_4^-$ (c) SeO_4^{2-} (d) BiF_5^{2-}
(e) SbF_4^+ (f) AlF_6^{3-} (g) IF_4^+

11.39 Butadiene (shown below) is a colorless gas used to make synthetic rubber and many other compounds:



(a) How many σ bonds and π bonds does the molecule have?
(b) Are *cis-trans* structural arrangements about the double bonds possible? Explain.

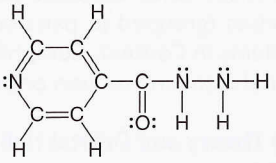
11.40 Epinephrine (or adrenaline) is a naturally occurring hormone that is also manufactured commercially for use as a heart stimulant, a nasal decongestant, and to treat glaucoma. A valid Lewis structure is



(a) What is the hybridization of each C, O, and N atom?
(b) How many σ bonds does the molecule have?
(c) How many π electrons are delocalized in the ring?

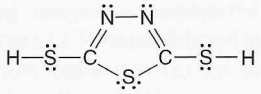
11.41 Use partial orbital diagrams to show how the atomic orbitals of the central atom lead to the hybrid orbitals in
(a) IF_2^- (b) ICl_3 (c) $XeOF_4$ (d) BHF_2

11.42 Isoniazid is an antibacterial agent that is very useful against many common strains of tuberculosis. A valid Lewis structure is



(a) How many σ bonds are in the molecule?
(b) What is the hybridization of each C and N atom?

11.43 Hydrazine, N_2H_4, and carbon disulfide, CS_2, form a cyclic molecule with the following Lewis structure:

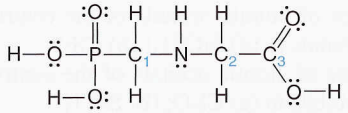


(a) Draw Lewis structures for N_2H_4 and CS_2.
(b) How do electron-group arrangement, molecular shape, and hybridization of N change when N_2H_4 reacts to form the product?
(c) How do electron-group arrangement, molecular shape, and hybridization of C change when CS_2 reacts to form the product?

11.44 In each of the following equations, what hybridization change, if any, occurs for the underlined atom?
(a) $\underline{B}F_3 + NaF \longrightarrow Na^+BF_4^-$
(b) $\underline{P}Cl_3 + Cl_2 \longrightarrow PCl_5$
(c) $H\underline{C}{\equiv}CH + H_2 \longrightarrow H_2C{=}CH_2$
(d) $\underline{Si}F_4 + 2F^- \longrightarrow SiF_6^{2-}$
(e) $\underline{S}O_2 + \frac{1}{2}O_2 \longrightarrow SO_3$

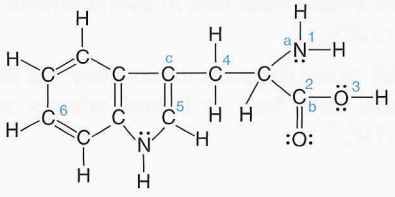
11.45 The ionosphere lies about 100 km above Earth's surface. This layer consists mostly of NO, O_2, and N_2, and photoionization creates NO^+, O_2^+, and N_2^+. (a) Use MO theory to compare the bond orders of the molecules and ions. (b) Does the magnetic behavior of each species change when its ion forms?

11.46 Glyphosate (*below*) is a common herbicide that is relatively harmless to animals but deadly to most plants. Describe the shape around and the hybridization of the P, N, and three numbered C atoms.



11.47 The sulfate ion can be represented with four S—O bonds or with two S—O and two S=O bonds. (a) Which representation is better from the standpoint of formal charges? (b) What is the shape of the sulfate ion, and what hybrid orbitals of S are postulated for the σ bonding? (c) In view of the answer to part (b), what orbitals of S must be used for the π bonds? What orbitals of O? (d) Draw a diagram to show how one atomic orbital from S and one from O overlap to form a π bond.

11.48 Tryptophan is one of the amino acids found in proteins:



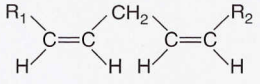
(a) What is the hybridization of each of the numbered C, N, and O atoms?
(b) How many σ bonds are present in tryptophan?
(c) Predict the bond angles at points a, b, and c.

11.49 Sulfur forms oxides, oxoanions, and halides. What is the hybridization of the central S in SO_2, SO_3, SO_3^{2-}, SCl_4, SCl_6, and S_2Cl_2 (atom sequence Cl—S—S—Cl)?

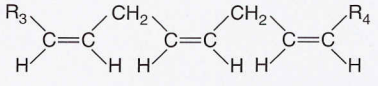
11.50 The hydrocarbon allene, $H_2C{=}C{=}CH_2$, is obtained indirectly from petroleum and used as a precursor for several types of plastics. What is the hybridization of each C atom in allene? Draw a bonding picture for allene with lines for σ bonds, and show the arrangement of the π bonds. Be sure to represent the geometry of the molecule in three dimensions.

11.51 Some species with two oxygen atoms only are the oxygen molecule, O_2, the peroxide ion, O_2^{2-}, the superoxide ion, O_2^-, and the dioxygenyl ion, O_2^+. Draw an MO diagram for each, rank them in order of increasing bond length, and find the number of unpaired electrons in each.

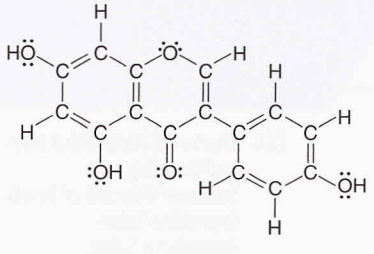
11.52 Linoleic acid is an essential fatty acid found in many vegetable oils, such as soy, peanut, and cottonseed. A key structural feature of the molecule is the *cis* orientation around its two double bonds, where R_1 and R_2 represent two different groups that form the rest of the molecule.



(a) How many different compounds are possible, changing only the *cis-trans* arrangements around these two double bonds?
(b) How many are possible for a similar compound with three double bonds?



11.53 There is concern in health-related government agencies that the American diet contains too much meat, and numerous recommendations have been made urging people to consume more fruit and vegetables. One of the richest sources of vegetable protein is soy, available in many forms. Among these is soybean curd, or tofu, which is a staple of many Asian diets. Chemists have isolated an anticancer agent called *genistein* from tofu, which may explain the much lower incidence of cancer among people in the Far East. A valid Lewis structure for genistein is

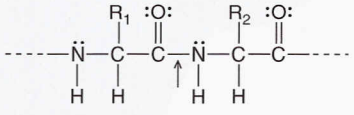


(a) Is the hybridization of each C in the right-hand ring the same? Explain.
(b) Is the hybridization of the O atom in the center ring the same as that of the O atoms in OH groups? Explain.
(c) How many carbon-oxygen σ bonds are there? How many carbon-oxygen π bonds?
(d) Do all the lone pairs on oxygens occupy the same type of hybrid orbital? Explain.

11.54 Molecular nitrogen, carbon monoxide, and cyanide ion are isoelectronic. (a) Draw an MO diagram for each. (b) CO and CN^- are toxic. What property may explain why N_2 isn't?

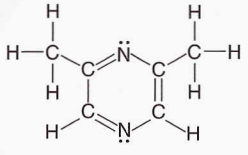
11.55 Silicon tetrafluoride reacts with F^- to produce the hexafluorosilicate ion, SiF_6^{2-}; GeF_4 behaves similarly, but CF_4 does not. (a) Draw Lewis structures for SiF_4, GeF_6^{2-}, and CF_4. (b) What is the hybridization of the central atom in each species? (c) Why doesn't CF_4 react with F^- to form CF_6^{2-}?

11.56 Simple proteins consist of amino acids linked together in a long chain; a small portion of such a chain is



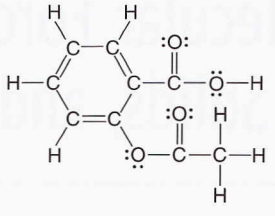
Experiment shows that rotation about the C—N bond (indicated by the arrow) is somewhat restricted. Explain with resonance structures, and show the types of bonding involved.

11.57 The compound 2,6-dimethylpyrazine gives chocolate its odor and is used in flavorings. A valid Lewis structure is

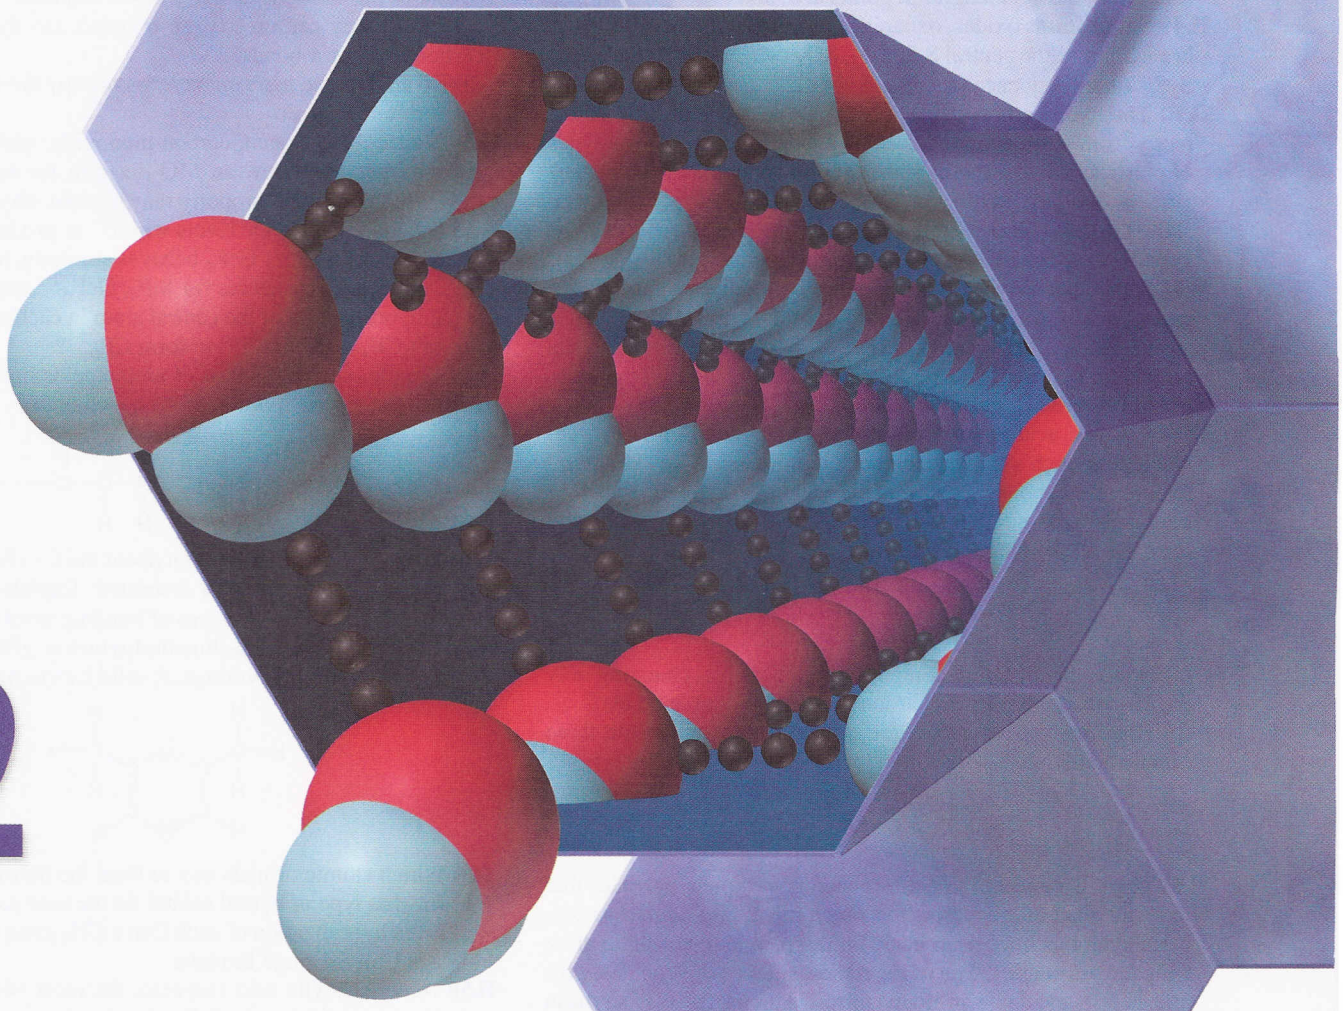


(a) Which atomic orbitals mix to form the hybrid orbitals of N?
(b) In what type of hybrid orbital do the lone pairs of N reside?
(c) Is the hybridization of each C in a CH_3 group the same as that of each C in the ring? Explain.

11.58 Acetylsalicylic acid (aspirin), the most widely used medicine in the world, has the following Lewis structure:



(a) What is the hybridization of each C and each O atom?
(b) How many localized π bonds are present?
(c) How many C atoms have a trigonal planar shape around them? A tetrahedral shape?



Solid water This molecular-scale view reveals the hexagonal order of crystalline water. When the solid melts, this order becomes chaos. In this chapter, we focus on the forces among the molecules that give rise to the liquid and solid states and highlight the unique physical behavior of each state and its applications to everyday life.

Intermolecular Forces: Liquids, Solids, and Phase Changes

12.1 **An Overview of Physical States and Phase Changes**

12.2 **Quantitative Aspects of Phase Changes**
- Heat Involved in Phase Changes
- Equilibrium Nature of Phase Changes
- Phase Diagrams

12.3 **Types of Intermolecular Forces**
- Ion-Dipole Forces
- Dipole-Dipole Forces
- The Hydrogen Bond
- Charge-Induced Dipole Forces
- Dispersion (London) Forces

12.4 **Properties of the Liquid State**
- Surface Tension
- Capillarity
- Viscosity

12.5 **The Uniqueness of Water**
- Solvent Properties
- Thermal Properties
- Surface Properties
- Density of Solid and Liquid Water

12.6 **The Solid State: Structure, Properties, and Bonding**
- Structural Features of Solids
- Crystalline Solids
- Amorphous Solids
- Bonding in Solids

12.7 **Advanced Materials**
- Electronic Materials
- Liquid Crystals
- Ceramic Materials
- Polymeric Materials
- Nanotechnology

All the matter around you occurs in one of three physical states—gas, liquid, or solid. Under specific conditions, many pure substances can exist in any of the states. We're all familiar with the three states of water: we inhale and exhale gaseous water; drink, excrete, and wash with liquid water; and shovel, slide on, or cool our drinks with solid water. Look around and you'll find other examples of solids (jewelry, table salt), liquids (gasoline, antifreeze), and gases (air, CO_2 bubbles) that can exist in one or both of the other states, even though the conditions needed may be unusual.

The three states were introduced in Chapter 1 and their properties compared when we examined gases in Chapter 5; now we turn our attention to liquids and solids. A physical state is one type of **phase,** any physically distinct, homogeneous part of a system. The water in a glass constitutes a single phase. Add some ice and you have two phases; or, if there are bubbles in the ice, you have three.

Liquids and solids are called *condensed* phases (or condensed states) because their particles are extremely close together. Electrostatic forces among the particles, called *interparticle forces* or, more commonly, **intermolecular forces,** combine with the particles' kinetic energy to create the properties of each phase as well as **phase changes,** the changes from one phase to another.

IN THIS CHAPTER . . . We begin with a kinetic-molecular overview of the states and then take a similarly close-up view of phase changes. We calculate the energy involved in phase changes and highlight the effects of temperature and pressure with *phase diagrams.* We consider the types of intermolecular forces and apply them first to the properties of liquids. We see how the unique physical properties of water arise inevitably from the electron configurations of its atoms. Then we discuss the properties of solids, emphasizing the relationship between type of bonding and intermolecular force. You will learn how the atomic-scale structures of solids are determined and, in the final section, how some exciting modern materials—semiconductors, liquid crystals, ceramics, polymers, and nanostructures—are produced and used.

Concepts & Skills to Review

before you study this chapter

- properties of gases, liquids, and solids (Section 5.1)
- kinetic-molecular theory of gases (Section 5.6)
- kinetic and potential energy (Section 6.1)
- enthalpy change, heat capacity, and Hess's law (Sections 6.2, 6.3, and 6.5)
- Coulomb's law (Section 9.2)
- chemical bonding models (Chapter 9)
- molecular polarity (Section 10.3)
- molecular orbital treatment of diatomic molecules (Section 11.3)

12.1 AN OVERVIEW OF PHYSICAL STATES AND PHASE CHANGES

Imagine yourself among the particles of a molecular substance, HF, and you'll discover two types of electrostatic forces at work:

- *Intra*molecular forces (bonding forces) exist *within* each molecule and influence the *chemical* properties of the substance.
- *Inter*molecular forces (nonbonding forces) exist *between* the molecules and influence the *physical* properties of the substance.

Now imagine a molecular view of the three states of water, as an example, and focus on just one molecule from each state. They look identical—bent, polar H—O—H molecules. In fact, the *chemical* behavior of the three states *is* identical because their molecules are held together by the same *intra*molecular bonding forces. However, the *physical* behavior of the states differs greatly because the strengths of the *inter*molecular nonbonding forces differ greatly.

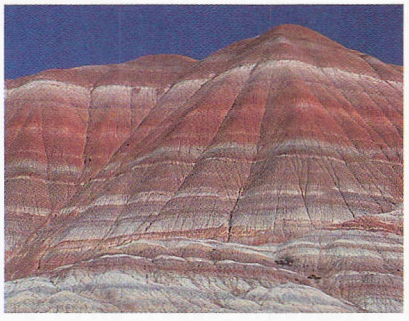
A Kinetic-Molecular View of the Three States Whether a substance is a gas, liquid, or solid depends on the interplay of the potential energy of the intermolecular attractions, which tends to draw the molecules together, and the kinetic energy of the molecules, which tends to disperse them. According to Coulomb's law, the potential energy depends on the charges of the particles and the distances between them (see Section 9.2). The average kinetic energy, which is related to the particles' average speed, is proportional to the absolute temperature.

Table 12.1 A Macroscopic Comparison of Gases, Liquids, and Solids

State	Shape and Volume	Compressibility	Ability to Flow
Gas	Conforms to shape and volume of container	High	High
Liquid	Conforms to shape of container; volume limited by surface	Very low	Moderate
Solid	Maintains its own shape and volume	Almost none	Almost none

In Table 12.1, we distinguish among the three states by focusing on three properties—shape, compressibility, and ability to flow. The following kinetic-molecular view of the three states is an extension of the model we used to understand gases (see Section 5.6):

- *In a gas,* the energy of attraction is small relative to the energy of motion; so, on average, the particles are far apart. This large interparticle distance has several macroscopic consequences. A gas moves randomly throughout its container and fills it. Gases are highly compressible, and they flow and diffuse easily through one another.
- *In a liquid,* the attractions are stronger because the particles are in virtual contact. But their kinetic energy still allows them to tumble randomly over and around each other. Therefore, a liquid conforms to the shape of its container but has a surface. With very little free space between the particles, liquids resist an applied external force and thus compress only very slightly. They flow and diffuse but *much* more slowly than gases.
- *In a solid,* the attractions dominate the motion so much that the particles remain in position relative to one another, jiggling in place. With the positions of the particles fixed, a solid has a specific shape and does not flow significantly. The particles are usually slightly closer together than in a liquid, so solids compress even less than liquids.



Environmental Flow The environment demonstrates beautifully the differences in the abilities of the three states to flow and diffuse. Atmospheric gases mix so well that the 80 km of air closest to Earth's surface has a uniform composition. Much less mixing occurs in the oceans, and differences in composition at various depths support different species. Rocky solids (see photo) intermingle so little that adjacent strata remain separated for millions of years.

Types of Phase Changes Phase changes are also determined by the interplay between kinetic energy and intermolecular forces. As the temperature increases, the average kinetic energy increases as well, so the faster moving particles can overcome attractions more easily; conversely, lower temperatures allow the forces to draw the slower moving particles together.

What happens when gaseous water is cooled? A mist appears as the particles form tiny microdroplets that then collect into a bulk sample of liquid with a single surface. The process by which a gas changes into a liquid is called **condensation;** the opposite process, changing from a liquid into a gas, is called **vaporization.** With further cooling, the particles move even more slowly and become fixed in position as the liquid solidifies in the process of **freezing;** the opposite change is called **melting,** or **fusion.** In common speech, the term *freezing* implies low temperature because we typically think of water. But, most metals, for example, freeze (solidify) at much higher temperatures, and this change has many medical, industrial, and artistic applications: gold dental crowns, steel auto bodies, bronze statues, and so forth.

Enthalpy changes accompany phase changes. As the molecules of a gas attract each other and come closer together in the liquid, and then become fixed in the solid, the system of particles loses energy, which is released as heat. Thus, *condensing and freezing are exothermic changes.* On the other hand, energy must be absorbed to overcome the attractive forces that keep the particles in a liquid

together and those that keep them fixed in place in a solid. Thus, *melting and vaporizing are endothermic changes.*

For a pure substance, each phase change has a specific enthalpy change *per mole* (measured at 1 atm and the temperature of the change). For vaporization, it is called the **heat of vaporization (ΔH^0_{vap}),** and for fusion, it is the **heat of fusion (ΔH^0_{fus}).** In the case of water, we have

$$H_2O(l) \longrightarrow H_2O(g) \qquad \Delta H = \Delta H^0_{vap} = 40.7 \text{ kJ/mol (at 100°C)}$$
$$H_2O(s) \longrightarrow H_2O(l) \qquad \Delta H = \Delta H^0_{fus} = 6.02 \text{ kJ/mol (at 0°C)}$$

The reverse processes, condensing and freezing, have enthalpy changes of the *same magnitude but opposite sign:*

$$H_2O(g) \longrightarrow H_2O(l) \qquad \Delta H = -\Delta H^0_{vap} = -40.7 \text{ kJ/mol}$$
$$H_2O(l) \longrightarrow H_2O(s) \qquad \Delta H = -\Delta H^0_{fus} = -6.02 \text{ kJ/mol}$$

Water is typical of most pure substances in that it takes less energy to melt 1 mol of solid water than to vaporize 1 mol of liquid water: $\Delta H^0_{fus} < \Delta H^0_{vap}$. Figure 12.1 shows several examples. The reason is that a phase change is essentially a change in intermolecular distance and freedom of motion. Less energy is needed to overcome the forces holding the molecules in fixed positions (melt a solid) than to separate them completely from each other (vaporize a liquid).

The three states of water are so common because they all are stable under ordinary conditions. Carbon dioxide, on the other hand, is familiar as a gas and a solid (dry ice), but liquid CO_2 occurs only at external pressures greater than 5 atm. At ordinary conditions, solid CO_2 becomes a gas without first becoming a liquid. This process is called **sublimation.** On a clear wintry day, you can dry clothes outside on a line, even though it may be too cold for ice to melt, because the ice sublimes. Freeze-dried foods are prepared by sublimation. The opposite process, changing from a gas directly into a solid, is called **deposition**—you may have seen ice crystals form on a cold window from the deposition of water vapor. The **heat of sublimation (ΔH^0_{subl})** is the enthalpy change when 1 mol of a substance sublimes. From Hess's law, it equals the sum of the heats of fusion and vaporization:

$$\begin{array}{lll} \text{Solid} \longrightarrow \text{liquid} & & \Delta H^0_{fus} \\ \text{Liquid} \longrightarrow \text{gas} & & \Delta H^0_{vap} \\ \hline \text{Solid} \longrightarrow \text{gas} & & \Delta H^0_{subl} \end{array}$$

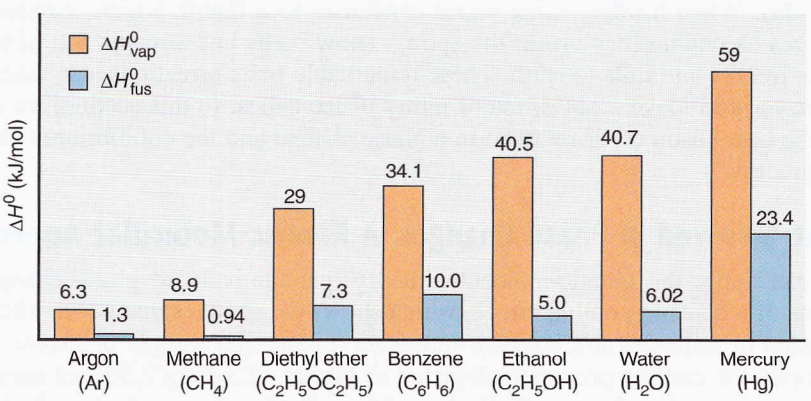


Figure 12.1 Heats of vaporization and fusion for several common substances. ΔH^0_{vap} is always larger than ΔH^0_{fus} because it takes more energy to separate particles completely than just to free them from their fixed positions in the solid.

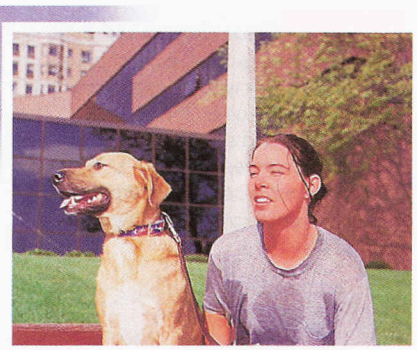

A Cooling Phase Change The evaporation of sweat has a cooling effect because heat from your body is used to vaporize the water. Many fur-covered animals achieve this cooling effect, too. Cats (and many rodents) lick themselves, transferring water from inside their bodies to the surface where it can evaporate, and dogs just open their mouths, hang out their tongues, and pant!

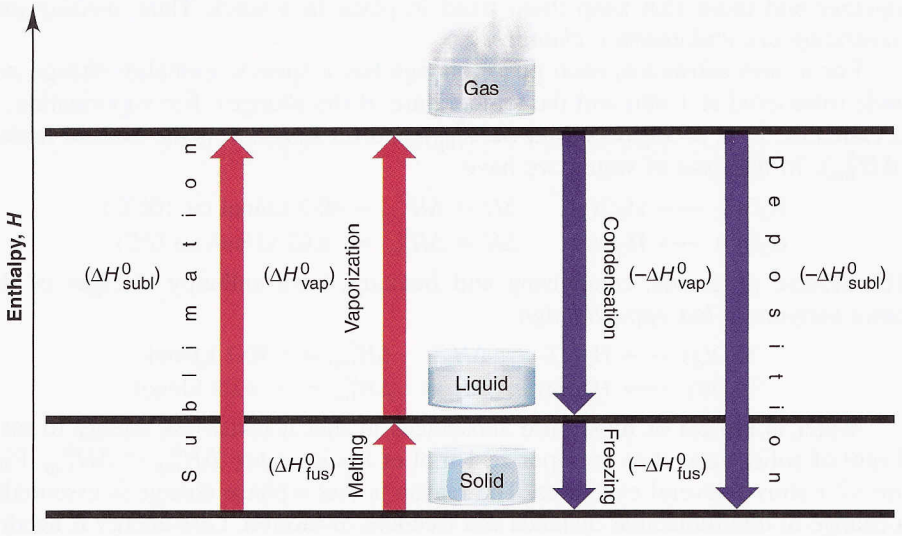

Figure 12.2 Phase changes and their enthalpy changes. Each type of phase change is shown with its associated enthalpy change. Fusion (or melting), vaporization, and sublimation are endothermic changes (positive ΔH^0), whereas freezing, condensation, and deposition are exothermic changes (negative ΔH^0).

Online Learning Center

Figure 12.2 summarizes the terminology of the various phase changes and shows the enthalpy changes associated with them.

SECTION SUMMARY

Because of the relative magnitudes of intermolecular forces and kinetic energy, the particles in a gas are far apart and moving randomly, those in a liquid are in contact but still moving relative to each other, and those in a solid are in contact and fixed relative to one another in a rigid structure. These molecular-level differences in the states of matter account for macroscopic differences in shape, compressibility, and ability to flow. When a solid becomes a liquid (melting, or fusion) or a liquid becomes a gas (vaporization), energy is absorbed to overcome intermolecular forces and increase the average distance between particles. When particles come closer together in the reverse changes (freezing and condensation), energy is released. Sublimation is the changing of a solid directly into a gas. Each phase change is associated with a given enthalpy change under specified conditions.

12.2 QUANTITATIVE ASPECTS OF PHASE CHANGES

Some of the most spectacular, and familiar, phase changes occur in the weather each day. When it rains, water vapor condenses to a liquid, which changes back to a gas as puddles dry up. In the spring, snow melts and streams fill; in winter, water freezes and falls to earth. These remarkable transformations also take place whenever you make a pot of tea or a tray of ice cubes. In this section, we examine the heat absorbed or released in a phase change and the equilibrium nature of the process.

Heat Involved in Phase Changes: A Kinetic-Molecular Approach

We can apply the kinetic-molecular theory quantitatively to phase changes by means of a **heating-cooling curve,** which shows the changes that occur when heat is added or removed at a constant rate from a particular sample of matter. As an example, the cooling process is depicted in Figure 12.3 for a 2.50-mol sample of gaseous water in a piston-cylinder assembly, with the pressure kept at 1 atm and the temperature changing from 130°C to −40°C. To an observer, the process is continuous, but we can divide it into five heat-releasing (exothermic) stages that correspond to the five portions of the curve—the gas cools, it condenses to a liquid, the liquid cools, it freezes to a solid, and the solid cools a bit further:

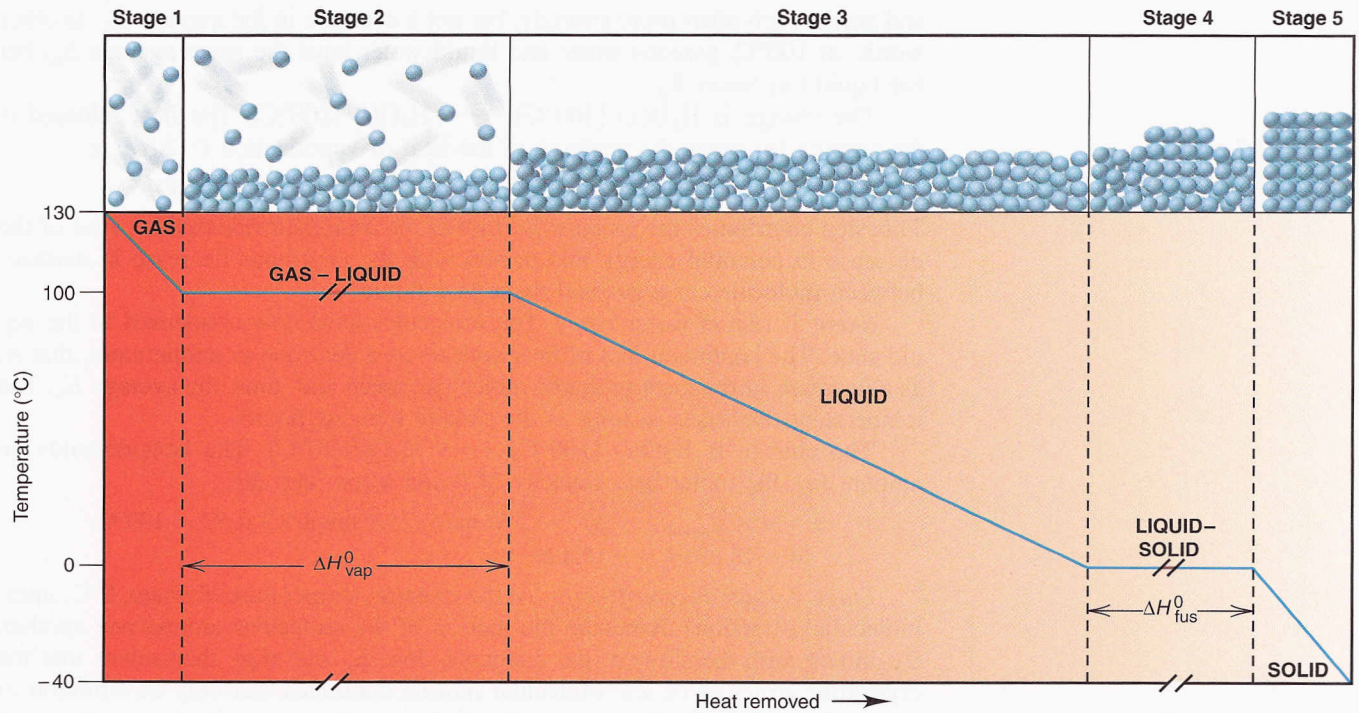

Figure 12.3 A cooling curve for the conversion of gaseous water to ice. A plot is shown of temperature vs. heat removed as gaseous water at 130°C changes to ice at −40°C. This process occurs in five stages, with a molecular-level depiction shown for each stage. Stage 1: Gaseous water cools. Stage 2: Gaseous water condenses. Stage 3: Liquid water cools. Stage 4: Liquid water freezes. Stage 5: Solid water cools. The slopes of the lines in stages 1, 3, and 5 reflect the magnitudes of the molar heat capacities of the phases. Although not drawn to scale, the line in stage 2 is longer than the line in stage 4 because ΔH^0_{vap} of water is greater than ΔH^0_{fus}. A plot of temperature vs. heat added would have the same steps but in reverse order.

Stage 1. Gaseous water cools. Picture a collection of water molecules behaving like a typical gas: zooming around chaotically at a range of speeds, smashing into each other and the container walls. At a high enough temperature, the most probable speed, and thus the average kinetic energy (E_k), of the molecules is high enough to overcome the potential energy (E_p) of attractions among them. As the temperature falls, the average E_k decreases, so the attractions become increasingly important.

The change is $H_2O(g)$ [130°C] ⟶ $H_2O(g)$ [100°C]. The heat (q) is the product of the amount (number of moles, n) of water, the molar heat capacity of *gaseous water,* $C_{water(g)}$, and the temperature change, ΔT ($T_{final} - T_{initial}$):

$$q = n \times C_{water(g)} \times \Delta T = (2.50 \text{ mol})\ (33.1 \text{ J/mol·°C})\ (100°C - 130°C)$$
$$= -2482 \text{ J} = -2.48 \text{ kJ}$$

The minus sign indicates that heat is released. (For purposes of canceling, the units for molar heat capacity, C, include °C, rather than K. The magnitude of C is not affected because the kelvin and the Celsius degree represent the same temperature increment.)

Stage 2. Gaseous water condenses. At the condensation point, the slowest of the molecules are near each other long enough for intermolecular attractions to form groups of molecules, which aggregate into microdroplets and then a bulk liquid. Note that while the state is changing from gas to liquid, *the temperature remains constant,* so the average E_k is constant. This means that, even though molecules in a gas certainly move *farther* between collisions than those in a liquid, their average *speed* is the same at a given temperature. Thus, removing heat from the system involves a decrease in the average E_p, as the molecules approach

and attract each other more strongly, but not a decrease in the average E_k. In other words, at 100°C, gaseous water and liquid water have the same average E_k, but the liquid has lower E_p.

The change is $H_2O(g)$ [100°C] $\longrightarrow$ $H_2O(l)$ [100°C]. The heat released is the amount (n) times the negative of the heat of vaporization ($-\Delta H^0_{vap}$):

$$q = n(-\Delta H^0_{vap}) = (2.50 \text{ mol}) (-40.7 \text{ kJ/mol}) = -102 \text{ kJ}$$

This step contributes the *greatest portion of the total heat released* because of the decrease in potential energy that occurs with the enormous decrease in distance between molecules in a gas and those in a liquid.

Stage 3. Liquid water cools. The molecules have now condensed to the liquid state. The continued loss of heat appears as a decrease in temperature, that is, as a decrease in the most probable molecular speed and, thus, the average E_k. The temperature decreases as long as the sample remains liquid.

The change is $H_2O(l)$ [100°C] $\longrightarrow$ $H_2O(l)$ [0°C]. The heat depends on amount (n), the molar heat capacity of *liquid water,* and ΔT:

$$q = n \times C_{water(l)} \times \Delta T = (2.50 \text{ mol}) (75.4 \text{ J/mol·°C}) (0°C - 100°C)$$
$$= -18{,}850 \text{ J} = -18.8 \text{ kJ}$$

Stage 4. Liquid water freezes. At the freezing temperature of water, 0°C, intermolecular attractions overcome the motion of the molecules around one another. Beginning with the slowest, the molecules lose E_p and align themselves into the crystalline structure of ice. Molecular motion continues, but only as vibration of atoms about their fixed positions. As during condensation, the temperature and average E_k remain constant during freezing.

The change is $H_2O(l)$ [0°C] $\longrightarrow$ $H_2O(s)$ [0°C]. The heat released is n times the negative of the heat of fusion ($-\Delta H^0_{fus}$):

$$q = n(-\Delta H^0_{fus}) = (2.50 \text{ mol}) (-6.02 \text{ kJ/mol}) = -15.0 \text{ kJ}$$

Stage 5. Solid water cools. With motion restricted to jiggling in place, further cooling merely reduces the average speed of this jiggling.

The change is $H_2O(s)$ [0°C] $\longrightarrow$ $H_2O(s)$ [−40°C]. The heat released depends on n, the molar heat capacity of *solid water,* and ΔT:

$$q = n \times C_{water(s)} \times \Delta T = (2.50 \text{ mol}) (37.6 \text{ J/mol·°C}) (-40°C - 0°C)$$
$$= -3760 \text{ J} = -3.76 \text{ kJ}$$

According to Hess's law, the total heat released is the sum of the heats released for the individual stages. The sum of q for stages 1 to 5 is −142 kJ.

Two key points stand out in this or any similar process (at constant pressure), whether exothermic or endothermic:

- *Within a phase,* a change in heat is accompanied by *a change in temperature,* which is associated with a change in average E_k as *the most probable speed of the molecules changes.* The heat lost or gained depends on the amount of substance, the molar heat capacity for that phase, and the change in temperature.
- *During a phase change,* a change in heat occurs at a *constant temperature,* which is associated with a change in E_p, as *the average distance between molecules changes.* Both physical states are present during a phase change. The heat lost or gained depends on the amount of substance and the enthalpy of the phase change (ΔH^0_{vap} or ΔH^0_{fus}).

The Equilibrium Nature of Phase Changes

In everyday experience, phase changes take place in open containers—the outdoors, a pot on a stove, the freezer compartment of a refrigerator—so such a change is not reversible. In a closed container under controlled conditions, however, *phase changes of many substances are reversible and reach equilibrium,* just as chemical changes do.

Liquid-Gas Equilibria Picture an *open* flask containing a pure liquid at constant temperature and focus on the molecules at the surface. Within their range of molecular speeds, some are moving fast enough and in the right direction to overcome attractions, so they vaporize. Nearby molecules immediately fill the gap, and with energy supplied by the constant-temperature surroundings, the process continues until the entire liquid phase is gone.

Now picture starting with a *closed* flask at constant temperature, as in Figure 12.4A, and assume that a vacuum exists above the liquid. As before, some of the molecules at the surface have a high enough E_k to vaporize. As the number of molecules in the vapor phase increases, the pressure of the vapor increases. At the same time, some of the molecules in the vapor that collide with the surface have a low enough E_k to become attracted too strongly to leave the liquid and they condense. For a given surface area, the number of molecules that make up the surface is constant; therefore, the rate of vaporization—the number of molecules leaving the surface per unit time—is also constant. On the other hand, as the vapor becomes more populated, molecules collide with the surface more often, so the rate of condensation slowly increases. As condensation continues to offset vaporization, the increase in the pressure of the vapor slows. Eventually, the rate of condensation equals the rate of vaporization, as depicted in Figure 12.4B. From this time onward, *the pressure of the vapor is constant at that temperature.* Macroscopically, the situation seems static, but at the molecular level, molecules are entering and leaving the liquid surface at equal rates. The system has reached a state of *dynamic equilibrium:*

$$\text{Liquid} \rightleftharpoons \text{gas}$$

Figure 12.4C depicts the entire process graphically.

The pressure exerted by the vapor at equilibrium is called the *equilibrium vapor pressure*, or just the **vapor pressure,** of the liquid at that temperature. If we use a larger flask, more molecules are present in the gas phase at equilibrium; as long as some liquid remains, however, the vapor pressure does not change. Suppose we disturb this equilibrium system by pumping out some of the vapor at constant temperature, thereby lowering the pressure. (If this were a cylinder with piston, we could lower the pressure by moving the piston outward to increase the volume.) The rate of condensation temporarily falls below the rate of vaporization (the forward process is faster). Fewer molecules re-enter the liquid than leave it, so the pressure of the vapor rises until, after a short period, the condensation rate increases enough for equilibrium to be reached again. Similarly, if we disturb the system by pumping in additional vapor (or moving the piston inward to decrease the volume) at constant temperature, thereby raising the pressure, the rate of condensation temporarily exceeds the rate of vaporization. More molecules enter the liquid than leave it (the backward process is faster), but soon the condensation rate decreases, and the pressure again reaches the equilibrium value.

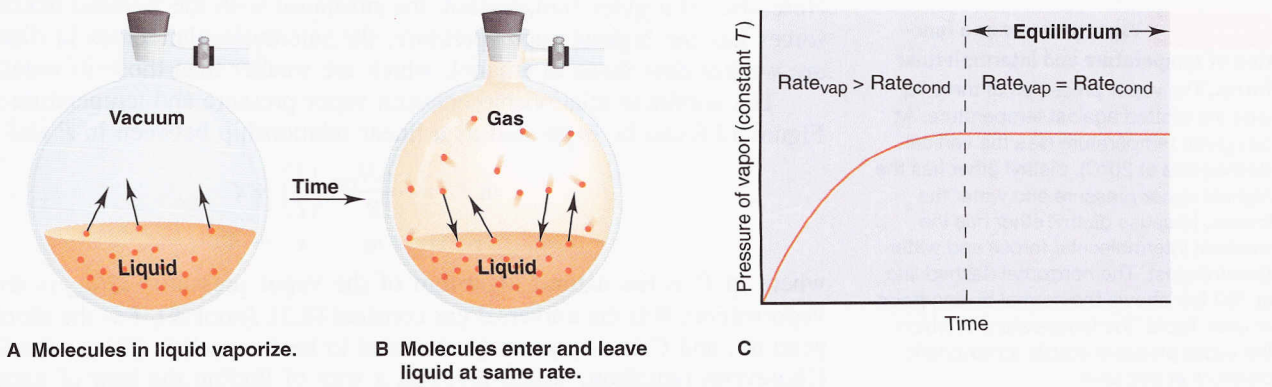

Figure 12.4 Liquid-gas equilibrium. **A,** In a closed flask at constant temperature with the air removed, the initial pressure is zero. As molecules leave the surface and enter the space above the liquid, the pressure of the vapor rises. **B,** At equilibrium, the same number of molecules leave as enter the liquid within a given time, so the pressure of the vapor reaches a constant value. **C,** A plot of pressure vs. time shows that the pressure of the vapor increases as long as the rate of vaporization is greater than the rate of condensation. At equilibrium, the rates are equal, so the pressure is constant. The pressure at this point is the *vapor pressure* of the liquid at that temperature.

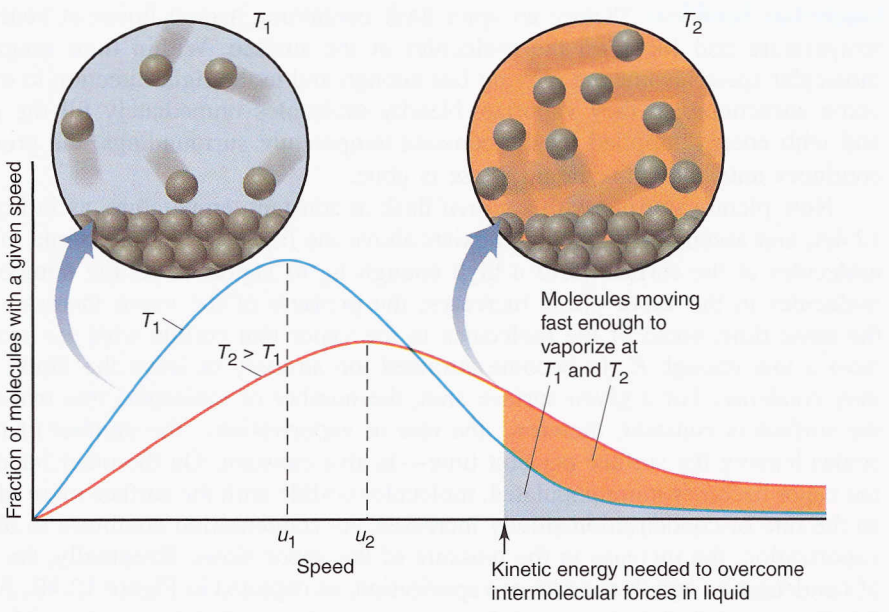

Figure 12.5 The effect of temperature on the distribution of molecular speeds in a liquid. With T_1 lower than T_2, the most probable molecular speed u_1 is less than u_2. (Note the similarity to Figure 5.14, p. 201.) The fraction of molecules with enough energy to escape the liquid *(shaded area)* is *greater at the higher temperature*. The molecular views show that at the higher T, equilibrium is reached with more gas molecules in the same volume and thus at a higher vapor pressure.

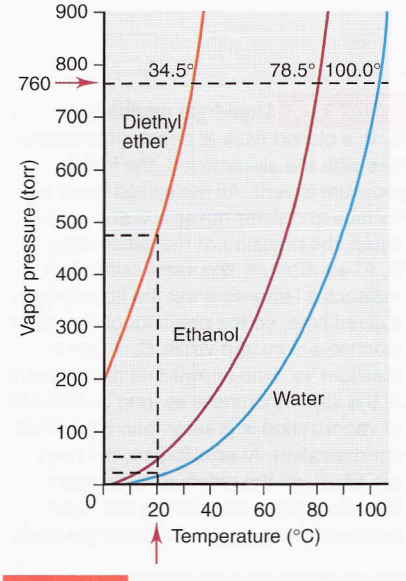

Figure 12.6 Vapor pressure as a function of temperature and intermolecular forces. The vapor pressures of three liquids are plotted against temperature. At any given temperature (see the vertical dashed line at 20°C), diethyl ether has the highest vapor pressure and water the lowest, because diethyl ether has the weakest intermolecular forces and water the strongest. The horizontal dashed line at 760 torr shows the normal boiling point of each liquid, the temperature at which the vapor pressure equals atmospheric pressure at sea level.

This behavior of a pure liquid in contact with its vapor is a general one for any system: *when a system at equilibrium is disturbed, it counteracts the disturbance and eventually re-establishes a state of equilibrium.* We'll return to this key idea often in later chapters.

The Effects of Temperature and Intermolecular Forces on Vapor Pressure The vapor pressure of a substance depends on the temperature. Raising the temperature of a liquid *increases* the fraction of molecules moving fast enough to escape the liquid and *decreases* the fraction moving slowly enough to be recaptured. This important idea is shown in Figure 12.5. In general, *the higher the temperature is, the higher the vapor pressure.*

The vapor pressure also depends on the intermolecular forces present. The average E_k is the same for different substances at a given temperature. Therefore, molecules with weaker intermolecular forces vaporize more easily. In general, *the weaker the intermolecular forces are, the higher the vapor pressure.*

Figure 12.6 shows the vapor pressure of three liquids as a function of temperature. Notice that each curve rises more steeply as the temperature increases. Note also, at a given temperature, the substance with the weakest intermolecular forces has the highest vapor pressure: the intermolecular forces in diethyl ether are weaker than those in ethanol, which are weaker than those in water.

The nonlinear relationship between vapor pressure and temperature shown in Figure 12.6 can be expressed as a linear relationship between ln P and $1/T$:

$$\ln P = \frac{-\Delta H_{vap}}{R}\left(\frac{1}{T}\right) + C$$
$$y = m \quad x + b$$

where ln P is the natural logarithm of the vapor pressure, ΔH_{vap} is the heat of vaporization, R is the universal gas constant (8.31 J/mol·K), T is the absolute temperature, and C is a constant (not related to heat capacity). This is the **Clausius-Clapeyron equation,** which gives us a way of finding the heat of vaporization,

the energy needed to vaporize 1 mol of molecules in the liquid state. The blue equation beneath the Clausius-Clapeyron equation is the equation for a straight line, where $y = \ln P$, $x = 1/T$, m (the slope) $= -\Delta H_{vap}/R$, and b (the y-axis intercept) $= C$. Figure 12.7 shows plots for diethyl ether and water. A two-point version of the equation allows a nongraphical determination of ΔH_{vap}:

$$\ln \frac{P_2}{P_1} = \frac{-\Delta H_{vap}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \qquad (12.1)$$

If ΔH_{vap} and P_1 at T_1 are known, we can calculate the vapor pressure (P_2) at any other temperature (T_2) or the temperature at any other pressure.

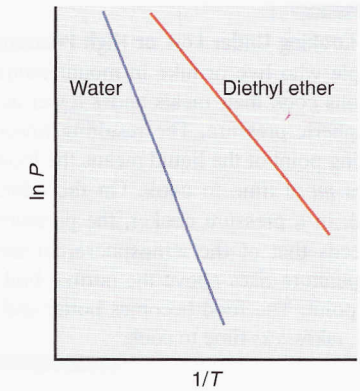

Figure 12.7 A linear plot of the relationship between vapor pressure and temperature. The Clausius-Clapeyron equation gives a straight line when the natural logarithm of the vapor pressure (ln P) is plotted against the inverse of the absolute temperature ($1/T$). The slopes ($-\Delta H_{vap}/R$) allow determination of the heats of vaporization of the two liquids. Note that the slope is steeper for water because its ΔH_{vap} is greater.

SAMPLE PROBLEM 12.1 Using the Clausius-Clapeyron Equation

Problem The vapor pressure of ethanol is 115 torr at 34.9°C. If ΔH_{vap} of ethanol is 40.5 kJ/mol, calculate the temperature (in °C) when the vapor pressure is 760 torr.

Plan We are given ΔH_{vap}, P_1, P_2, and T_1 and substitute them into Equation 12.1 to solve for T_2. The value of R here is 8.31 J/mol·K, so we must convert T_1 to K to obtain T_2, and then convert T_2 to °C.

Solution Substituting the values into Equation 12.1 and solving for T_2:

$$\ln \frac{P_2}{P_1} = \frac{-\Delta H_{vap}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

$$T_1 = 34.9°C + 273.15 = 308.0\ K$$

$$\ln \frac{760\ torr}{115\ torr} = \left(-\frac{40.5\times10^3\ J/mol}{8.314\ J/mol\cdot K}\right)\left(\frac{1}{T_2} - \frac{1}{308.0\ K}\right)$$

$$1.888 = (-4.87\times10^3)\left[\frac{1}{T_2} - (3.247\times10^{-3})\right]$$

$$T_2 = 350.\ K$$

Converting T_2 from K to °C:

$$T_2 = 350.\ K - 273.15 = 77°C$$

Check Round off to check the math. The change is in the right direction: higher P should occur at higher T. As we discuss next, a substance has a vapor pressure of 760 torr at its normal boiling point. Checking the *CRC Handbook of Chemistry and Physics* shows that the boiling point of ethanol is 78.5°C, very close to our answer.

FOLLOW-UP PROBLEM 12.1 At 34.1°C, the vapor pressure of water is 40.1 torr. What is the vapor pressure at 85.5°C? The ΔH_{vap} of water is 40.7 kJ/mol.

Vapor Pressure and Boiling Point In an *open* container, the atmosphere bears down on the liquid surface. As the temperature rises, molecules leave the surface more often, and they also move more quickly throughout the liquid. At some temperature, the average E_k of the molecules in the liquid is great enough for bubbles of vapor to form *in the interior,* and the liquid boils. At any lower temperature, the bubbles collapse as soon as they start to form because the external pressure is greater than the vapor pressure inside the bubbles. Thus, the **boiling point** is *the temperature at which the vapor pressure equals the external pressure,* usually that of the atmosphere. Once boiling begins, the temperature remains constant until the liquid phase is gone because the applied heat is used by the molecules to overcome attractions and enter the gas phase.

The boiling point varies with elevation, because the atmospheric pressure does. At high elevations, a lower pressure is exerted on the liquid surface, so molecules in the interior need less kinetic energy to form bubbles. At low elevations, the opposite is true. Thus, *the boiling point depends on the applied pressure.* The *normal boiling point* is observed at standard atmospheric pressure (760 torr, or 101.3 kPa; see the horizontal dashed line in Figure 12.6).

Cooking Under Low or High Pressure People who live or hike in mountainous regions cook their meals under lower atmospheric pressure. The resulting lower boiling point of the liquid means the food takes *more* time to cook. On the other hand, in a pressure cooker, the pressure exceeds that of the atmosphere, so the temperature rises above the normal boiling point. The food becomes hotter and, thus, takes *less* time to cook.

Since the boiling point is the temperature at which the vapor pressure equals the external pressure, we can also interpret the curves in Figure 12.6 as a plot of external pressure vs. boiling point. For instance, the H_2O curve shows that water boils at 100°C at 760 torr (sea level), at 94°C at 610 torr (Boulder, Colorado), and at about 72°C at 270 torr (top of Mt. Everest).

Solid-Liquid Equilibria At the molecular level, the particles in a crystal are continually vibrating about their fixed positions. As the temperature rises, the particles vibrate more violently, until some have enough kinetic energy to break free of their positions, and melting begins. As more molecules enter the liquid (molten) phase, some collide with the solid and become fixed again. Because the phases remain in contact, a dynamic equilibrium is established when the melting rate equals the freezing rate. The temperature at which this occurs is the **melting point;** it is the same temperature as the freezing point, differing only in the direction of the energy flow. As with the boiling point, the temperature remains at the melting point as long as both phases are present.

Because liquids and solids are nearly incompressible, a change in pressure has little effect on the rate of movement to or from the solid. Therefore, in contrast to the boiling point, the melting point is affected by pressure only very slightly, and a plot of pressure (*y* axis) vs. temperature (*x* axis) for a solid-liquid phase change is typically a straight, *nearly* vertical line.

Solid-Gas Equilibria Solids have much lower vapor pressures than liquids. Sublimation, the process of a solid changing directly into a gas, is much less familiar than vaporization because the necessary conditions of pressure and temperature are uncommon for most substances. Some solids *do* have high enough vapor pressures to sublime at ordinary conditions, including dry ice (carbon dioxide), iodine (Figure 12.8), and solid room deodorizers. A substance sublimes rather than melts because the combination of intermolecular attractions and atmospheric pressure is not great enough to keep the particles near one another when they leave the solid state. The pressure vs. temperature plot for the solid-gas transition shows a large effect of temperature on the pressure of the vapor; thus, this curve resembles the liquid-gas line in curving upward at higher temperatures.

Figure 12.8 Iodine subliming. At ordinary atmospheric pressure, solid iodine sublimes (changes directly from a solid into a gas). When the I_2 vapor comes in contact with a cold surface, such as the water-filled inner test tube, it deposits I_2 crystals. Sublimation is a means of purification that, along with distillation, was probably discovered by alchemists.

Phase Diagrams: Effect of Pressure and Temperature on Physical State

To describe the phase changes of a substance at various conditions of temperature and pressure, we construct a **phase diagram,** which combines the liquid-gas, solid-liquid, and solid-gas curves. The shape of the phase diagram for CO_2 is typical for most substances (Figure 12.9A). A phase diagram has these four features:

1. *Regions of the diagram.* Each region corresponds to one phase of the substance. A particular phase is stable for any combination of pressure and temperature within its region. If any of the other phases is placed under those conditions, it will change to the stable phase. In general, the solid is stable at low temperature and high pressure, the gas at high temperature and low pressure, and the liquid at intermediate conditions.

2. *Lines between regions.* The lines separating the regions represent the phase-transition curves discussed earlier. Any point along a line shows the pressure and temperature at which the two phases exist in equilibrium. Note that the solid-liquid line has a *positive* slope (slants to the *right* with increasing pressure) because, for most substances, the solid is more dense than the liquid. Because the liquid occupies slightly more space than the solid, an increase in pressure favors the solid phase. (Water is the major exception, as you'll soon see.)

3. *The critical point.* The liquid-gas line ends at the **critical point.** Picture a liquid in a closed container. As it is heated, it expands, so its density decreases. At the same time, more liquid vaporizes, so the density of the vapor increases. The liquid and vapor densities become closer and closer to each other until, at

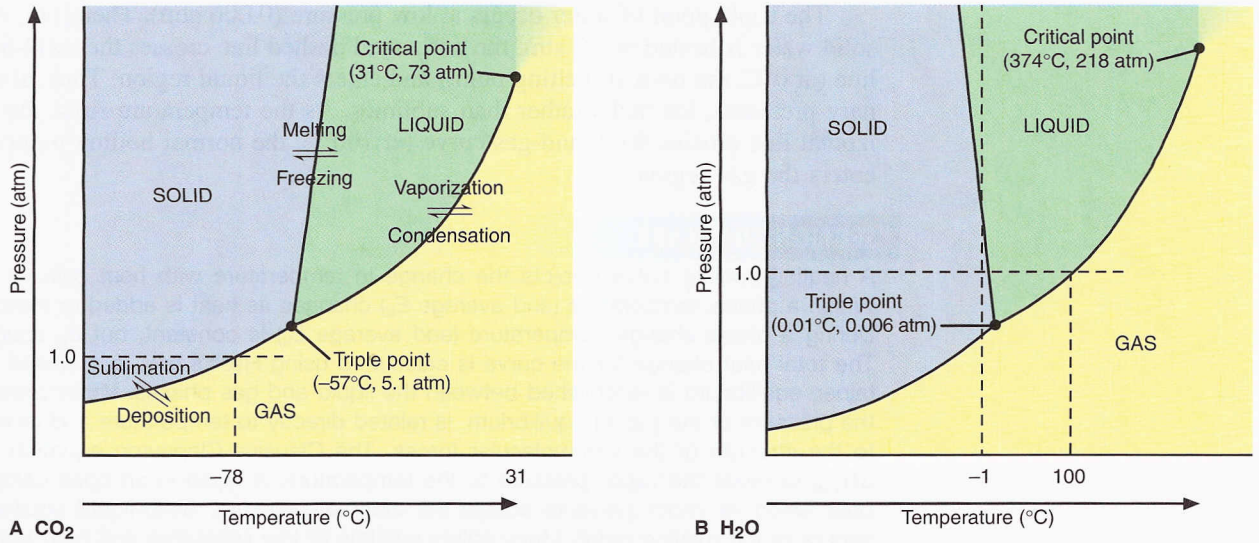

Figure 12.9 Phase diagrams for CO_2 and H_2O. Each region depicts the temperatures and pressures under which the phase is stable. Lines between two regions show conditions at which the two phases exist in equilibrium. The critical point shows conditions beyond which separate liquid and gas phases no longer exist. At the triple point, the three phases exist in equilibrium. (The axes are not linear.) **A,** The phase diagram for CO_2 is typical of most substances in that the solid-liquid line slopes to the right with increasing pressure: the solid is *more* dense than the liquid. **B,** Water is one of the few substances whose solid-liquid line slopes to the left with increasing pressure: the solid is *less* dense than the liquid. (The slopes of the solid-liquid lines in both diagrams are exaggerated.)

Animation: Phase Diagrams of the States of Matter
Online Learning Center

the *critical temperature* (T_c), the two densities are equal and the phase boundary disappears. The pressure at this temperature is the *critical pressure* (P_c). At this point, the average E_k of the molecules is so high that the vapor cannot be condensed no matter what pressure is applied. The two most common gases in air have critical temperatures far below room temperature: no matter what the pressure, O_2 will not condense above $-119°C$, and N_2 will not condense above $-147°C$. Beyond the critical temperature, a *supercritical fluid* exists rather than separate liquid and gaseous phases.

4. *The triple point.* The three phase-transition curves meet at the **triple point:** the pressure and temperature at which three phases are in equilibrium. As strange as it sounds, at the triple point in Figure 12.9A, CO_2 is subliming and depositing, melting and freezing, and vaporizing and condensing simultaneously! Phase diagrams for substances with several solid forms, such as sulfur, have more than one triple point.

The CO_2 phase diagram explains why dry ice (solid CO_2) doesn't melt under ordinary conditions. The triple-point pressure for CO_2 is 5.1 atm; therefore, at around 1 atm, liquid CO_2 does not occur. By following the horizontal dashed line in Figure 12.9A, you can see that when solid CO_2 is heated at 1.0 atm, it sublimes at $-78°C$ to gaseous CO_2 rather than melting. If normal atmospheric pressure were 5.2 atm, liquid CO_2 would be common.

The phase diagram for water differs in one key respect from the general case and reveals an extremely important property (Figure 12.9B). Unlike almost every other substance, solid water is *less dense* than liquid water. Because the solid occupies more space than the liquid, *water expands on freezing*. This behavior results from the unique open crystal structure of ice, which we discuss in a later section. As always, an increase in pressure favors the phase that occupies less space, but in the case of water, this is the *liquid* phase. Therefore, the solid-liquid line for water has a *negative* slope (slants to the *left* with increasing pressure): the higher the pressure, the lower the temperature at which water freezes. In Figure 12.9B, the vertical dashed line at $-1°C$ crosses the solid-liquid line, which means that ice melts at that temperature with only an increase in pressure.

The Remarkable Behavior of a Supercritical Fluid (SCF) What material lies beyond the familiar regions of liquid and gas? An SCF expands and contracts like a gas but has the solvent properties of a liquid, which chemists can alter by controlling the density. Supercritical CO_2 has received the most attention so far. It extracts nonpolar ingredients from complex mixtures, such as caffeine from coffee beans, nicotine from tobacco, and fats from potato chips, while leaving taste and aroma ingredients behind, for healthier consumer products. Lower the pressure and the SCF disperses immediately as a harmless gas. Supercritical CO_2 dissolves the fat from meat, along with pesticide and drug residues, which can then be quantified and monitored. It is being studied as an environmentally friendly dry cleaning agent. In an unexpected finding of great potential use, supercritical H_2O was shown to dissolve nonpolar substances even though liquid water does not! Studies are under way to carry out the large-scale removal of nonpolar organic toxins, such as PCBs, from industrial waste by extracting them into supercritical H_2O; after this step, O_2 gas is added to oxidize the toxins to small, harmless molecules.

The triple point of water occurs at low pressure (0.006 atm). Therefore, when solid water is heated at 1.0 atm, the horizontal dashed line crosses the solid-liquid line (at 0°C, the normal melting point) and enters the liquid region. Thus, at ordinary pressures, ice melts rather than sublimes. As the temperature rises, the horizontal line crosses the liquid-gas curve (at 100°C, the normal boiling point) and enters the gas region.

SECTION SUMMARY

A heating-cooling curve depicts the change in temperature with heat gain or loss. Within a phase, temperature (and average E_k) changes as heat is added or removed. During a phase change, temperature (and average E_k) is constant, but E_p changes. The total heat change for the curve is calculated using Hess's law. In a closed container, equilibrium is established between the liquid and gas phases. Vapor pressure, the pressure of the gas at equilibrium, is related directly to temperature and inversely to the strength of the intermolecular forces. The Clausius-Clapeyron equation uses ΔH_{vap} to relate the vapor pressure to the temperature. A liquid in an open container boils when its vapor pressure equals the external pressure. Solid-liquid equilibrium occurs at the melting point. Many solids sublime at low pressures and high temperatures. A phase diagram shows the phase that exists at a given pressure and temperature and the conditions at the critical point and the triple point of a substance. Water differs from most substances in that its solid phase is less dense than its liquid phase, so its solid-liquid line has a negative slope.

12.3 TYPES OF INTERMOLECULAR FORCES

As we said, the nature of the phases and their changes are due primarily to forces among the molecules. Both bonding (intramolecular) forces and intermolecular forces arise from electrostatic attractions between opposite charges. Bonding forces are due to the attraction between cations and anions (ionic bonding), nuclei and electron pairs (covalent bonding), or metal cations and delocalized valence electrons (metallic bonding). Intermolecular forces, on the other hand, are due to the attraction between molecules as a result of partial charges, or the attraction between ions and molecules. The two types of forces differ in magnitude, and Coulomb's law explains why:

- *Bonding forces are relatively strong* because they involve larger charges that are closer together.
- *Intermolecular forces are relatively weak* because they typically involve smaller charges that are farther apart.

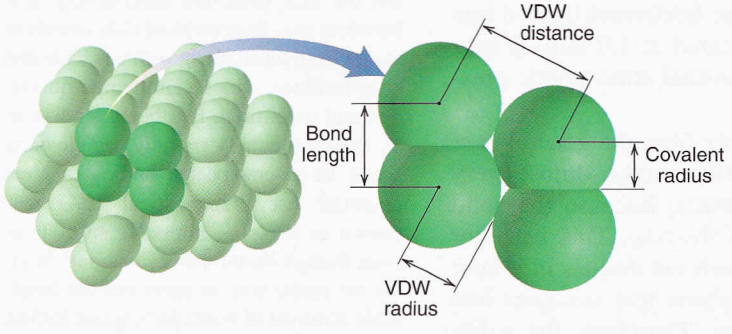

Figure 12.10 Covalent and van der Waals radii. As shown here for solid chlorine, the van der Waals (VDW) radius is one-half the distance between adjacent *nonbonded* atoms ($\frac{1}{2}$ × VDW distance), and the covalent radius is one-half the distance between *bonded* atoms ($\frac{1}{2}$ × bond length).

How far apart are the charges between molecules that give rise to intermolecular forces? Consider Cl_2 as an example. When we measure the distances between two Cl nuclei in a sample of solid Cl_2, we obtain two different values, as shown in Figure 12.10. The shorter distance is between *two* ***bonded*** *Cl atoms in the same molecule*. It is, as you know, called the *bond length*, and one-half this distance is the *covalent radius*. The longer distance is between *two* ***nonbonded*** *Cl atoms in adjacent molecules*. It is called the *van der Waals distance* (named after the Dutch physicist Johannes van der Waals, who studied the effects of intermolecular forces on the behavior of real gases). This distance is the closest one Cl_2 molecule can approach another, the point at which intermolecular attractions balance electron-

Table 12.2 Comparison of Bonding and Nonbonding (Intermolecular) Forces

Force	Model	Basis of Attraction	Energy (kJ/mol)	Example
Bonding				
Ionic		Cation–anion	400–4000	NaCl
Covalent		Nuclei–shared e^- pair	150–1100	H—H
Metallic		Cations–delocalized electrons	75–1000	Fe
Nonbonding (Intermolecular)				
Ion-dipole		Ion charge–dipole charge	40–600	H bond		Polar bond to H–dipole charge (high EN of N, O, F)	10–40	Dipole-dipole		Dipole charges	5–25	I—Cl···· I—Cl
Ion–induced dipole		Ion charge–polarizable e^- cloud	3–15	Fe^{2+}···· O_2
Dipole–induced dipole		Dipole charge–polarizable e^- cloud	2–10	H—Cl···· Cl—Cl
Dispersion (London)		Polarizable e^- clouds	0.05–40	F—F···· F—F

cloud repulsions. One-half this distance is the **van der Waals radius,** one-half the closest distance between the nuclei of identical *nonbonded* Cl atoms. *The van der Waals radius of an atom is always larger than its covalent radius,* but van der Waals radii decrease across a period and increase down a group, just as covalent radii do. Figure 12.11 shows these relationships for many of the nonmetals.

There are several types of intermolecular forces: ion-dipole, dipole-dipole, hydrogen bonding, dipole–induced dipole, and dispersion forces. As we discuss these *intermolecular* forces (also called *van der Waals forces*), look at Table 12.2, which compares them with the stronger *intramolecular* (bonding) forces.

Ion-Dipole Forces

When an ion and a nearby polar molecule (dipole) attract each other, an **ion-dipole force** results. The most important example takes place when an ionic compound dissolves in water. The ions become separated because the attractions

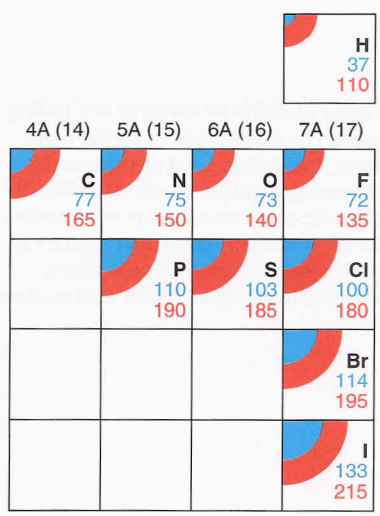

Figure 12.11 Periodic trends in covalent and van der Waals radii (in pm). Like covalent radii (*blue quarter-circles and top numbers*), van der Waals radii (*red quarter-circles and bottom numbers*) increase down a group and decrease across a period. The covalent radius of an element is *always* less than its van der Waals radius.

between the ions and the oppositely charged poles of the H_2O molecules overcome the attractions between the ions themselves. Ion-dipole forces in solutions and their associated energy are discussed fully in Chapter 13.

Dipole-Dipole Forces

In Figure 10.12 (p. 387), you saw how an external electric field can orient gaseous polar molecules. When polar molecules lie near one another, as in liquids and solids, their partial charges act as tiny electric fields that orient them and give rise to **dipole-dipole forces:** the positive pole of one molecule attracts the negative pole of another (Figure 12.12).

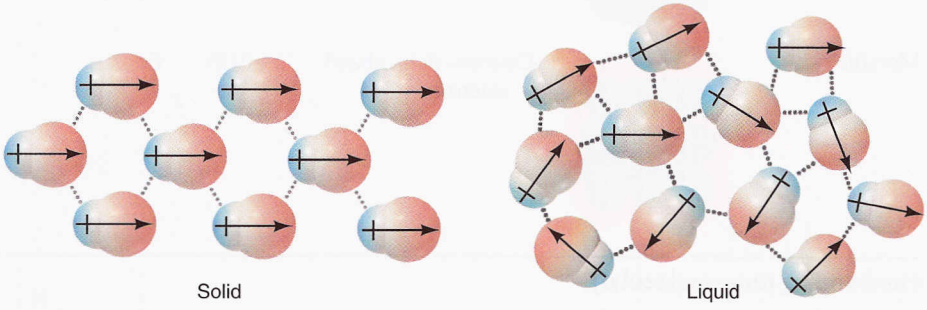

Figure 12.12 Polar molecules and dipole-dipole forces. In a solid or a liquid, the polar molecules are close enough for the partially positive pole of one molecule to attract the partially negative pole of a nearby molecule. The orientation is more orderly in the solid (*left*) than in the liquid (*right*) because, at the lower temperatures required for freezing, the average kinetic energy of the particles is lower. (Interparticle spaces are increased for clarity.)

These are the forces that give polar *cis*-1,2-dichloroethylene a higher boiling point than the nonpolar *trans* compound (see p. 389). In fact, for molecular compounds of approximately the same size and molar mass, the greater the dipole moment, the greater the dipole-dipole forces between the molecules are, and so the more energy it takes to separate them. Consider the boiling points of the compounds in Figure 12.13. Methyl chloride, for instance, has a smaller dipole moment than acetaldehyde, so less energy is needed to overcome the dipole-dipole forces between its molecules and it boils at a lower temperature.

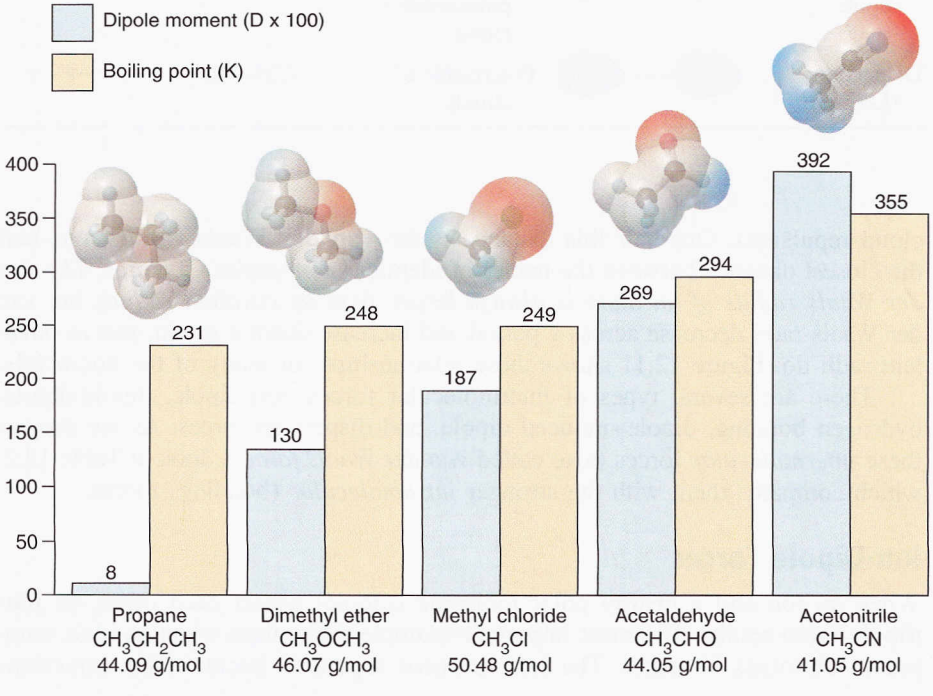

Figure 12.13 Dipole moment and boiling point. For compounds of similar molar mass, the boiling point increases with increasing dipole moment. (Note the increasing color intensities in the electron-density models.) The greater dipole moment creates stronger dipole-dipole forces, which require higher temperatures to overcome.

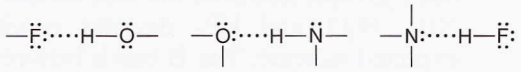
The Hydrogen Bond

A special type of dipole-dipole force arises between molecules that have *an H atom bonded to a small, highly electronegative atom with lone electron pairs.* The most important atoms that fit this description are N, O, and F. The H—N, H—O, and H—F bonds are very polar, so electron density is withdrawn from H. As a result, the partially positive H of one molecule is attracted to the partially negative lone pair on the N, O, or F of another molecule, and a **hydrogen bond (H bond)** forms. Thus, the atom sequence that allows an H bond (dotted line) to form is —B:····H—A—, where *both* A and B are N, O, or F. Three examples are



The small sizes of N, O, and F* are essential to H bonding for two reasons:

1. It makes these atoms so electronegative that their covalently bonded H is highly positive.
2. It allows the lone pair on the other N, O, or F to come close to the H.

SAMPLE PROBLEM 12.2 Drawing Hydrogen Bonds Between Molecules of a Substance

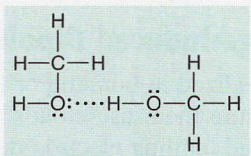
Problem Which of the following substances exhibits H bonding? For those that do, draw two molecules of the substance with the H bond(s) between them.

(a) C_2H_6 **(b)** CH_3OH **(c)** $CH_3\overset{\overset{O}{\|}}{C}—NH_2$

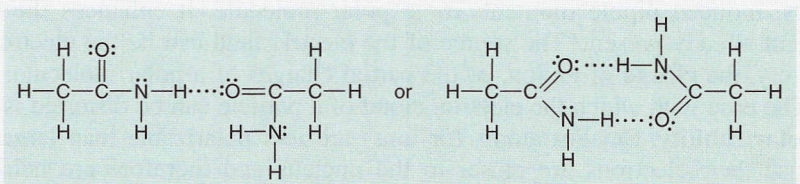
Plan We draw each structure to see if it contains N, O, or F covalently bonded to H. If it does, we draw two molecules of the substance in the —B:····H—A— pattern.

Solution **(a)** For C_2H_6. No H bonds are formed.

(b) For CH_3OH. The H covalently bonded to the O in one molecule forms an H bond to the lone pair on the O of an adjacent molecule:



(c) For $CH_3\overset{\overset{O}{\|}}{C}—NH_2$. Two of these molecules can form one H bond between an H bonded to N and the O, or they can form two such H bonds:



A third possibility (not shown) could be between an H attached to N in one molecule and the lone pair of N in another molecule.

Check The —B:····H—A— sequence (with A and B either N, O, or F) is present.

Comment Note that *H covalently bonded to C does not form H bonds* because carbon is not electronegative enough to make the C—H bond very polar.

FOLLOW-UP PROBLEM 12.2

Which of these substances exhibits H bonding? Draw the H bond(s) between two molecules of the substance where appropriate.

(a) $CH_3\overset{\overset{O}{\|}}{C}—OH$ **(b)** CH_3CH_2OH **(c)** $CH_3\overset{\overset{O}{\|}}{C}CH_3$

*H-bond–type interactions occur with the larger atoms P, S, and Cl, but those are so much weaker than the interactions with N, O, and F that we will not consider them.

The Significance of Hydrogen Bonding Hydrogen bonding has a profound impact in many systems. Here we'll examine one major effect on physical properties and preview its enormous importance in biological systems, which we address in Chapter 13.

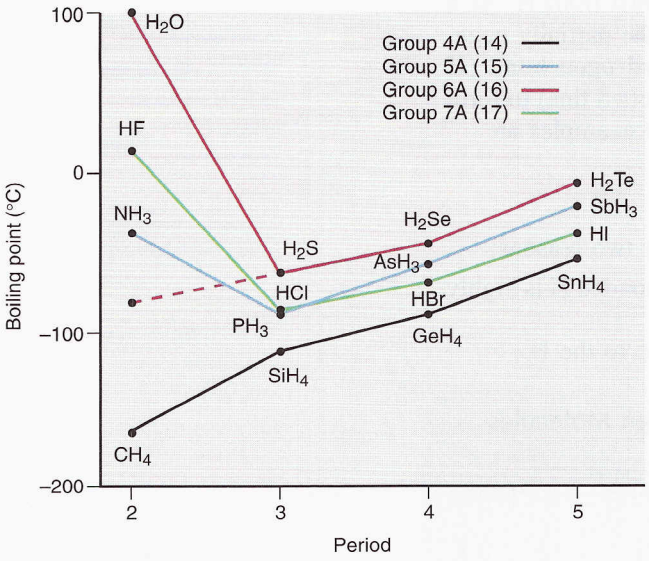


Figure 12.14 Hydrogen bonding and boiling point. Boiling points of the binary hydrides of Groups 4A(14) to 7A(17) are plotted against period number. H bonds in NH_3, H_2O, and HF give them much higher boiling points than if the trend were based on molar mass, as it is for Group 4A. The red dashed line extrapolates to the boiling point H_2O would have if it formed no H bonds.

Figure 12.14 shows the effect of H bonding on the boiling points of the binary hydrides of Groups 4A(14) through 7A(17). For reasons we'll discuss shortly, boiling points typically rise as molar mass increases, as you can see in the Group 4A hydrides, CH_4 through SnH_4. In the other groups, however, the first member in each series—NH_3, H_2O, and HF—deviates enormously from this expected increase. The H bonds between the molecules in these substances require additional energy to break before the molecules can separate and enter the gas phase. For example, on the basis of molar mass alone, we would expect water to boil about 200°C lower than it actually does (dashed line). (In Section 12.5 we'll discuss the effects that H bonds in water have in nature.)

The significance of hydrogen bonding in biological systems cannot be emphasized too strongly. It is a principal feature in the structures of the three major biopolymers—proteins, nucleic acids, and carbohydrates. In addition, it is responsible for the action of many *enzymes*, the specialized proteins that speed all metabolic reactions. In Chapter 13, after we discuss intermolecular forces in solution, you'll be amazed at the essential roles H bonds and the other intermolecular forces play in the structure and function of the molecules of life.

Polarizability and Charge-Induced Dipole Forces

Even though electrons are localized in bonding or lone pairs, they are in constant motion, so that we often picture them as "clouds" of negative charge. A nearby electric field can distort a cloud, pulling electron density toward a positive charge or pushing it away from a negative charge. In effect, the field *induces* a distortion in the electron cloud. For a nonpolar molecule, this distortion creates a temporary, induced dipole moment; for a polar molecule, it enhances the dipole moment already present. The source of the electric field can be the electrodes of a battery, the charge of an ion, or the partial charges of a polar molecule.

The ease with which the electron cloud of a particle can be distorted is called its **polarizability.** Smaller atoms (or ions) are less polarizable than larger ones because their electrons are closer to the nucleus and therefore are held more tightly. Thus, we observe several trends:

- *Polarizability increases down a group* because size increases, so the larger electron clouds are farther from the nucleus and, thus, more easily distorted.
- *Polarizability decreases from left to right across a period* because the increasing Z_{eff} shrinks atomic size and holds the electrons more tightly.
- Cations are *less* polarizable than their parent atoms because they are smaller; anions are *more* polarizable because they are larger.

Ion–induced dipole and dipole–induced dipole forces are the two types of charge-induced dipole forces; they are most important in solution, so we'll focus on them in Chapter 13. Nevertheless, polarizability affects all intermolecular forces.

Dispersion (London) Forces

Polarizability plays the central role in the most universal intermolecular force. Up to this point, we've discussed forces that depend on an existing charge, of either an ion or a polar molecule. But what forces cause nonpolar substances like octane, chlorine, and argon to condense and solidify? Some force must be acting between the particles, or these substances would be gases under any conditions. *The intermolecular force primarily responsible for the condensed states of nonpolar substances is the* ***dispersion force*** (or ***London force,*** named for Fritz London, the physicist who explained the quantum-mechanical basis of the attraction).

Dispersion forces are caused by *momentary oscillations of electron charge in atoms and, therefore, are present between all particles (atoms, ions, and molecules).* Picture one atom in a sample of argon gas. Averaged over time, the 18 electrons are distributed uniformly around the nucleus, so the atom is nonpolar. But at any instant, there may be more electrons on one side of the nucleus than on the other, so the atom has an *instantaneous dipole*. When far apart, a pair of argon atoms do not influence each other. But when close together, *the instantaneous dipole in one atom induces a dipole in its neighbor.* The result is a synchronized motion of the electrons in the two atoms, which causes an attraction between them. This process occurs with other nearby atoms and, thus, throughout the sample. At low enough temperatures, the attractions among the dipoles keep all the atoms together. Thus, dispersion forces are *instantaneous dipole–induced dipole forces*. Figure 12.15 depicts the dispersion forces among nonpolar particles.

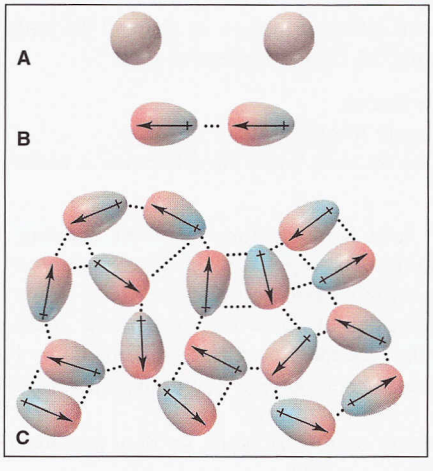

Figure 12.15 Dispersion forces among nonpolar particles. The dispersion force is responsible for the condensed states of noble gases and nonpolar molecules. **A,** Separated Ar atoms are nonpolar. **B,** An instantaneous dipole in one atom induces a dipole in its neighbor. These partial charges attract the atoms together. **C,** This process takes place among atoms throughout the sample.

As we noted, the dispersion force is the *only* force existing between nonpolar particles, but because they exist between *all* particles, *dispersion forces contribute to the overall energy of attraction of all substances*. In fact, except in cases involving small, polar molecules with large dipole moments or those forming strong H bonds, the *dispersion force is the dominant intermolecular force*. Calculations show, for example, that 85% of the total energy of attraction between HCl molecules is due to dispersion forces and only 15% is from dipole-dipole forces. Even for water, estimates indicate that 75% of the total energy of attraction comes from the strong H bonds and nearly 25% from dispersion forces!

Dispersion forces are very weak for small particles, like H_2 and He, but much stronger for larger particles, like I_2 and Xe. The relative strength of the dispersion force depends on the polarizability of the particle. *Polarizability depends on the number of electrons, which correlates closely with molar mass* because heavier particles are either larger atoms or composed of more atoms and thus have more electrons. For example, molar mass increases down the halogens and the noble gases, so dispersion forces increase and so do boiling points (Figure 12.16).

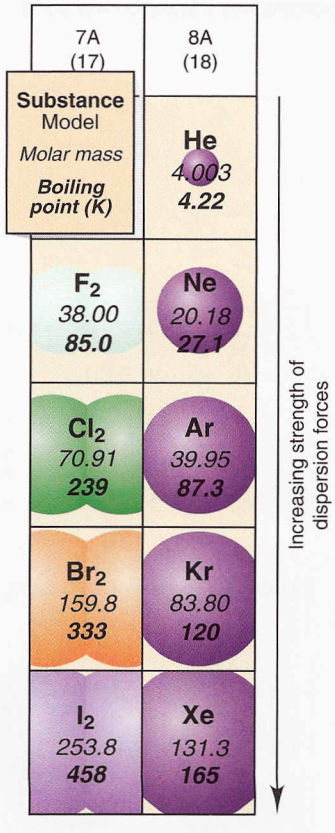

Figure 12.16 Molar mass and boiling point. The strength of dispersion forces increases with number of electrons, which usually correlates with molar mass. As a result, boiling points increase down the halogens and the noble gases.

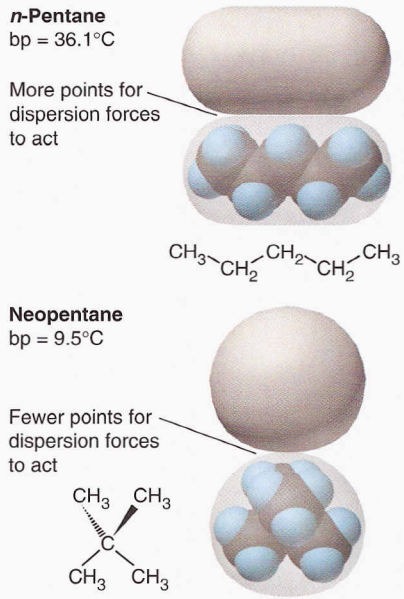

Figure 12.17 Molecular shape and boiling point. Spherical neopentane molecules make less contact with each other than do cylindrical *n*-pentane molecules, so neopentane has a lower boiling point.

For nonpolar substances with the same molar mass, the strength of the dispersion forces is influenced by molecular shape. Shapes that allow more points of contact have more area over which electron clouds can be distorted, so stronger attractions result. Consider the two five-carbon alkanes pentane (also called *n-pentane*) and 2,2-dimethylpropane (also called *neopentane*). These isomers have the same molecular formula (C_5H_{12}) but different shapes. *n*-Pentane is shaped like a cylinder, whereas neopentane has a more compact, spherical shape, as shown in Figure 12.17. Thus, two *n*-pentane molecules make more contact than do two neopentane molecules. Greater contact allows the dispersion forces to act at more points, so *n*-pentane has a higher boiling point. Figure 12.18 summarizes how to analyze the intermolecular forces in a sample.

SAMPLE PROBLEM 12.3 Predicting the Types of Intermolecular Force

Problem For each pair of substances, identify the key intermolecular force(s) in each substance, and select the substance with the higher boiling point:

(a) $MgCl_2$ or PCl_3

(b) CH_3NH_2 or CH_3F

(c) CH_3OH or CH_3CH_2OH

(d) Hexane ($CH_3CH_2CH_2CH_2CH_2CH_3$) or 2,2-dimethylbutane ($CH_3C(CH_3)_2CH_2CH_3$)

Plan We examine the formulas and picture (or draw) the structures to identify key differences between members of each pair: Are ions present? Are molecules polar or nonpolar? Is N, O, or F bonded to H? Do the molecules have different masses or shapes? To rank the boiling points, we consult Table 12.2 and Figure 12.18 and remember that

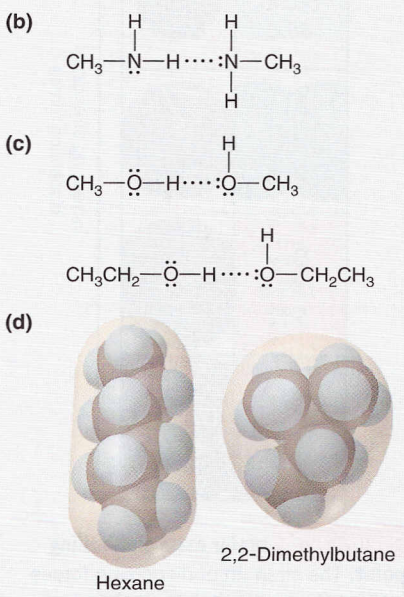
- Bonding forces are stronger than intermolecular forces.
- Hydrogen bonding is a strong type of dipole-dipole force.
- Dispersion forces are always present, but they are decisive when the difference is molar mass or molecular shape.

Solution **(a)** $MgCl_2$ consists of Mg^{2+} and Cl^- ions held together by ionic bonding forces; PCl_3 consists of polar molecules, so intermolecular dipole-dipole forces are present. The forces in $MgCl_2$ are stronger, so it has a higher boiling point.

(b) CH_3NH_2 and CH_3F both consist of polar molecules of about the same molar mass. CH_3NH_2 has N—H bonds, so it can form H bonds (see margin). CH_3F contains a C—F bond but no H—F bond, so dipole-dipole forces occur but not H bonds. Therefore, CH_3NH_2 has the higher boiling point.

(c) CH_3OH and CH_3CH_2OH molecules both contain an O—H bond, so they can form H bonds (see margin). CH_3CH_2OH has an additional $-CH_2-$ group and thus a larger molar mass, which correlates with stronger dispersion forces; therefore, it has a higher boiling point.

(d) Hexane and 2,2-dimethylbutane are nonpolar molecules of the same molar mass but different molecular shapes (see margin). Cylindrical hexane molecules can make more extensive intermolecular contact than the more spherical 2,2-dimethylbutane molecules can, so hexane should have greater dispersion forces and a higher boiling point.



Check The actual boiling points show that our predictions are correct:

(a) $MgCl_2$ (1412°C) and PCl_3 (76°C)

(b) CH_3NH_2 (−6.3°C) and CH_3F (−78.4°C)

(c) CH_3OH (64.7°C) and CH_3CH_2OH (78.5°C)

(d) Hexane (69°C) and 2,2-dimethylbutane (49.7°C)

Comment Dispersion forces are *always* present, but in parts (a) and (b), they are much less significant than the other forces involved.

FOLLOW-UP PROBLEM 12.3 In each pair, identify all the intermolecular forces present for each substance, and select the substance with the higher boiling point:

(a) CH_3Br or CH_3F **(b)** $CH_3CH_2CH_2OH$ or $CH_3CH_2OCH_3$ **(c)** C_2H_6 or C_3H_8

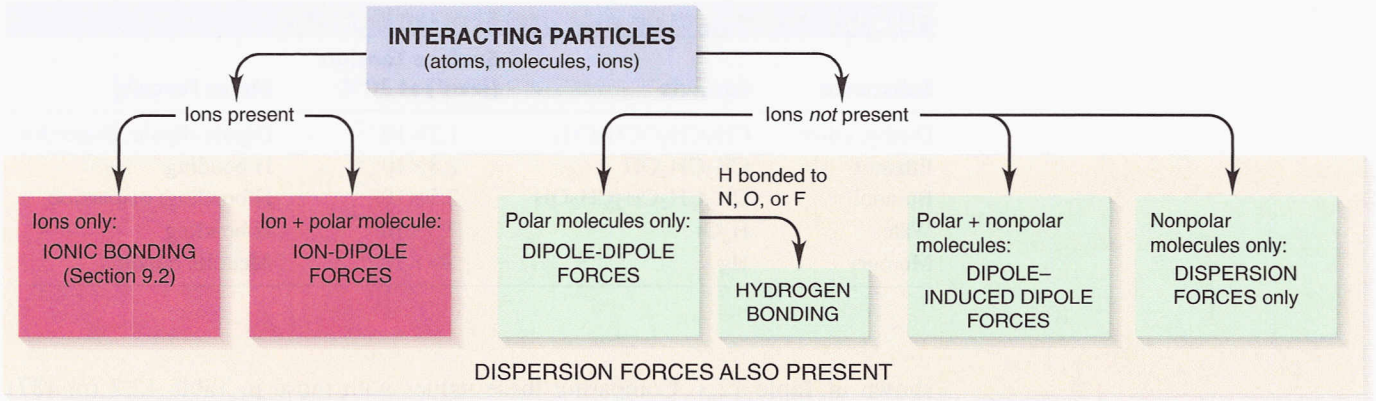


Figure 12.18 Summary diagram for analyzing the intermolecular forces in a sample.

SECTION SUMMARY

The van der Waals radius determines the shortest distance over which intermolecular forces operate; it is always larger than the covalent radius. Intermolecular forces are much weaker than bonding (intramolecular) forces. Ion-dipole forces occur between ions and polar molecules. Dipole-dipole forces occur between oppositely charged poles on polar molecules. Hydrogen bonding, a special type of dipole-dipole force, occurs when H bonded to N, O, or F is attracted to the lone pair of N, O, or F in another molecule. Electron clouds can be distorted (polarized) in an electric field. Ion– and dipole–induced dipole forces arise between a charge and the dipole it induces in another molecule. Dispersion (London) forces are instantaneous dipole–induced dipole forces that occur among all particles and increase with number of electrons (molar mass). Molecular shape determines the extent of contact between molecules and can be a factor in the strength of dispersion forces.

12.4 PROPERTIES OF THE LIQUID STATE

Of the three states of matter, the liquid is the least understood at the molecular level. Because of the *randomness* of the particles in a gas, any region of the sample is virtually identical to any other. As you'll see in Section 12.6, different regions of a crystalline solid are identical because of the *orderliness* of the particles. Liquids, however, have a combination of these attributes that changes continually: a region that is orderly one moment becomes random the next, and vice versa. Despite this complexity at the molecular level, the macroscopic properties of liquids are well understood. In this section, we discuss three liquid properties —surface tension, capillarity, and viscosity.

Surface Tension

In a liquid sample, intermolecular forces exert different effects on a molecule at the surface than on one in the interior (Figure 12.19). Interior molecules are attracted by others on all sides, whereas molecules at the surface have others only below and to the sides. As a result, molecules at the surface experience a *net attraction downward* and move toward the interior to increase attractions and become more stable. Therefore, *a liquid surface tends to have the smallest possible area,* that of a sphere, and behaves like a "taut skin" covering the interior.

To increase the surface area, molecules must move to the surface by breaking some attractions in the interior, which requires energy. The **surface tension** is the energy required to increase the surface area by a unit amount; units of J/m^2 are

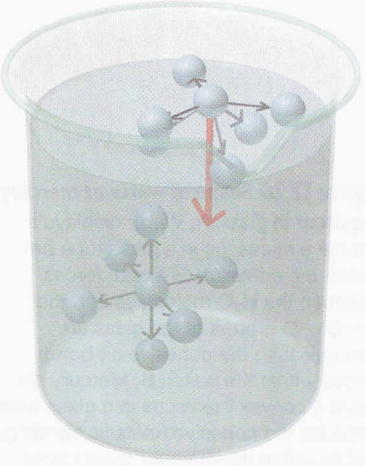

Figure 12.19 The molecular basis of surface tension. Molecules in the interior of a liquid experience intermolecular attractions in all directions. Molecules at the surface experience a net attraction downward (*red arrow*) and move toward the interior. Thus, a liquid tends to minimize the number of molecules at the surface, which results in surface tension.

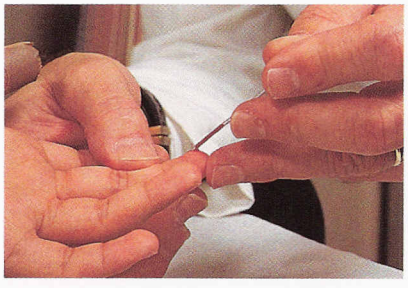
Table 12.3 Surface Tension and Forces Between Particles

Substance	Formula	Surface Tension (J/m^2) at 20°C	Major Force(s)
Diethyl ether	$CH_3CH_2OCH_2CH_3$	1.7×10^{-2}	Dipole-dipole; dispersion
Ethanol	CH_3CH_2OH	2.3×10^{-2}	H bonding
Butanol	$CH_3CH_2CH_2CH_2OH$	2.5×10^{-2}	H bonding; dispersion
Water	H_2O	7.3×10^{-2}	H bonding
Mercury	Hg	48×10^{-2}	Metallic bonding

shown in Table 12.3. Comparing these values with those in Table 12.2 (p. 437) shows that, in general, *the stronger the forces are between the particles in a liquid, the greater the surface tension.* Water has a high surface tension because its molecules form multiple H bonds. *Surfactants* (*surface-active agents*), such as soaps, petroleum recovery agents, and biological fat emulsifiers, decrease the surface tension of water by congregating at the surface and disrupting the H bonds.

Capillarity



Blood being drawn into a capillary tube for a medical test.

The rising of a liquid through a narrow space against the pull of gravity is called *capillary action,* or **capillarity.** In blood-screening tests, a narrow *capillary tube* is held against the skin opening made by pricking a finger (see photo). Capillarity results from a competition between the intermolecular forces within the liquid (cohesive forces) and those between the liquid and the tube walls (adhesive forces).

Picture what occurs at the molecular level when you place a glass capillary tube in water. Glass is mostly silicon dioxide (SiO_2), so the water molecules form H bonds to the oxygen atoms of the tube's inner wall. Because the adhesive forces (H bonding) between the water and the wall are stronger than the cohesive forces (H bonding) within the water, a thin film of water creeps up the wall. At the same time, the cohesive forces that give rise to surface tension pull the liquid surface taut. These adhesive and cohesive forces combine to raise the water level and produce the familiar concave meniscus (Figure 12.20A). The liquid rises until gravity pulling down is balanced by the adhesive forces pulling up.

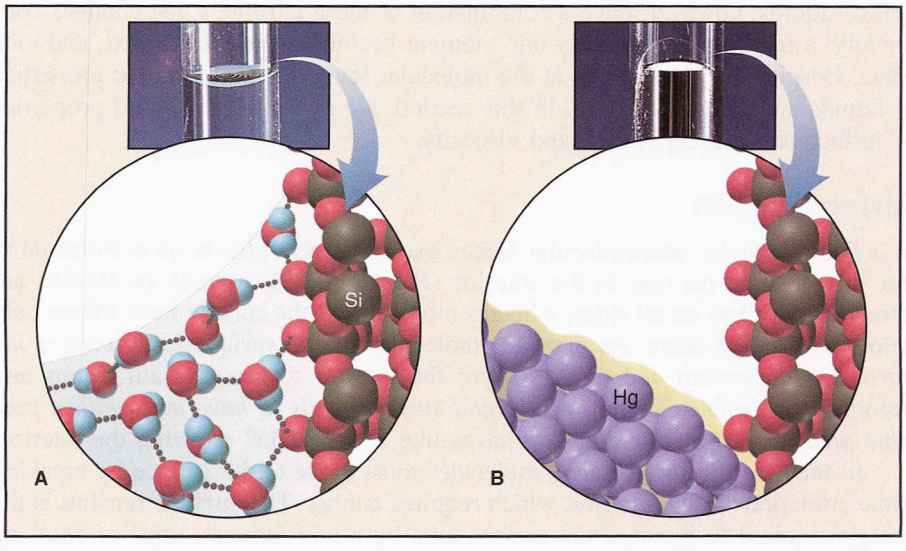


Figure 12.20 Shape of water or mercury meniscus in glass. A, Water displays a concave meniscus in a glass tube because the adhesive (H-bond) forces between the H_2O molecules and the O—Si—O groups of the glass are *stronger* than the cohesive (H-bond) forces within the water. **B,** Mercury displays a convex meniscus in a glass tube because the cohesive (metallic bonding) forces within the mercury are *stronger* than the adhesive (dispersion) forces between the mercury and the glass.

On the other hand, if you place a glass capillary tube in a dish of mercury, the mercury level in the tube drops below that in the dish. Mercury has a higher surface tension than water (see Table 12.3), which means it has stronger cohesive forces (metallic bonding). The cohesive forces among the mercury atoms are much stronger than the adhesive forces (mostly dispersion) between mercury and glass, so the liquid tends to pull away from the walls. At the same time, the surface atoms are being pulled toward the interior of the mercury by its high surface tension, so the level drops. These combined forces produce a convex meniscus (Figure 12.20B, seen in a laboratory barometer or manometer).

Viscosity

When a liquid flows, the molecules slide around and past each other. A liquid's **viscosity,** its resistance to flow, results from intermolecular attractions that impede this movement. Both gases and liquids flow, but liquid viscosities are *much* higher because the intermolecular forces operate over much shorter distances.

Viscosity decreases with heating, as Table 12.4 shows for water. When molecules move faster at higher temperatures, they can overcome intermolecular forces more easily, so the resistance to flow decreases. Next time you put cooking oil in a pan and heat it, watch the oil flow more easily and spread out in a thin layer.

Molecular shape plays a key role in a liquid's viscosity. Small, spherical molecules make little contact and, like buckshot in a glass, pour easily. Long molecules make more contact and, like spaghetti in a glass, become entangled and pour slowly. Thus, given the same types of forces, liquids containing longer molecules have higher viscosities. A striking example of a change in viscosity occurs during the making of syrup. Even at room temperature, a concentrated aqueous sugar solution has a higher viscosity than water because of H bonding among the many hydroxyl (—OH) groups on the ring-shaped sugar molecules. When the solution is slowly heated to boiling, the sugar molecules react with each other and link covalently, gradually forming long chains. Hydrogen bonds and dispersion forces occur at many points along the chains, and the resulting syrup is a viscous liquid that pours slowly and clings to a spoon. When a viscous syrup is cooled, it may become stiff enough to be picked up and stretched—into taffy candy. The Gallery on the next page shows other familiar examples of these three liquid properties.

Table 12.4 Viscosity of Water at Several Temperatures

Temperature (°C)	Viscosity ($N \cdot s/m^2$)*
20	1.00×10^{-3}
40	0.65×10^{-3}
60	0.47×10^{-3}
80	0.35×10^{-3}

*The units of viscosity are newton-seconds per square meter.

SECTION SUMMARY

Surface tension is a measure of the energy required to increase a liquid's surface area. Greater intermolecular forces within a liquid create higher surface tension. Capillary action, the rising of a liquid through a narrow space, occurs when the forces between a liquid and a solid surface (adhesive) are greater than those within the liquid itself (cohesive). Viscosity, the resistance to flow, depends on molecular shape and decreases with temperature. Stronger intermolecular forces create higher viscosity.

12.5 THE UNIQUENESS OF WATER

Water is absolutely amazing stuff, but it is so familiar that we take it for granted. In fact, water has some of the most unusual properties of any substance. These properties, which are vital to our very existence, arise inevitably from the nature of the H and O atoms that make up the molecule. Each atom attains a filled outer level by sharing electrons in single covalent bonds. With two bonding pairs and two lone pairs around the O atom and a large electronegativity difference in each O—H bond, the H_2O molecule is bent and highly polar. This arrangement is crucial because it allows each water molecule to engage in four H bonds with its neighbors (Figure 12.21). From these fundamental atomic and molecular properties emerges unique and remarkable macroscopic behavior.

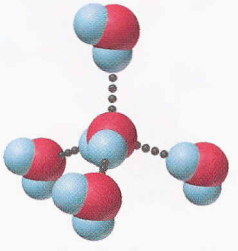

Figure 12.21 The H-bonding ability of the water molecule. Because it has two O—H bonds and two lone pairs, one H_2O molecule can engage in as many as four H bonds to surrounding H_2O molecules, which are arranged tetrahedrally.

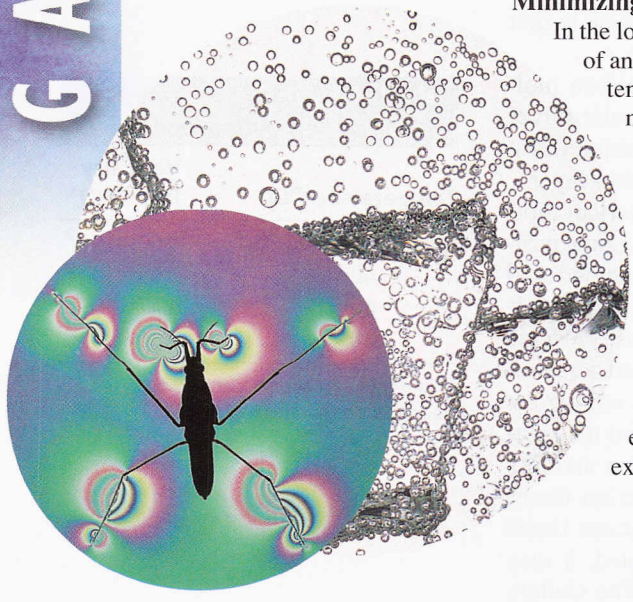
GALLERY

Properties of a Liquid

Of the three states of matter, only liquids combine the ability to flow with the strength that comes from intermolecular contact, and this combination appears in numerous applications.

Beaded droplets on waxy surfaces

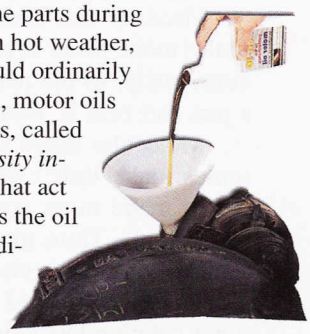
The adhesive (dipole–induced dipole) forces between water and a nonpolar surface are much weaker than the cohesive (H-bond) forces within water. As a result, water pulls away from a nonpolar surface and forms beaded droplets. You have seen this effect when water beads on a flower petal or a freshly waxed car after a rainfall.



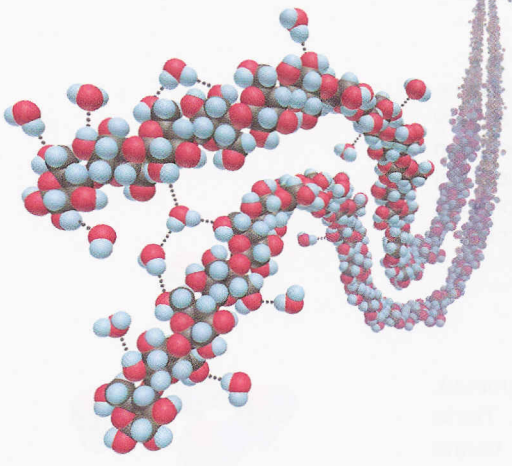
Minimizing a surface

In the low-gravity environment of an orbiting space shuttle, the tendency of a liquid to minimize its surface creates perfectly spherical droplets, unlike the flattened drops we see on Earth. For the same reason, bubbles in a soft drink are spherical because the liquid uses the minimum number of molecules needed to surround the gas. A water strider flits across a pond on widespread legs that do not exert enough pressure to exceed the surface tension.

Maintaining motor oil viscosity



To protect engine parts during long drives or in hot weather, when an oil would ordinarily become too thin, motor oils contain additives, called *polymeric viscosity index improvers,* that act as thickeners. As the oil heats up, the additive molecules change shape from compact spheres to spaghetti-like strands and become tangled with the hydrocarbon oil molecules. As a result of the greater dispersion forces, there is an increase in viscosity that compensates for the decrease due to heating.



Capillary action after a shower

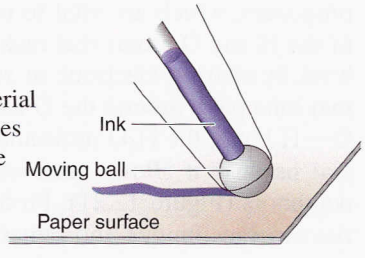
Paper and cotton consist of fibers of cellulose, long carbon-containing molecules with many attached hydroxyl (—OH) groups. A towel dries you in two ways:

First, capillary action draws the water molecules away from your body between the closely spaced cellulose molecules.

Second, the water molecules themselves form adhesive H bonds to the —OH groups of cellulose.

How a ballpoint pen works

The essential parts of a ballpoint pen are the moving ball and the viscous ink. The material of the ball is chosen for the strong adhesive forces between it and the ink. Cohesive forces within the ink are replaced by those adhesive forces when the ink "wets" the ball. As the ball rolls along the paper, the adhesive forces between ball and ink are overcome by those between ink and paper. The rest of the ink stays in the pen because of its high viscosity.



Solvent Properties of Water

The *great solvent power* of water is the result of its polarity and exceptional H-bonding ability. It dissolves ionic compounds through ion-dipole forces that separate the ions from the solid and keep them in solution (see Figure 4.2, p. 136). Water dissolves many polar nonionic substances, such as ethanol (CH_3CH_2OH) and glucose ($C_6H_{12}O_6$), by forming H bonds to them. It even dissolves nonpolar gases, such as those in the atmosphere, to a limited extent, through dipole–induced dipole and dispersion forces. Chapter 13 highlights these solvent properties.

Because it can dissolve so many substances, water is the environmental and biological solvent, forming the complex solutions we know as oceans, rivers, lakes, and cellular fluids. Aquatic animals could not survive without dissolved O_2, nor could aquatic plants survive without dissolved CO_2. The coral reefs that girdle the sea bottom in tropical latitudes are composed of carbonates made from dissolved CO_2 and HCO_3^- by tiny marine animals. Life is thought to have begun in a "primordial soup," an aqueous mixture of simple biomolecules from which emerged the larger molecules whose self-sustaining reactions are characteristic of living things. From a chemical point of view, all organisms, from bacteria to humans, can be thought of as highly organized systems of membranes enclosing and compartmentalizing complex aqueous solutions.

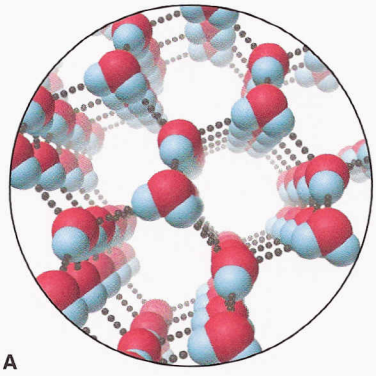
Thermal Properties of Water

Water has an exceptionally *high specific heat capacity,* higher than almost any other liquid. Recall from Section 6.3 that heat capacity is a measure of the heat absorbed by a substance for a given temperature rise. When a substance is heated, some of the energy increases the average molecular speed, some increases molecular vibration and rotation, and some is used to overcome intermolecular forces. Because water has so many strong H bonds, it has a high specific heat capacity. With oceans and seas covering 70% of Earth's surface, daytime heat from the Sun causes relatively small changes in temperature, allowing our planet to support life. On the waterless, airless Moon, temperatures can range from 100°C (212°F) to −150°C (−238°F) in the same lunar day. Even in Earth's deserts, where a dense atmosphere tempers these extremes, day-night temperature differences of 40°C (72°F) are common.

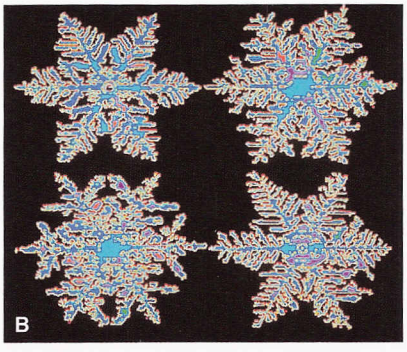
Numerous strong H bonds also give water an exceptionally *high heat of vaporization.* A quick calculation shows how essential this property is to our existence. When 1000 g of water absorbs about 4 kJ of heat, its temperature rises 1°C. With a ΔH^0_{vap} of 2.3 kJ/g, however, less than 2 g of water must evaporate to keep the temperature constant for the remaining 998 g. The average human adult has 40 kg of body water and generates about 10,000 kJ of heat each day from metabolism. If this heat were used only to increase the average E_k of body water, the temperature rise would mean immediate death. Instead, the heat is converted to E_p as it breaks H bonds and evaporates sweat, resulting in a stable body temperature and minimal loss of body fluid. On a planetary scale, the Sun's energy supplies the heat of vaporization for ocean water. Water vapor, formed in warm latitudes, moves through the atmosphere, and its potential energy is released as heat to warm cooler regions when the vapor condenses to rain. The enormous energy involved in this cycling of water powers storms all over the planet.

Surface Properties of Water

The H bonds that give water its remarkable thermal properties are also responsible for its *high surface tension* and *high capillarity.* Except for some metals and molten salts, water has the highest surface tension of any liquid. This property is vital for surface aquatic life because it keeps plant debris resting on a pond surface, which provides shelter and nutrients for many fish, microorganisms, and



A



B

Figure 12.22 The hexagonal structure of ice. A, The geometric arrangement of the H bonds in H_2O leads to the open, hexagonally shaped crystal structure of ice. Thus, when liquid water freezes, the volume *increases*. **B,** The delicate six-pointed beauty of snowflakes reflects the hexagonal crystal structure of ice.

Figure 12.23 The expansion and contraction of water. As water freezes and thaws repeatedly, the stress due to expanding and contracting can break rocks. Over eons of geologic time, this process creates sand and soil.

insects. Water's high capillarity, a result of its high surface tension, is crucial to land plants. During dry periods, plant roots absorb deep groundwater, which rises by capillary action through the tiny spaces between soil particles.

The Density of Solid and Liquid Water

As you saw in Figure 12.21, through the H bonds of water, each O atom becomes connected to as many as four other O atoms via four H atoms. Continuing this tetrahedral pattern through many molecules in a fixed array leads to the hexagonal, *open structure* of ice shown in Figure 12.22A. The symmetrical beauty of snowflakes, as shown in Figure 12.22B, reflects this hexagonal organization.

This organization explains the negative slope of the solid-liquid line in the phase diagram for water (see Figure 12.9B, p. 435): As pressure is applied, some H bonds break; as a result, some water molecules enter the spaces. The crystal structure breaks down, and the sample liquefies.

The large spaces within ice give *the solid state a lower density than the liquid state*. When the surface of a lake freezes in winter, the ice floats on the liquid water below. If the solid were denser than the liquid, as is true for nearly every other substance, the surface of a lake would freeze and sink repeatedly until the entire lake was solid. Aquatic life would not survive from year to year.

The density of water changes in a complex way. When ice melts at 0°C, the tetrahedral arrangement around each O atom breaks down, and the loosened molecules pack much more closely, filling spaces in the collapsing solid structure. As a result, water is most dense (1.000 g/mL) at around 4°C (3.98°C). With more heating, the density decreases through normal thermal expansion.

This change in density is vital for freshwater life. As lake water becomes colder in the fall and early winter, it becomes more dense *before* it freezes. Similarly, in spring, less dense ice thaws to form more dense water *before* the water expands. During both of these seasonal density changes, the top layer of water reaches the high-density point first and sinks. The next layer of water rises because it is slightly less dense, reaches 4°C, and likewise sinks. This sinking and rising distribute nutrients and dissolved oxygen.

The expansion and contraction of water dramatically affect the land as well. When rain fills the crevices in rocks and then freezes, great outward stress is applied, to be relieved only when the ice melts. In time, this repeated freeze-thaw stress cracks the rocks apart (Figure 12.23). Over eons of geologic change, this effect has helped to produce the sand and soil of the planet.

The properties of water and their far-reaching consequences illustrate the theme that runs throughout this book: the world we know is the stepwise, macroscopic outgrowth of the atomic world we seek to know. Figure 12.24 offers a fanciful summary of water's unique properties in the form of a tree whose "roots" (atomic properties) give foundation to the base of the "trunk" (molecular properties), which strengthens the next portion (polarity), from which grows another portion (H bonding). These two portions of the trunk "branch" out to the other properties of water and their global effects.

SECTION SUMMARY

The atomic properties of hydrogen and oxygen atoms result in the water molecule's bent shape, polarity, and H-bonding ability. These properties of water enable it to dissolve many ionic and polar compounds. Water's H bonding results in a high specific heat capacity and a high heat of vaporization, which combine to give Earth and its organisms a narrow temperature range. H bonds also confer high surface tension and capillarity, which are essential to plant and animal life. Water expands on freezing because of its H bonds, which lead to an open crystal structure in ice. Seasonal density changes foster nutrient mixing in lakes. Seasonal freeze-thaw stress on rocks results eventually in soil formation.

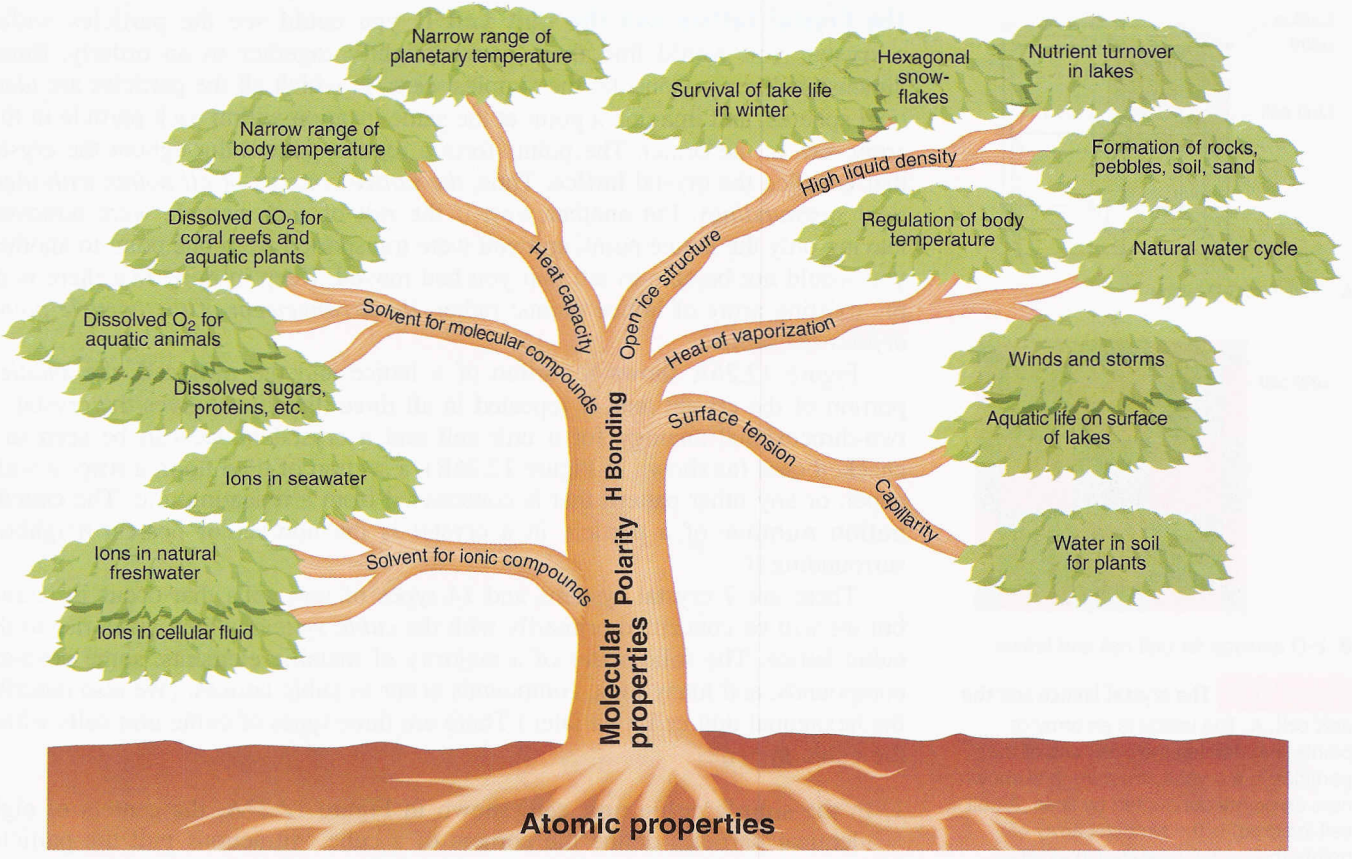


Figure 12.24 **The macroscopic properties of water and their atomic and molecular "roots."**

12.6 THE SOLID STATE: STRUCTURE, PROPERTIES, AND BONDING

Stroll through the mineral collection of any school or museum, and you'll be struck by the extraordinary variety and beauty of these solids. In this section, we first discuss the general structural features of crystalline solids and then examine a laboratory method for studying them. We survey the properties of the major types of solids and find the whole range of intermolecular forces at work. We then present a model for bonding in solids that explains many of their properties.

Structural Features of Solids

We can divide solids into two broad categories based on the orderliness of their shapes, which in turn is based on the orderliness of their particles. **Crystalline solids** generally have a well-defined shape, as shown in Figure 12.25, because their particles—atoms, molecules, or ions—occur in an orderly arrangement. **Amorphous solids** have poorly defined shapes because their particles lack long-range ordering throughout the sample. In this discussion, we focus, for the most part, on crystalline solids.

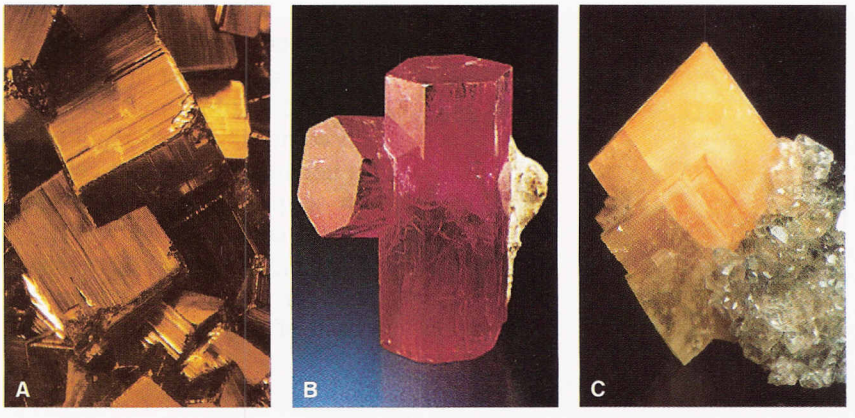

Figure 12.25 **The striking beauty of crystalline solids. A,** Pyrite. **B,** Beryl. **C,** Barite (*left*) on calcite (*right*).

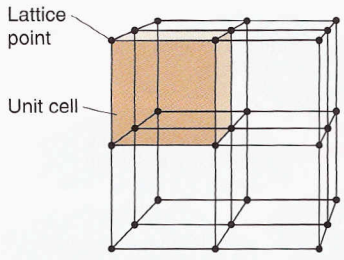
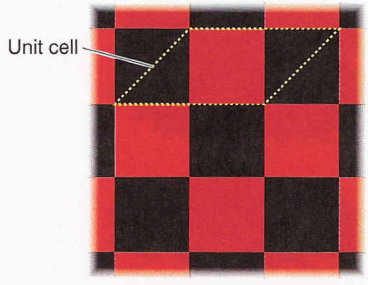


A Portion of 3-D lattice



B 2-D analogy for unit cell and lattice

Figure 12.26 The crystal lattice and the unit cell. A, The lattice is an array of points that defines the positions of the particles in a crystal structure. It is shown here as points connected by lines. A unit cell *(colored)* is the simplest array of points that, when repeated in all directions, produces the lattice. A simple cubic unit cell, one of 14 types in nature, is shown. **B,** A checkerboard is a two-dimensional analogy for a lattice.

The Crystal Lattice and the Unit Cell If you could see the particles within a crystal, you would find them packed tightly together in an orderly, three-dimensional array. Consider the simplest case, in which all the particles are *identical* spheres, and imagine a point at the same location within each particle in this array, say, at the center. The points form a regular pattern throughout the crystal that is called the crystal **lattice.** Thus, *the lattice consists of all points with identical surroundings.* Put another way, if the rest of each particle were removed, leaving only the lattice point, and you were transported from one point to another, you would not be able to tell that you had moved. Keep in mind that there is no pre-existing array of lattice points; rather, *the arrangement of the particle points defines the lattice.*

Figure 12.26A shows a portion of a lattice and the **unit cell**, the *smallest* portion of the crystal that, if repeated in all three directions, gives the crystal. A two-dimensional analogy for a unit cell and a crystal lattice can be seen in a checkerboard (as shown in Figure 12.26B), a section of tiled floor, a strip of wallpaper, or any other pattern that is constructed from a repeating unit. The **coordination number** of a particle in a crystal is the number of nearest neighbors surrounding it.

There are 7 crystal systems and 14 types of unit cells that occur in nature, but we will be concerned primarily with the *cubic system,* which gives rise to the cubic lattice. The solid states of a majority of metallic elements, some covalent compounds, and many ionic compounds occur as cubic lattices. (We also describe the hexagonal unit cell a bit later.) There are three types of cubic unit cells within the cubic system:

1. In the **simple cubic unit cell,** shown in Figure 12.27A, the centers of eight identical particles define the corners of a cube. Attractions pull the particles together, so they touch along the cube's edges; but they do not touch diagonally along the cube's faces or through its center. The coordination number of each particle is 6: four in its own layer, one in the layer above, and one in the layer below.
2. In the **body-centered cubic unit cell,** shown in Figure 12.27B, identical particles lie at each corner *and* in the center of the cube. Those at the corners do not touch each other, but they all touch the one in the center. Each particle is surrounded by eight nearest neighbors, four above and four below, so the coordination number is 8.
3. In the **face-centered cubic unit cell,** shown in Figure 12.27C, identical particles lie at each corner *and* in the center of each face but not in the center of the cube. Those at the corners touch those in the faces but not each other. The coordination number is 12.

One unit cell lies adjacent to another throughout the crystal, with no gaps, so a particle at a corner or face is *shared* by adjacent unit cells. As you can see from Figure 12.27 (third row from the top), in the three cubic unit cells, the particle at each corner is part of eight adjacent cells, so one-eighth of each of these particles belongs to each unit cell (bottom row). There are eight corners in a cube, so each simple cubic unit cell contains $8 \times \frac{1}{8}$ particle $= 1$ particle. The body-centered cubic unit cell contains one particle from the eight corners and one in the center, for a total of two particles; and the face-centered cubic unit cell contains four particles, one from the eight corners and three from the half-particles in each of the six faces.

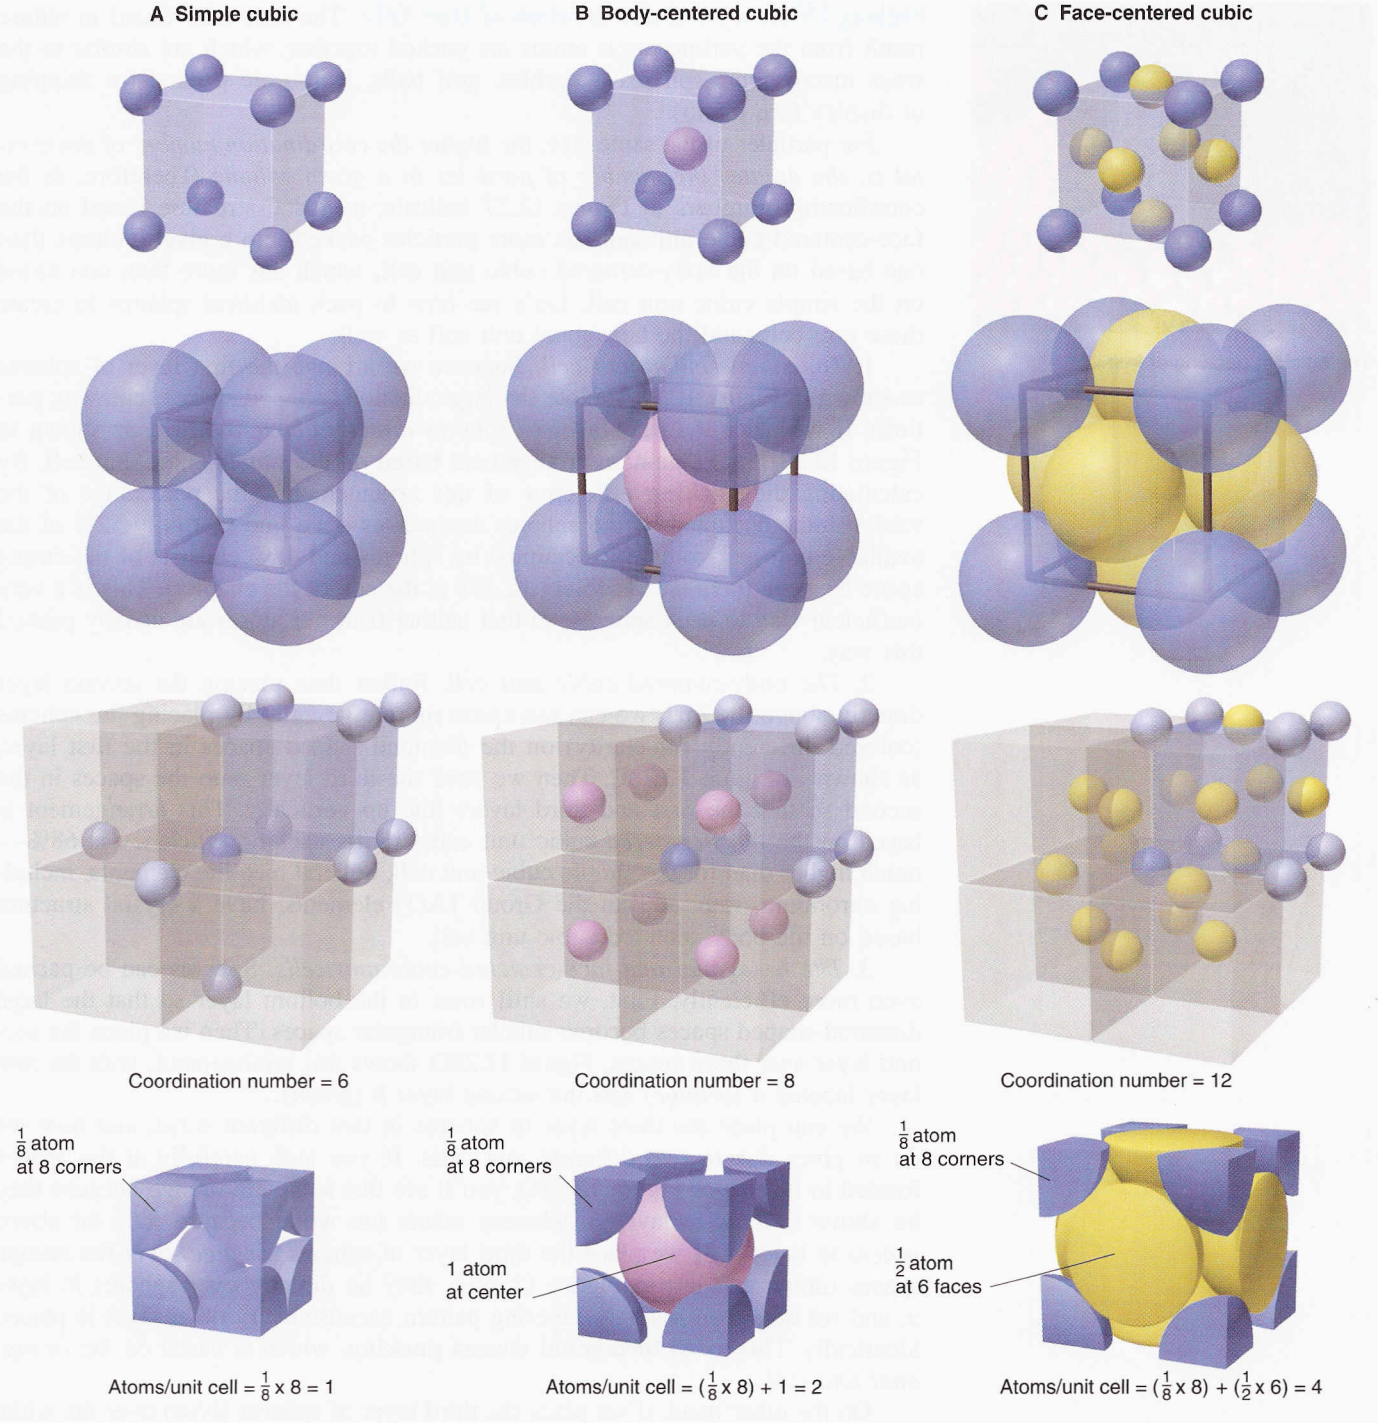


Figure 12.27 The three cubic unit cells. **A,** Simple cubic unit cell. **B,** Body-centered cubic unit cell. **C,** Face-centered cubic unit cell. *Top row:* Cubic arrangements of atoms in expanded view. *Second row:* Space-filling view of these cubic arrangements. All atoms are identical but, for clarity, corner atoms are blue, body-centered atoms pink, and face-centered atoms yellow. *Third row:* A unit cell (*shaded blue*) in a portion of the crystal. The number of nearest neighbors around one particle (*dark blue in center*) is the coordination number. *Bottom row:* The total numbers of atoms in the actual unit cell. The simple cubic has one atom; the body-centered has two; and the face-centered has four.

Animation: Cubic Unit Cells and Their Origins

The efficient packing of fruit.

Packing Efficiency and the Creation of Unit Cells The unit cells found in nature result from the various ways atoms are packed together, which are similar to the ways macroscopic spheres—marbles, golf balls, fruit—are packed for shipping or display (see photo).

For particles of the same size, *the higher the coordination number of the crystal is, the greater the number of particles in a given volume.* Therefore, as the coordination numbers in Figure 12.27 indicate, a crystal structure based on the face-centered cubic unit cell has more particles packed into a given volume than one based on the body-centered cubic unit cell, which has more than one based on the simple cubic unit cell. Let's see how to pack *identical* spheres to create these unit cells and the hexagonal unit cell as well:

1. *The simple cubic unit cell.* Suppose we arrange the first layer of spheres as shown in Figure 12.28A. Note the large diamond-shaped spaces (cutaway portion). If we place the next layer of spheres *directly above* the first, as shown in Figure 12.28B, we obtain an arrangement based on the *simple* cubic unit cell. By calculating the **packing efficiency** of this arrangement—the percentage of the total volume occupied by the spheres themselves—we find that only 52% of the available unit-cell volume is occupied by spheres and 48% consists of the empty space between them (see Problem 12.128 at the end of the chapter). This is a very inefficient way to pack spheres, so that neither fruit nor atoms are usually packed this way.

2. *The body-centered cubic unit cell.* Rather than placing the second layer directly above the first, we can use space more efficiently by placing the spheres (colored differently for clarity) on the diamond-shaped spaces in the first layer, as shown in Figure 12.28C. Then we pack the third layer onto the spaces in the second so that the first and third layers line up vertically. This arrangement is based on the *body-centered* cubic unit cell, and its packing efficiency is 68%—much higher than for the simple cubic unit cell. Several metallic elements, including chromium, iron, and all the Group 1A(1) elements, have a crystal structure based on the body-centered cubic unit cell.

3. *The hexagonal and face-centered cubic unit cells.* Spheres can be packed even more efficiently. First, we shift rows in the bottom layer so that the large diamond-shaped spaces become smaller triangular spaces. Then we place the second layer over these spaces. Figure 12.28D shows this arrangement, with the first layer labeled *a* (*orange*) and the second layer *b* (*green*).

We can place the third layer of spheres in two different ways, and how we do so gives rise to two different unit cells. If you look carefully at the spaces formed in layer *b* of Figure 12.28D, you'll see that some are orange because they lie above *spheres* in layer *a*, whereas others are white because they lie above *spaces* in layer *a*. If we place the third layer of spheres (*orange*) over the orange spaces (down and left to Figure 12.28E), they lie directly over spheres in layer *a*, and we obtain an *abab*. . . layering pattern because every other layer is placed identically. This gives **hexagonal closest packing,** which is based on the *hexagonal unit cell.*

On the other hand, if we place the third layer of spheres (*blue*) over the white spaces (down and right to Figure 12.28F), the spheres lie over spaces in layer *a*. This placement is different from both layers *a* and *b*, so we obtain an *abcabc*. . . pattern. This gives **cubic closest packing,** which is based on the *face-centered* cubic unit cell.

The packing efficiency of both hexagonal and cubic closest packing is 74%, and the coordination number of both is 12. There is no way to pack identical spheres more efficiently. Most metallic elements crystallize in either of these arrangements. Magnesium, titanium, and zinc are some elements that adopt the

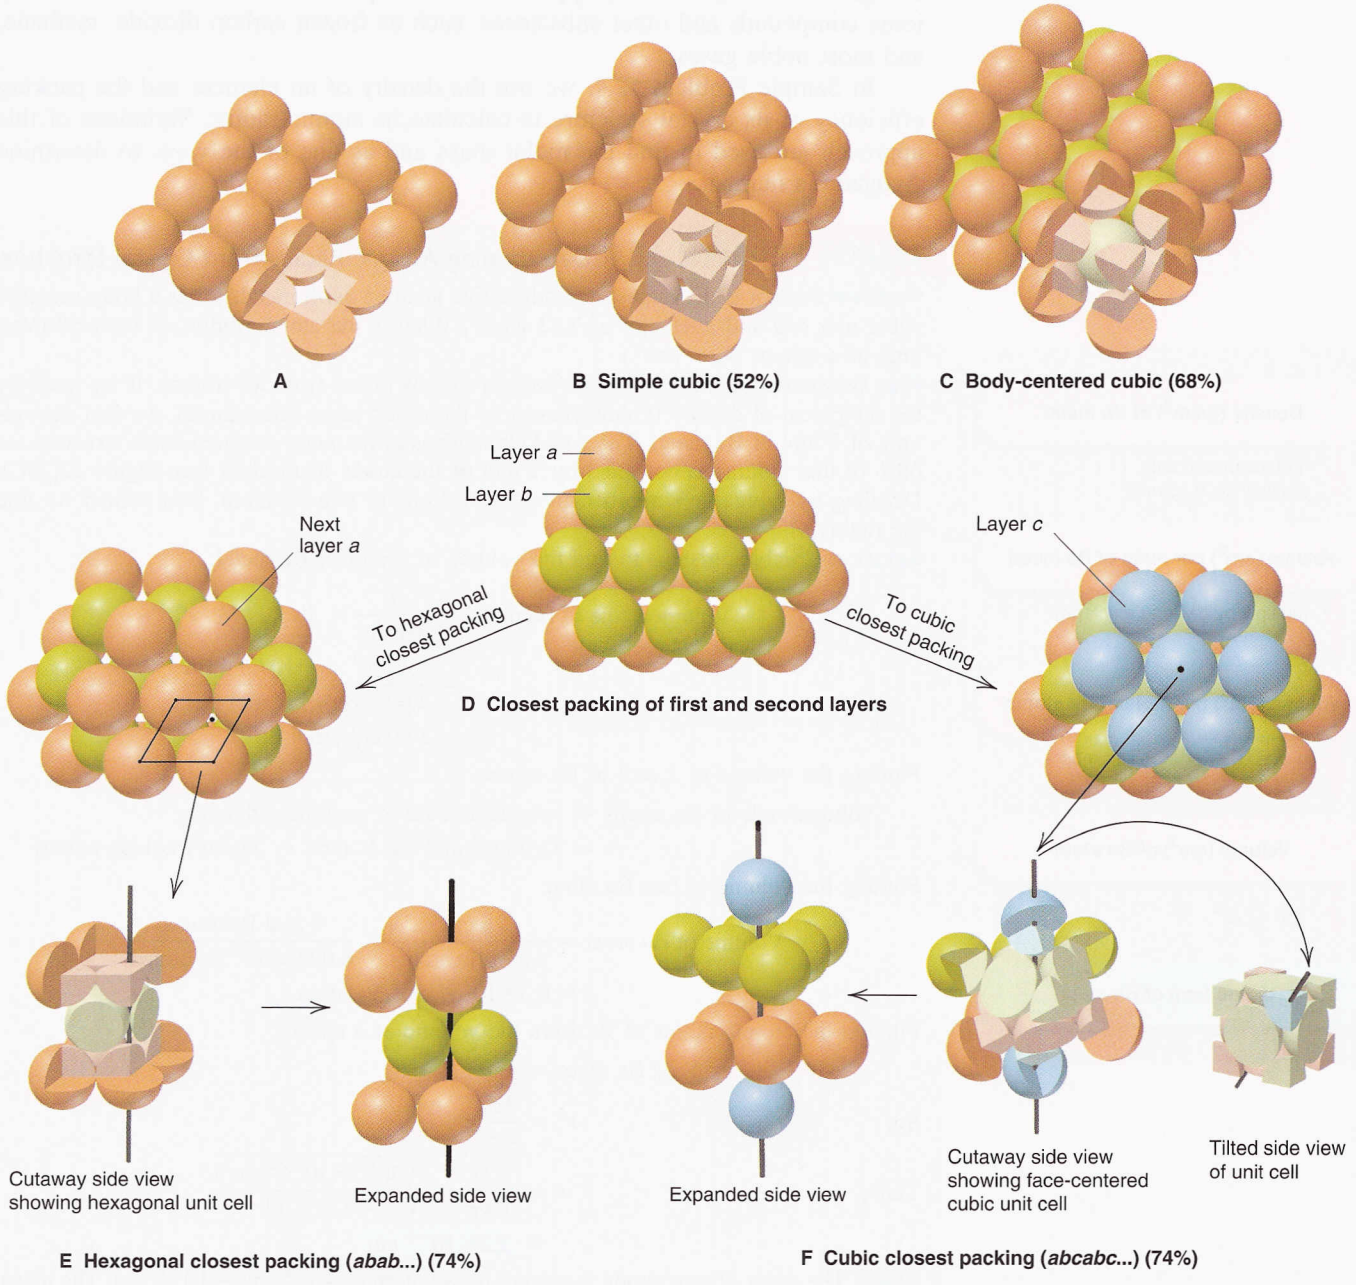

Figure 12.28 Packing identical spheres. A, In the first layer, each sphere lies next to another horizontally and vertically; note the large diamond-shaped spaces (*see cutaway*). **B,** If the spheres in the next layer lie *directly* over those in the first, the packing is based on the *simple cubic* unit cell (*pale orange cube, lower right corner*). **C,** If the spheres in the next layer lie in the diamond-shaped spaces of the first layer, the packing is based on the *body-centered cubic* unit cell (*lower right corner*). **D,** The closest possible packing of the first layer (*layer a, orange*) is obtained by shifting every other row in part A, thus reducing the diamond-shaped spaces to smaller triangular spaces. The spheres of the second layer (*layer b, green*) are placed above these spaces; note the orange and white spaces that result. **E,** Follow the left arrow from part D to obtain hexagonal closest packing. When the third layer (*next layer a, orange*) is placed directly over the first, that is, over the orange spaces, we obtain an *abab. . .* pattern. Rotating the layers 90° produces the side view, with the hexagonal unit cell shown as a cutaway segment, and the expanded side view. **F,** Follow the right arrow from part D to obtain cubic closest packing. When the third layer (*layer c, blue*) covers the white spaces, it lies in a different position from the first *and* second layers to give an *abcabc. . .* pattern. Rotating the layers 90° shows the side view, with the face-centered cubic unit cell as a cutaway, and a further tilt shows the unit cell clearly; finally, we see the expanded view. The packing efficiency for each type of unit cell is given in parentheses.

hexagonal structure; nickel, copper, and lead adopt the cubic structure, as do many ionic compounds and other substances, such as frozen carbon dioxide, methane, and most noble gases.

In Sample Problem 12.4, we use the density of an element and the packing efficiency of its crystal structure to calculate its atomic radius. Variations of this approach are used to find the molar mass and as one of the ways to determine Avogadro's number.

SAMPLE PROBLEM 12.4 Determining Atomic Radius from Crystal Structure

Problem Barium is the largest nonradioactive alkaline earth metal. It has a body-centered cubic unit cell and a density of 3.62 g/cm^3. What is the atomic radius of barium? (Volume of a sphere: $V = \frac{4}{3}\pi r^3$.)

Plan Because an atom is spherical, we can find its radius from its volume. If we multiply the reciprocal of density (volume/mass) by the molar mass (mass/mole), we find the volume of 1 mol of Ba metal. The metal crystallizes in the body-centered cubic structure, so 68% of this volume is occupied by 1 mol of the atoms themselves (see Figure 12.28C). Dividing by Avogadro's number gives the volume of one Ba atom, from which we find the radius.

Density (g/cm^3) of Ba metal
↓ find reciprocal and multiply by $\mathcal{M}$ (g/mol)
Volume (cm^3) per mole of Ba metal
↓ multiply by packing efficiency
Volume (cm^3) per mole of Ba atoms
↓ divide by Avogadro's number
Volume (cm^3) of Ba atom
↓ $V = \frac{4}{3}\pi r^3$
Radius (cm) of Ba atom

Solution Combining steps to find the volume of 1 mol of Ba metal:

$$\text{Volume/mole of Ba metal} = \frac{1}{\text{density}} \times \mathcal{M}$$
$$= \frac{1\text{ cm}^3}{3.62\text{ g Ba}} \times \frac{137.3\text{ g Ba}}{1\text{ mol Ba}}$$
$$= 37.9\text{ cm}^3/\text{mol Ba}$$

Finding the volume of 1 mol of Ba *atoms:*

$$\text{Volume/mole of Ba atoms} = \text{volume/mol Ba} \times \text{packing efficiency}$$
$$= 37.9\text{ cm}^3/\text{mol Ba} \times 0.68 = 26\text{ cm}^3/\text{mol Ba atoms}$$

Finding the volume of one Ba atom:

$$\text{Volume of Ba atom} = \frac{26\text{ cm}^3}{1\text{ mol Ba atoms}} \times \frac{1\text{ mol Ba atoms}}{6.022\times10^{23}\text{ Ba atoms}}$$
$$= 4.3\times10^{-23}\text{ cm}^3/\text{Ba atom}$$

Finding the atomic radius of Ba from the volume of a sphere:

$$V \text{ of Ba atom} = \tfrac{4}{3}\pi r^3$$

So,
$$r^3 = \frac{3V}{4\pi}$$

Thus,
$$r = \sqrt[3]{\frac{3V}{4\pi}} = \sqrt[3]{\frac{3(4.3\times10^{-23}\text{ cm}^3)}{4 \times 3.14}}$$
$$= 2.2\times10^{-8}\text{ cm}$$

Check The order of magnitude is correct for an atom ($\sim10^{-8}$ cm $\approx 10^{-10}$ m). The actual value for barium is, in fact, 2.22×10^{-8} cm (see Figure 8.15, p. 307).

FOLLOW-UP PROBLEM 12.4 Iron crystallizes in a body-centered cubic structure. The volume of one Fe atom is 8.38×10^{-24} cm^3, and the density of Fe is 7.874 g/cm^3. Calculate an approximate value for Avogadro's number.

Our understanding of solids is based on the ability to "see" their crystal structures. Two techniques for doing this are described in the upcoming Tools of the Laboratory essay.

X-Ray Diffraction Analysis and Scanning Tunneling Microscopy

In this chapter and in Chapter 10, we have discussed crystal structures and molecular shapes as if they have actually been seen. You may have been wondering how chemists know atomic radii, bond lengths, and bond angles when the objects exhibiting them are so incredibly minute. Various tools exist for peering into the molecular world and measuring its dimensions, but two of the most powerful are **x-ray diffraction analysis** and **scanning tunneling microscopy.**

X-Ray Diffraction Analysis

This technique has been used for decades to determine crystal structures. In Chapter 7, we discussed wave diffraction and saw how interference patterns of bright and dark regions appear when light passes through slits that are spaced at the distance of the light's wavelength (see Figure 7.5, p. 261). In 1912, the Swiss physicist Max von Laue suggested that, since x-ray wavelengths are about the same size as the spaces between layers of particles in many solids, the layers might diffract x-rays. (Actually, the suggestion was made to test whether x-rays were particulate or wavelike.) X-ray diffraction was soon recognized as a powerful tool for determining the structure of a solid.

Let's see how this technique is used to measure a key parameter in a crystal structure: the distance (d) between layers of atoms. Figure B12.1 depicts a side view of two layers in a simplified lattice. Two waves impinge on the crystal at an angle θ and are diffracted at the same angle by adjacent layers. When the first wave strikes the top layer and the second strikes the next layer, the waves are *in phase* (peaks aligned with peaks and troughs with troughs). If they are still in phase after being diffracted, a spot appears on a nearby photographic plate. Note that this will occur only if the additional distance traveled by the second wave ($DE + EF$ in the figure) is a whole number of wavelengths, $n\lambda$, where n is an integer (1, 2, 3, and so on). From trigonometry, we find that

$$n\lambda = 2d \sin \theta$$

where θ is the known angle of incoming light, λ is its known wavelength, and d is the unknown distance between the layers in the crystal. This relationship is the *Bragg equation,* named for W. H. Bragg and his son W. L. Bragg, who shared the Nobel Prize in physics in 1915 for their work on crystal structure analysis.

Rotating the crystal changes the angle of incoming radiation and produces a different set of spots, eventually yielding a complete diffraction pattern that is used to determine the distances and angles within the lattice (Figure B12.2). The diffraction pattern is not an actual picture of the structure; the pattern must be analyzed mathematically to obtain the dimensions of the crystal. Modern x-ray diffraction equipment automatically rotates the crystal and measures thousands of diffractions, and a computer calculates the parameters of interest.

(continued)

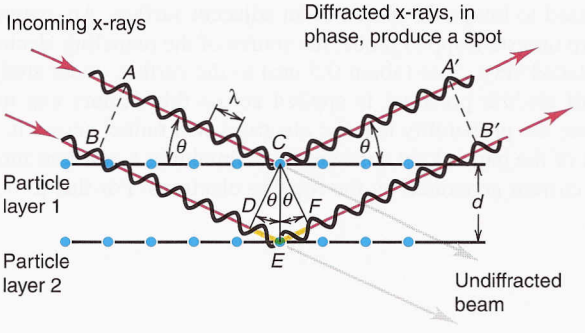

Figure B12.1 Diffraction of x-rays by crystal planes. As in-phase x-ray beams A and B pass into a crystal at angle θ, they are diffracted by interaction with the particles. Beam B travels the distance $DE + EF$ farther than beam A. If this additional distance is equal to a whole number of wavelengths, the beams remain in phase and create a spot on a screen or photographic plate. From the pattern of spots and the Bragg equation, $n\lambda = 2d \sin \theta$, the distance d between layers of particles can be calculated.

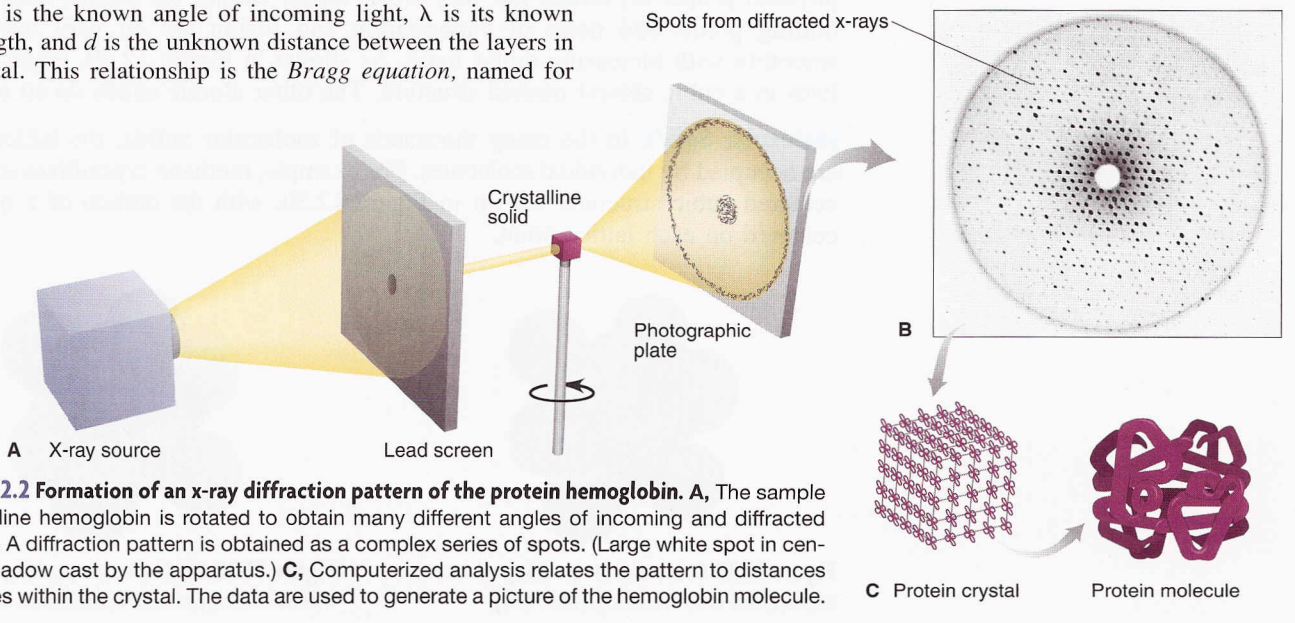

Figure B12.2 Formation of an x-ray diffraction pattern of the protein hemoglobin. A, The sample of crystalline hemoglobin is rotated to obtain many different angles of incoming and diffracted x-rays. **B,** A diffraction pattern is obtained as a complex series of spots. (Large white spot in center is a shadow cast by the apparatus.) **C,** Computerized analysis relates the pattern to distances and angles within the crystal. The data are used to generate a picture of the hemoglobin molecule.

X-ray diffraction analysis is used to answer questions in many branches of chemistry, but its greatest impact has been in biochemistry. It has shown that DNA exists as a double helix, and it is currently helping biochemists learn how a protein's three-dimensional structure is related to its function.

Scanning Tunneling Microscopy

This technique, a much newer method than x-ray diffraction analysis, is used to observe surfaces on the atomic scale. It was invented in the early 1980s by Gerd Binnig and Heinrich Rohrer, two Swiss physicists who won the Nobel Prize in physics in 1986 for their work. The technique is based on the idea that an electron in an atom has a small probability of existing far from the nucleus, so given the right conditions, it can move ("tunnel") to end up closer to another atom.

In practice, the tunneling electrons create a current that can be used to image the atoms of an adjacent surface. An extremely sharp tungsten-tipped probe, the source of the tunneling electrons, is placed very close (about 0.5 nm) to the surface under study. A small electric potential is applied across this minute gap to increase the probability that the electrons will tunnel across it. The size of the gap is kept constant by maintaining a constant tunneling current generated by the moving electrons. For this to occur, the probe must move tiny distances up and down, thus following the atomic contour of the surface. This movement is electronically monitored, and after many scans, a three-dimensional map of the surface is obtained. The method has revealed magnificent images of atoms and molecules coated on surfaces and is being used to study many aspects of surfaces, such as the nature of defects and the adhesion of films (Figure B12.3).

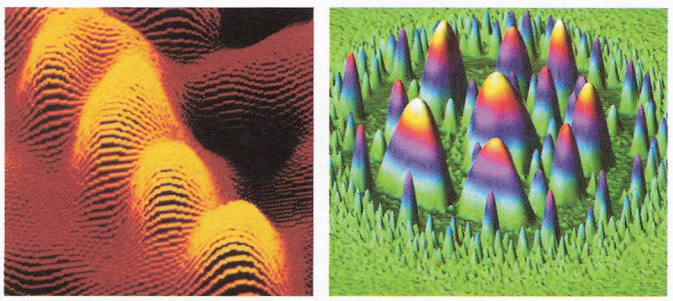

Figure B12.3 Scanning tunneling micrographs. A view of the DNA double helix (*left;* magnification ×1,000,000). Yttrium(II) oxide on an yttrium surface (*right*).

Types and Properties of Crystalline Solids

Now we can turn to the five most important types of solids, which are summarized in Table 12.5. Each is defined by the type of particle in the crystal, which determines the forces between them. You may want to review the bonding models (Chapter 9) to clarify how they relate to the properties of different solids.

Atomic Solids Individual atoms held together by dispersion forces form an **atomic solid.** The noble gases [Group 8A(18)] are the only examples, and their physical properties reflect the very weak forces among the atoms. Melting and boiling points and heats of vaporization and fusion are all very low, rising smoothly with increasing molar mass. As shown in Figure 12.29, argon crystallizes in a cubic closest packed structure. The other atomic solids do so as well.

Molecular Solids In the many thousands of **molecular solids,** the lattice points are occupied by individual molecules. For example, methane crystallizes in a face-centered cubic structure, shown in Figure 12.30, with the carbon of a molecule centered on each lattice point.

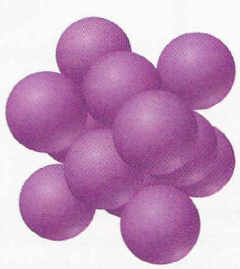

Figure 12.29 Cubic closest packing of frozen argon (face-centered cubic unit cell).

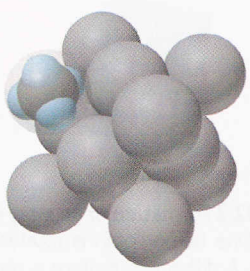

Figure 12.30 Cubic closest packing of frozen methane. Only one CH_4 molecule is shown.

Table 12.5 Characteristics of the Major Types of Crystalline Solids

Type	Particle(s)	Interparticle Forces	Physical Properties	Examples [mp, °C]
Atomic	Atoms	Dispersion	Soft, very low mp, poor thermal and electrical conductors	Group 8A(18) [Ne (−249) to Rn (−71)]
Molecular	Molecules	Dispersion, dipole-dipole, H bonds	Fairly soft, low to moderate mp, poor thermal and electrical conductors	*Nonpolar** O_2 [−219], C_4H_{10} [−138] Cl_2 [−101], C_6H_{14} [−95], P_4 [44.1] *Polar* SO_2 [−73], $CHCl_3$ [−64], HNO_3 [−42], H_2O [0.0], CH_3COOH [17]
Ionic	Positive and negative ions	Ion-ion attraction	Hard and brittle, high mp, good thermal and electrical conductors when molten	NaCl [801] CaF_2 [1423] MgO [2852]
Metallic	Atoms	Metallic bond	Soft to hard, low to very high mp, excellent thermal and electrical conductors, malleable and ductile	Na [97.8] Zn [420] Fe [1535]
Network covalent	Atoms	Covalent bond	Very hard, very high mp, usually poor thermal and electrical conductors	SiO_2 (quartz) [1610] C (diamond) [~4000]

*Nonpolar molecular solids are arranged in order of increasing molar mass. Note the correlation with increasing melting point (mp).

Various combinations of dipole-dipole, dispersion, and H-bonding forces are at work in molecular solids, which accounts for their wide range of physical properties. Dispersion forces are the principal force acting in nonpolar substances, so melting points generally increase with molar mass (Table 12.5). Among polar molecules, dipole-dipole forces and, where possible, H bonding dominate. Except for those substances consisting of the simplest molecules, molecular solids have higher melting points than the atomic solids (noble gases). Nevertheless, intermolecular forces are still relatively weak, so the melting points are much lower than those of ionic, metallic, and network covalent solids.

Ionic Solids In crystalline **ionic solids,** the unit cell contains particles with whole, rather than partial, charges. As a result, the interparticle forces (ionic bonds) are *much* stronger than the van der Waals forces in atomic or molecular solids. To maximize attractions, cations are surrounded by as many anions as possible, and vice versa, with *the smaller of the two ions lying in the spaces (holes) formed by the packing of the larger.* Since the unit cell is the smallest portion of the crystal that maintains the overall spatial arrangement, it is also the smallest portion that maintains the overall chemical composition. In other words, *the unit cell has the same cation:anion ratio as the empirical formula.*

Ionic compounds adopt several different crystal structures, but many use cubic closest packing. Let's first consider two structures that have a 1:1 ratio of ions. The *sodium chloride structure* is found in many compounds, including most of the alkali metal [Group 1A(1)] halides and hydrides, the alkaline earth metal [Group 2A(2)] oxides and sulfides, several transition-metal oxides and sulfides, and most of the silver halides. To visualize this structure, first imagine Cl^- anions

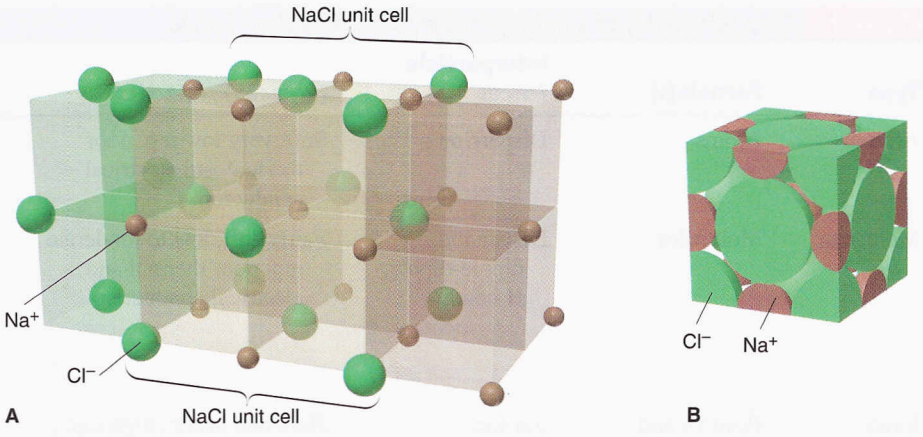

Figure 12.31 The sodium chloride structure. A, In an expanded view, the sodium chloride structure is pictured as resulting from the interpenetration of two face-centered cubic arrangements, one of Na^+ ions (*brown*) and the other of Cl^- ions (*green*). **B,** A space-filling view of the NaCl unit cell (central overlapped portion in part A), which consists of four Cl^- ions and four Na^+ ions.

and Na^+ cations organized separately in face-centered cubic (cubic closest packing) arrays. The crystal structure arises when these two arrays penetrate each other such that the smaller Na^+ ions end up in the holes between the larger Cl^- ions, as shown in Figure 12.31A. Thus, each Na^+ is surrounded by six Cl^-, and vice versa (coordination number = 6). Figure 12.31B is a space-filling depiction of the unit cell showing a face-centered cube of Cl^- ions with Na^+ ions between them. Note the four Cl^- $[(8 \times \frac{1}{8}) + (6 \times \frac{1}{2}) = 4\ Cl^-]$ and four Na^+ $[(12 \times \frac{1}{4}) + 1$ in the center $= 4\ Na^+]$, giving a 1:1 ion ratio.

Another structure with a 1:1 ion ratio is the *zinc blende (ZnS) structure*. It can be pictured as two face-centered cubic arrays, one of Zn^{2+} ions and the other of S^{2-} ions, interpenetrating such that each ion is tetrahedrally surrounded by four ions of opposite charge (coordination number = 4). Note the 1:1 ratio of ions in the unit cell shown in Figure 12.32. Many other compounds, including AgI, CdS, and the Cu(I) halides adopt the zinc blende structure.

The *fluorite (CaF_2) structure* is common among salts with a 1:2 cation:anion ratio, especially those having relatively large cations and relatively small anions.

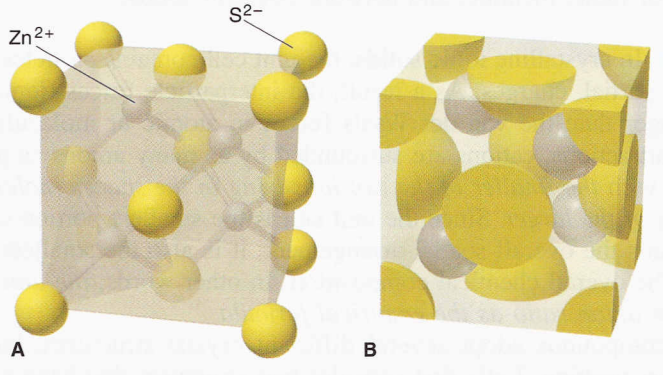

Figure 12.32 The zinc blende structure. Zinc sulfide adopts the zinc blende structure. **A,** The translucent cube shows a face-centered cubic array of four $[(8 \times \frac{1}{8}) + (6 \times \frac{1}{2}) = 4]$ S^{2-} ions (*yellow*) tetrahedrally surrounding each of four Zn^{2+} ions (*gray*) to give the 1:1 empirical formula. (Bonds are shown only for clarity.) **B,** The actual unit cell slightly expanded to show the interior ions.

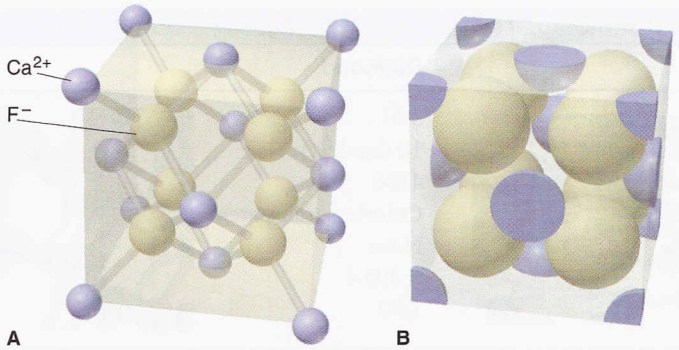

Figure 12.33 The fluorite structure. Calcium fluoride adopts the fluorite structure. **A,** The translucent cube shows a face-centered cubic array of four Ca^{2+} ions (*blue*) tetrahedrally surrounding each of eight F^- ions (*yellow*) to give the 4:8, or 1:2, ratio. **B,** The actual unit cell (slightly expanded).

In the case of CaF_2, the unit cell is a face-centered cubic array of Ca^{2+} ions with F^- ions occupying *all* eight available holes (Figure 12.33). This results in a Ca^{2+}:F^- ratio of 4:8, or 1:2. SrF_2 and $BaCl_2$ have the fluorite structure also. The *antifluorite structure* is often seen in compounds having a cation:anion ratio of 2:1 and a relatively large anion (for example, K_2S). In this structure, the cations occupy all eight holes formed by the cubic closest packing of the anions, just the opposite of the fluorite structure.

The properties of ionic solids are a direct consequence of the *fixed ion positions* and *very strong interionic forces,* which create a high lattice energy. Thus, ionic solids typically have high melting points and low electrical conductivities. When a large amount of heat is supplied and the ions gain enough kinetic energy to break free of their positions, the solid melts and the mobile ions conduct a current. Ionic compounds are hard because only a strong external force can change the relative positions of many trillions of interacting ions. If enough force *is* applied to move them, ions of like charge are brought near each other, and their repulsions crack the crystal (see Figure 9.8, p. 337).

Metallic Solids In contrast to the weak dispersion forces between the atoms in atomic solids, powerful metallic bonding forces hold individual atoms together in **metallic solids.** Most metallic elements crystallize in one of the two closest packed structures (Figure 12.34).

The properties of metals—high electrical and thermal conductivity, luster, and malleability—result from the presence of delocalized electrons, the essential feature of metallic bonding (introduced in Section 9.6). Metals have a wide range of melting points and hardnesses, which are related to the packing efficiency of the crystal structure and the number of valence electrons available for bonding. For example, Group 2A metals are harder and higher melting than Group 1A metals (see Figure 9.26, p. 358), because the 2A metals have closest packed structures (except Ba) and twice as many delocalized valence electrons.

Network Covalent Solids In the final type of crystalline solid, separate particles are not present. Instead, strong covalent bonds link the atoms together throughout a **network covalent solid.** As a consequence of the strong bonding, all these substances have extremely high melting and boiling points, but their conductivity and hardness depend on the details of their bonding.

The two common crystalline forms of elemental carbon are examples of network covalent solids. Although graphite and diamond have the same composition,

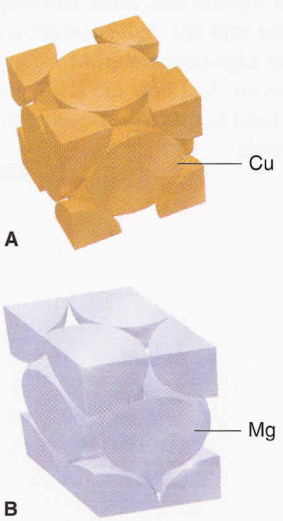

Figure 12.34 Crystal structures of metals. Most metals crystallize in one of the two closest packed arrangements. **A,** Copper adopts cubic closest packing. **B,** Magnesium adopts hexagonal closest packing.

Table 12.6 Comparison of the Properties of Diamond and Graphite

Property	Graphite		Diamond	
Density (g/cm^3)	2.27		3.51	Hardness	<1 (very soft)		10 (hardest)	
Melting point (K)	4100		4100	
Color	Shiny black		Colorless transparent	
Electrical conductivity	High (along sheet)		None	
ΔH^0_{comb} (kJ/mol)	−393.5		−395.4	
ΔH^0_f (kJ/mol)	0 (standard state)		1.90	

A Diamond Film on Every Pot In the 1950s, synthetic diamonds were manufactured slowly and expensively by exposing graphite to extreme temperatures (~1400°C) and pressures (50,000 atm). In the 1960s, a much cheaper method was discovered; by the 1990s, it was being used to deposit thin films of diamond onto virtually any surface. In the process of chemical vapor deposition (CVD), a stream of methane molecules break down at moderate temperatures (~600°C) and low pressures (~0.001 atm), and the carbon atoms deposit on the surface at rates that build up a thickness greater than 100 μm per hour. Because diamond is incredibly hard and has high thermal conductivity, applications for diamond films are myriad: scratch-proof cookware, watch crystals, hard disks, and eyeglasses; lifetime drill bits, ball bearings, and razor blades; high-temperature semiconductors, and so on. And now the CVD process is even used to make gem-quality synthetic diamonds.

their properties are strikingly different, as Table 12.6 shows. Graphite occurs as stacked flat sheets of hexagonal carbon rings with a strong σ-bond framework and delocalized π bonds, reminiscent of benzene. The arrangement of hexagons looks like chicken wire or honeycomb. Whereas the π-bonding electrons of benzene are delocalized over one ring, those of graphite are delocalized over the entire sheet. These mobile electrons allow graphite to conduct electricity, but only in the plane of the sheets. Graphite is a common electrode material and was once used for lightbulb filaments. The sheets interact via dispersion forces. Common impurities, such as O_2, that lodge between the sheets allow them to slide past each other easily, which explains why graphite is so soft. Diamond crystallizes in a face-centered cubic unit cell, with each carbon atom tetrahedrally surrounded by four others in one virtually endless array. Strong, single bonds throughout the crystal make diamond the hardest substance known. Because of its localized bonding electrons, diamond (like most network covalent solids) is unable to conduct electricity.

By far the most important network covalent solids are the *silicates*. They utilize a variety of bonding patterns, but nearly all consist of extended arrays of covalently bonded silicon and oxygen atoms. Quartz (SiO_2) is a common example. We'll discuss silicates, which form the structure of clays, rocks, and many minerals, when we consider the chemistry of silicon in Chapter 14.

Amorphous Solids

Amorphous solids are noncrystalline. Many have small, somewhat ordered regions connected by large disordered regions. Charcoal, rubber, and glass are some familiar examples of amorphous solids.

The process that forms quartz glass is typical of that for many amorphous solids. Crystalline quartz (SiO_2) has a cubic closest packed structure. The crystalline form is melted, and the viscous liquid is cooled rapidly to prevent it from recrystallizing. The chains of silicon and oxygen atoms cannot orient themselves quickly enough into an orderly structure, so they solidify in a distorted jumble containing many gaps and misaligned rows (Figure 12.35). The absence of regularity in the structure confers some properties of a liquid; in fact, glasses are sometimes referred to as *supercooled liquids*.

Bonding in Solids: Molecular Orbital Band Theory

Chapter 9 introduced a qualitative model of metallic bonding that pictures metal ions submerged in a "sea" of mobile, delocalized valence electrons. Quantum mechanics offers another model, an extension of molecular orbital (MO) theory, called **band theory.** It is more quantitative than the electron-sea model, and therefore more useful. We'll pay special attention to bonding in metals and differences in electrical conductivity of metals, metalloids, and nonmetals.

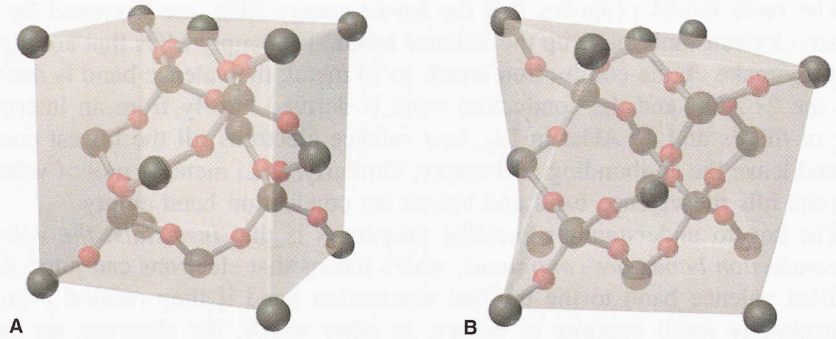

Figure 12.35 Crystalline and amorphous silicon dioxide. A, The atomic arrangement of cristobalite, one of the many crystalline forms of silica (SiO_2), shows the regularity of cubic closest packing. **B,** The atomic arrangement of a quartz glass is amorphous with a generally disordered structure.

Recall that when two atoms form a diatomic molecule, their atomic orbitals (AOs) combine to form an equal number of molecular orbitals (MOs). Let's consider lithium as an example. Figure 12.36 shows the formation of MOs in lithium. In dilithium, Li_2, each atom has four valence orbitals (one 2*s* and three 2*p*). (Recall that in Section 11.3, we focused primarily on the 2*s* orbitals.) They combine to form eight MOs, four bonding and four antibonding, spread over both atoms. If two more Li atoms combine, they form Li_4, a slightly larger aggregate, with 16 delocalized MOs. As more Li atoms join the cluster, more MOs are created, their energy levels lying closer and closer together. Extending this process to a 7-g sample of lithium metal (the molar mass) results in 1 mol of Li atoms (Li_{N_A}) combining to form an extremely large number (4 × Avogadro's number) of delocalized MOs, with *energies so closely spaced that they form a continuum, or band, of MOs*. It is almost as though the entire piece of metal were one enormous Li molecule.

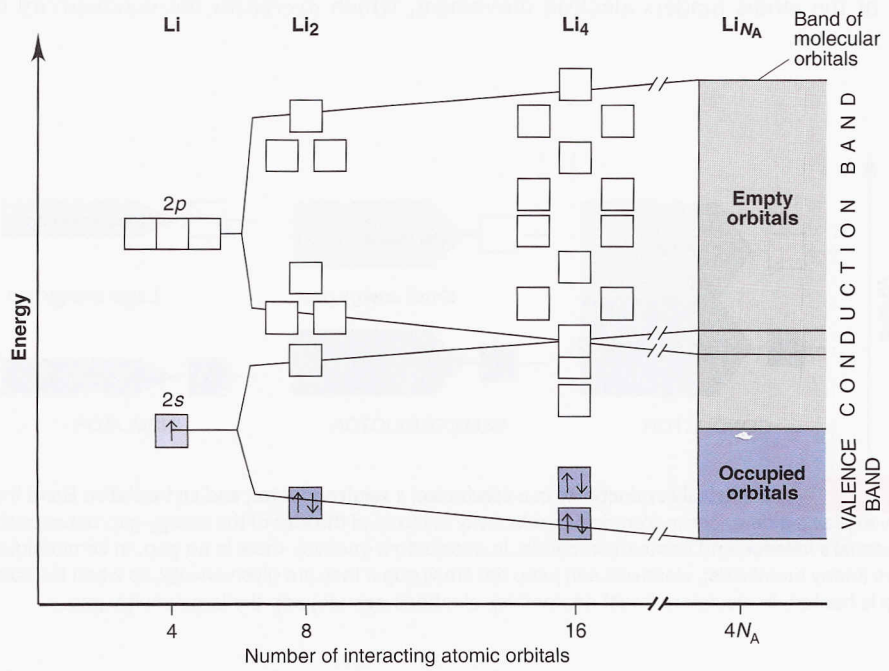

Figure 12.36 The band of molecular orbitals in lithium metal. Lithium atoms contain four valence orbitals, one 2*s* and three 2*p* *(left)*. When two lithium atoms combine (Li_2), their AOs form eight MOs within a certain range of energy. Four Li atoms (Li_4) form 16 MOs. A mole of Li atoms forms $4N_A$ MOs (N_A = Avogadro's number). The orbital energies are so close together that they form a continuous band. The valence electrons enter the lower energy portion (valence band), while the higher energy portion (conduction band) remains empty. In lithium (and other metals), the valence and conduction bands have no gap between them.

The band model proposes that the lower energy MOs are occupied by the valence electrons and make up the **valence band.** The empty MOs that are higher in energy make up the **conduction band.** In Li metal, the valence band is derived from the 2*s* AOs, and the conduction band is derived mostly from an intermingling of the 2*s* and 2*p* AOs. In Li_2, two valence electrons fill the lowest energy MO and leave the antibonding MO empty. Similarly, in Li metal, 1 mol of valence electrons fills the valence band and leaves the conduction band empty.

The key to understanding metallic properties is that *in metals, the valence and conduction bands are contiguous,* which means that electrons can jump from the filled valence band to the unfilled conduction band if they receive even an infinitesimally small quantity of energy. In other words, the electrons are completely delocalized: *they are free to move throughout the piece of metal.* Thus, metals conduct electricity so well because an applied electric field easily excites the highest energy electrons into empty orbitals, and they move through the sample.

Metallic luster (shininess) is another effect of the continuous band of MO energy levels. With so many closely spaced levels available, electrons can absorb and release photons of many frequencies as they move between the valence and conduction bands. Malleability and thermal conductivity also result from the completely delocalized electrons. Under an externally applied force, layers of positive metal ions simply move past each other, always protected from mutual repulsions by the presence of the delocalized electrons (see Figure 9.27B, p. 359). When a metal wire is heated, the highest energy electrons are excited and their extra energy is transferred as kinetic energy along the wire's length.

Large numbers of nonmetal or metalloid atoms can also combine to form bands of MOs. Metals conduct a current well (conductors), whereas most nonmetals do not (insulators), and the conductivity of metalloids lies somewhere in between (semiconductors). Band theory explains these differences in terms of the size of the energy gaps between the valence and conduction bands, as shown in Figure 12.37:

1. *Conductors (metals).* The valence and conduction bands of a **conductor** have no gap between them, so electrons flow when even a tiny electrical potential difference is applied. When the temperature is raised, greater random motion of the atoms hinders electron movement, which *decreases* the conductivity of a metal.

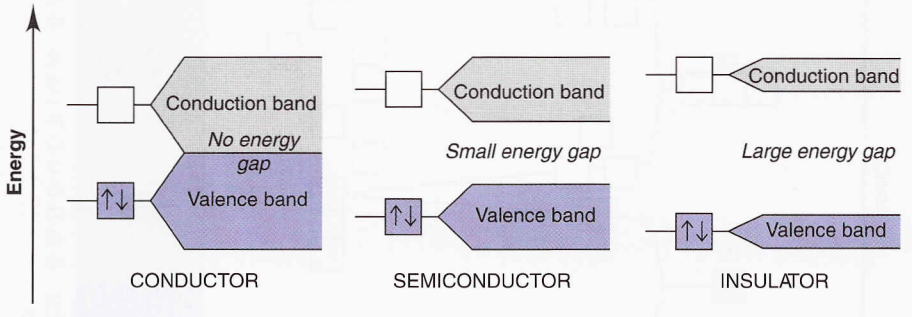

Figure 12.37 Electrical conductivity in a conductor, a semiconductor, and an insulator. Band theory explains differences in electrical conductivity in terms of the size of the energy gap between the material's valence and conduction bands. In conductors (metals), there is no gap. In semiconductors (many metalloids), electrons can jump the small gap if they are given energy, as when the sample is heated. In insulators (most nonmetals), electrons cannot jump the large energy gap.

2. *Semiconductors (metalloids).* In a **semiconductor,** a relatively small energy gap exists between the valence and conduction bands. Thermally excited electrons can cross the gap, allowing a small current to flow. Thus, in contrast to a conductor, the conductivity of a semiconductor *increases* when it is heated.
3. *Insulators (nonmetals).* In an **insulator,** the gap between the bands is too large for electrons to jump even when the substance is heated, so no current is observed.

Another type of electrical conductivity, called **superconductivity,** has been generating intense interest for more than two decades. When metals conduct at ordinary temperatures, electron flow is restricted by collisions with atoms vibrating in their lattice sites. Such restricted flow appears as resistive heating and represents a loss of energy. To conduct with no energy loss—to superconduct—requires extreme cooling to minimize atom movement. This remarkable phenomenon had been observed in metals only by cooling them to near absolute zero, which can be done only with liquid helium (bp = 4 K; price = \$11/L).

In 1986, all this changed with the synthesis of certain ionic oxides that superconduct near the boiling point of liquid nitrogen (bp = 77 K; price = \$0.25/L). Like metal conductors, oxide superconductors have no band gap. In the case of $YBa_2Cu_3O_7$, x-ray analysis shows that the Cu ions in the oxide lattice are aligned, which may be related to the superconducting property. In 1989, oxides with Bi and Tl instead of Y and Ba were synthesized and found to superconduct at 125 K; recently, an oxide with Hg, Ba, and Ca, in addition to Cu and O, was shown to superconduct at 133 K. Engineering dreams for these materials include storage and transmission of electricity with no loss of energy (allowing power plants to be located far from cities), ultrasmall microchips for ultrafast computers, electromagnets to levitate superfast railway trains (Figure 12.38), and inexpensive medical diagnostic equipment with remarkable image clarity.

However, manufacturing problems must be overcome. The oxides are very brittle, but some recent developments may remedy this drawback. A more fundamental concern is that when the oxide is warmed or placed in a strong magnetic field, the superconductivity may disappear and not return again on cooling. Clearly, research into superconductivity will involve chemists, physicists, and engineers for many years to come. We consider other remarkable materials in the next section.

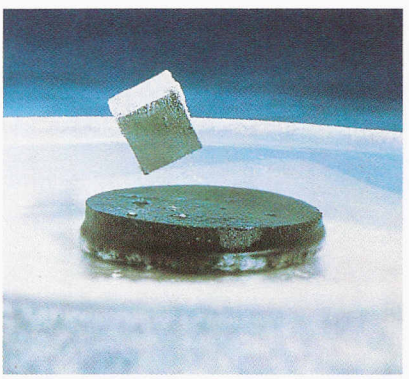

Figure 12.38 The levitating power of a superconducting oxide. A magnet is suspended above a cooled high-temperature superconductor. Someday, this phenomenon may be used to levitate trains above their tracks for quiet, fast travel.

SECTION SUMMARY

The particles in crystalline solids lie at points that form a structure of repeating unit cells. The three types of unit cells in the cubic system are simple, body-centered, and face-centered. The most efficient packing arrangements are cubic closest packing and hexagonal closest packing. Bond angles and distances in a crystal structure can be determined with x-ray diffraction analysis and scanning tunneling microscopy. Atomic solids have a closest packed structure, with atoms held together by very weak dispersion forces. Molecular solids have molecules at the lattice points, often in a cubic closest packed structure. Their intermolecular forces (dispersion, dipole-dipole, H bonding) and resulting physical properties vary greatly. Ionic solids often crystallize with one type of ion filling holes in a cubic closest packed structure of the other. The high melting points, hardness, and low conductivity of these solids arise from strong ionic attractions. Most metals have a closest packed structure. The atoms of network covalent solids are covalently bonded throughout the sample. Amorphous solids have very little regularity among their particles. Band theory proposes that orbitals in the atoms of solids combine to form a continuum, or band, of molecular orbitals. Metals are electrical conductors because electrons move freely from the filled (valence band) to the empty (conduction band) portions of this energy continuum. Insulators have a large energy gap between the two portions; semiconductors have a small gap.

12.7 ADVANCED MATERIALS

In the last few decades, the exciting field of materials science has grown from solid-state chemistry, physics, and engineering, and it is changing our lives in astonishing ways. Objects that were once considered futuristic fantasies of science-fiction writers are realities or soon will be: powerful, ultrafast computers no bigger than this book, connected electronically to millions of others throughout the world; cars powered by sunlight and made of nonmetallic parts stronger than steel and lighter than aluminum; sporting goods made of the materials of space vehicles; ultrasmall machines constructed by manipulating individual atoms and molecules. In this section, we briefly discuss some of these remarkable materials.

Electronic Materials

The ideal of a perfectly ordered crystal is attainable only if the crystal is grown very slowly under carefully controlled conditions. When crystals form more rapidly, **crystal defects** inevitably form. Planes of particles are misaligned, particles are out of place or missing entirely, and foreign particles are lodged in the lattice.

Although crystal defects usually weaken a substance, they are sometimes introduced intentionally to create materials with improved properties, such as increased strength or hardness or, as you'll see in a moment, to increase a material's conductivity for use in electronic devices. In the process of welding two metals together, for example, *vacancies* form near the surface when atoms vaporize, and then these vacancies move deeper as atoms from lower rows rise to fill the gaps. Welding causes the two types of metal atoms to intermingle and fill each other's vacancies. Metal alloying introduces several kinds of crystal defects, as when some atoms of a second metal occupy lattice sites of the first. Often, the alloy is harder than the pure metal; an example is brass, an alloy of copper with zinc. One reason the welded metals are stronger and the alloy is harder is that the second metal contributes additional valence electrons for metallic bonding.

Doped Semiconductors The manufacture and miniaturization of doped semiconductors have revolutionized the communications, home-entertainment, and information industries. By controlling the number of valence electrons through the creation of specific types of defects, chemists and engineers can greatly increase the conductivity of a semiconductor.

Pure silicon (Si), which lies below carbon in Group 4A(14), conducts poorly at room temperature because an energy gap separates its filled valence band from its conduction band (Figure 12.39A). Its conductivity can be greatly enhanced by **doping,** adding small amounts of other elements to increase or decrease the number of valence electrons in the bands. When Si is doped with phosphorus [or another Group 5A(15) element], P atoms occupy some of the lattice sites. Since P has one more valence electron than Si, this additional electron must enter an empty orbital in the conduction band, thus bridging the energy gap and increasing conductivity. Such doping creates an *n-type semiconductor,* so called because extra *n*egative charges (electrons) are present (Figure 12.39B).

When Si is doped with gallium [or another Group 3A(13) element], Ga atoms occupy some sites (Figure 12.39C). Since Ga has one fewer valence electron than Si, some of the orbitals in the valence band are empty, which creates a positive site. Si electrons can migrate to these empty orbitals, thereby increasing conductivity. Such doping creates a *p-type semiconductor,* so called because the empty orbitals act as *p*ositive holes.

In contact with each other, an n-type and a p-type semiconductor form a *p-n junction.* When the negative terminal of a battery is connected to the

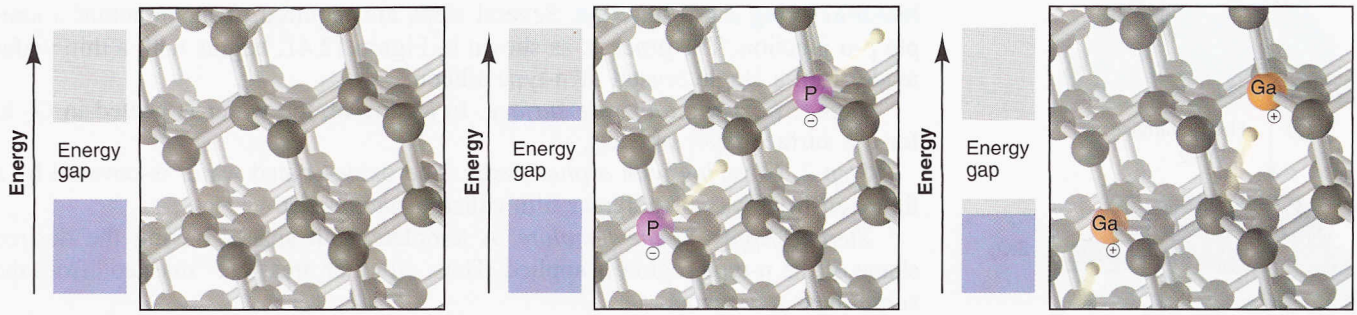

Figure 12.39 Crystal structures and band representations of doped semiconductors. A, Pure silicon has the same crystal structure as diamond but acts as a semiconductor; the energy gap between its valence and conduction bands keeps conductivity low at room temperature. **B,** Doping silicon with phosphorus *(purple)* adds additional valence electrons, which are free to move through the crystal. They enter the lower portion of the conduction band, which is adjacent to higher energy empty orbitals, thereby increasing conductivity. **C,** Doping silicon with gallium *(orange)* removes electrons from the valence band and introduces positive holes. Nearby Si electrons can enter these empty orbitals, thereby increasing conductivity. The orbitals from which the Si electrons move become vacant; in effect, the holes move.

n-type portion and the positive terminal to the p-type portion, electrons flow freely in the n-to-p direction, which has the simultaneous effect of moving holes in the p-to-n direction (Figure 12.40). ⬣ No current flows if the terminals are reversed. Such unidirectional current flow makes a p-n junction act as a *rectifier,* a device that converts alternating current into direct current. A p-n junction in a modern integrated circuit can be made smaller than a square 10 μm on a side. Before the p-n junction was created, rectifiers were bulky, expensive vacuum tubes.

A modern computer chip the size of a nickel may incorporate millions of p-n junctions in the form of *transistors*. One of the most common types, an n-p-n transistor, is made by sandwiching a p-type portion between two n-type portions to form adjacent p-n junctions. The current flowing through one junction controls the current flowing through the other and results in an amplified signal. Once again, to accomplish signal amplification before the advent of doped semiconductors required large, and often unreliable, vacuum tubes. Today, minute transistors are found in every radio, TV, and computer and have made possible the multibillion-dollar electronics industry.

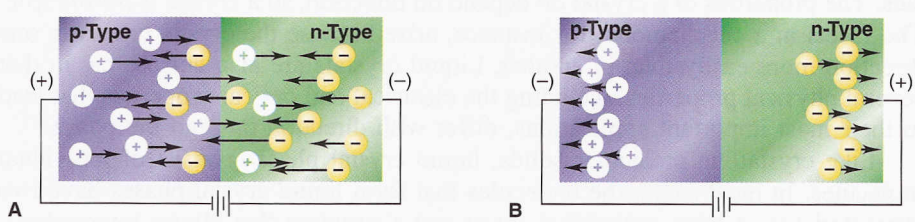

Figure 12.40 The p-n junction. Placing a p-type semiconductor adjacent to an n-type creates a p-n junction. **A,** If the negative battery terminal is connected to the n-type portion, electrons *(yellow sphere with minus sign)* flow toward the p-type portion, which, in effect, moves holes *(white circle with plus sign)* toward the n-type portion. The small arrows indicate the net direction of movement. Note that any hole in the n-type portion lies opposite an electron that moved to the p-type portion. **B,** If the positive battery terminal is connected to the n-type portion, electrons are attracted to it, so no flow takes place across the junction.

⬣ **Solar Cells** One of the more common types of solar cell is, in essence, a p-n junction with an n-type surface exposed to a light source. The light provides the energy to free electrons from the n-type region and accelerate them through an external circuit into the p-type region, thus producing a current to power a calculator, light a bulb, and so on. Arrays of solar cells supply electric power to many residences and businesses, as well as to the space shuttle and most communications satellites (see the photo).

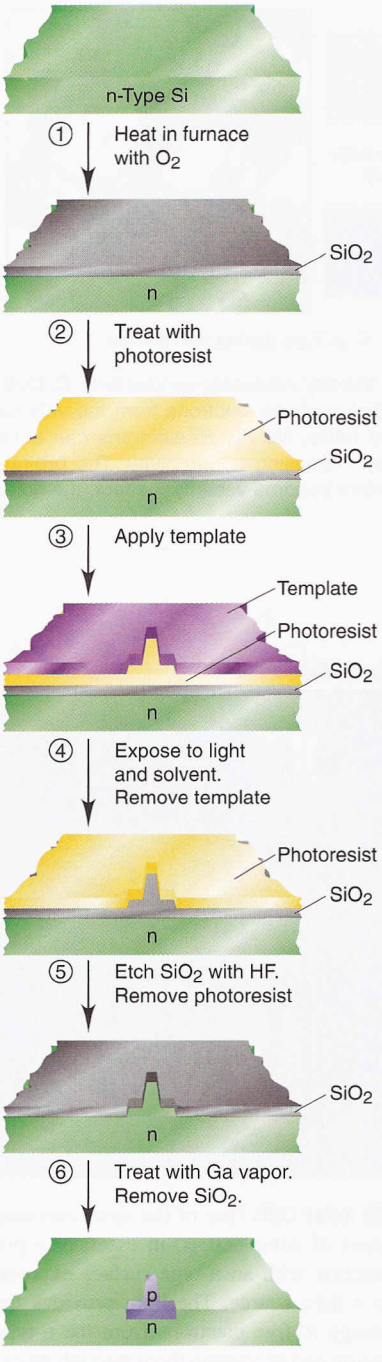

Figure 12.41 Steps in manufacturing a p-n junction. Steps 1 to 5 prepare the desired shape of the p-type portion on the n-type wafer. Step 6 dopes that shape with the Group 3A(13) element.

Manufacturing a p-n Junction Several steps are required to manufacture a simple p-n junction. The process, as shown in Figure 12.41, begins with a thin wafer made from a single crystal of n-type silicon:

Step 1. Forming an oxide surface. In a furnace, the wafer is heated in O_2 to form a surface layer of SiO_2.

Step 2. Covering with a photoresist. The oxide-coated wafer is covered by a light-sensitive wax or polymer film called a *photoresist.*

Step 3. Applying the template. A template with spaces having the desired shape of the p-type region is applied. Thus, all other areas are "masked" from the subsequent treatments.

Step 4. Exposing the photoresist and removing the template. Light shining on the template alters the exposed areas of photoresist so that it can be dissolved away in specific solvents, revealing the oxide surface. The template is removed.

Step 5. Etching the oxide surface and removing the photoresist. Treatment with hydrofluoric acid etches the template-shaped area of oxide coating to expose the n-type Si surface. Following this, the remaining photoresist is also removed.

Step 6. Creating the p-n junction. The wafer is exposed at high temperature to vapor of a Group 3A(13) element, which diffuses into the bare areas to create a template-shaped region of p-type Si adjacent to the n-type Si. The remaining SiO_2 is removed at this point also.

Typically, these steps are repeated to create an n-type region adjacent to the newly formed p-type region, thus forming an n-p-n transistor.

Liquid Crystals

Incorporated in the membrane of every cell in your body and in the display of just about every digital watch, pocket calculator, and laptop computer are unique substances known as **liquid crystals.** These materials flow like liquids but, like crystalline solids, pack at the molecular level with a high degree of order.

Properties, Preparation, and Types of Liquid Crystals To understand the properties of liquid crystals, let's first examine how particles are ordered in the three common physical states and how this affects their properties. The extent of order among particles distinguishes crystalline solids clearly from gases and liquids. Gases have no order, and liquids have little more. Both are considered *isotropic,* which means that their physical properties are the same in every direction within the phase. For example, the viscosity of a gas or a liquid is the same regardless of direction. Glasses and other amorphous solids are also isotropic because they have no regular lattice structure.

In contrast, crystalline solids have a high degree of order among their particles. The properties of a crystal *do* depend on direction, so a crystal is *anisotropic.* The facets in a cut diamond, for instance, arise because the crystal cracks in one direction more easily than in another. Liquid crystals are also anisotropic in that several physical properties, including the electrical and optical properties that lead to their most important applications, differ with direction through the phase.

Like crystalline molecular solids, liquid crystal phases consist of individual molecules. In most cases, the molecules that form liquid crystal phases have two characteristics: a long, cylindrical shape and a structure that allows intermolecular attractions through dispersion and dipole-dipole or H-bonding forces, but that inhibits perfect crystalline packing. Figure 12.42 shows the structures of two molecules that form liquid crystal phases. Note the rodlike shapes and the presence of certain groups—in these cases, flat, benzene-like ring systems—that keep the molecules extended. Many of these types of molecules also have a molecular dipole associated with the long molecular axis. A sufficiently strong electric field

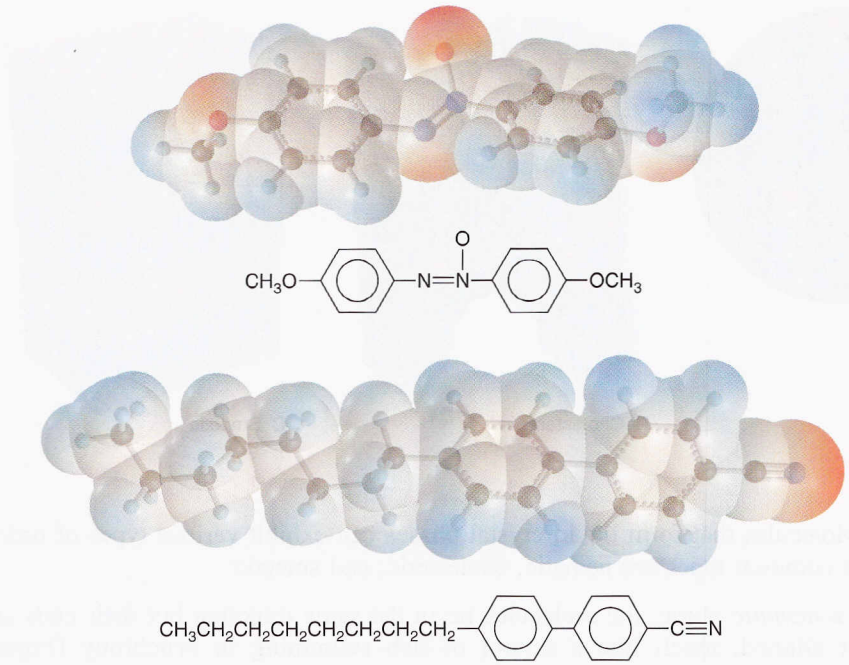

Figure 12.42 Structures of two typical molecules that form liquid crystal phases. Note the long, extended shapes and the regions of high (*red*) and low (*blue*) electron density.

can orient large numbers of these polar molecules in approximately the same direction, like compass needles in a magnetic field.

The viscosity of a liquid crystal phase is lowest in the direction parallel to the long axis. Like moistened microscope slides, it is easier for the molecules to slide along each other (because the total attractive force remains the same), than it is for them to pull apart from each other sideways. As a result, the molecules tend to align while the phase flows.

Liquid crystal phases can arise in two general ways, and, sometimes, either way can occur in the same substance. A *thermotropic* phase develops as a result of a change in temperature. As a crystalline solid is heated, the molecules leave their lattice sites, but the intermolecular interactions are still strong enough to keep the molecules aligned with each other along their long axes. Like any other phase, the liquid crystal phase has sharp transition temperatures; however, it exists over a relatively small temperature range. Further heating provides enough kinetic energy for the molecules to become disordered, as in a normal liquid. The typical range for liquid crystal phases of pure substances is from $<1°C$ to around 10°C, but mixing phases of two or more substances can greatly extend this range. For this reason, the liquid crystal phases used within display devices, as well as those within cell membranes, consist of mixtures of molecules.

A *lyotropic* phase occurs in solution as the result of changes in concentration, but the conditions for forming such a phase vary for different substances. For example, when purified, some biomolecules that exist naturally in mammalian cell membranes form lyotropic phases in water at the moderate temperature that occurs within the organism. At the other extreme, Kevlar, a fiber used in bullet-proof vests and high-performance sports equipment, forms a lyotropic phase at high temperatures in concentrated H_2SO_4 solution.

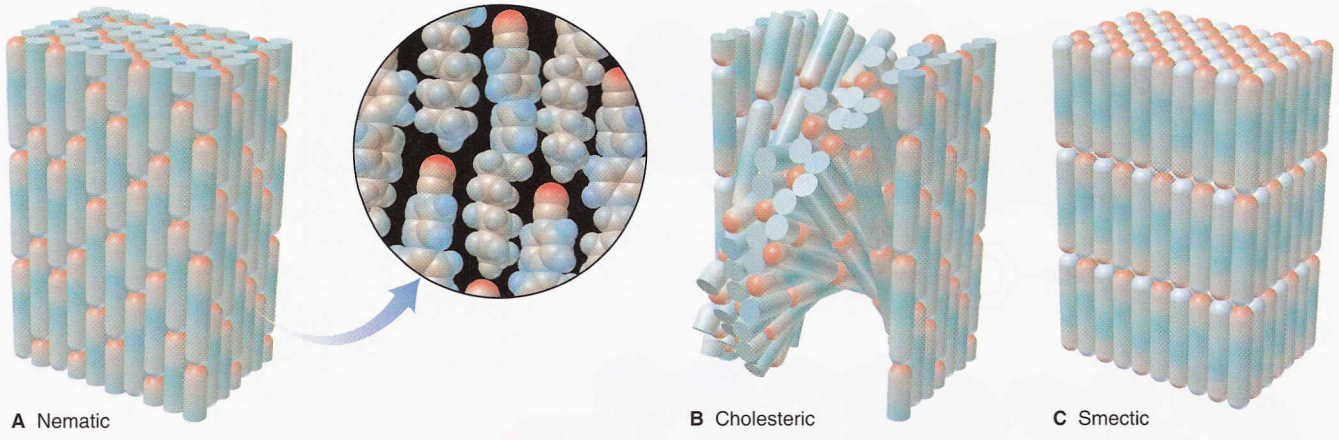

Figure 12.43 The three common types of liquid crystal phases. A, Nematic phase. A rectangular volume of the phase, with expanded view, shows a close-up of the arrangement of molecules. **B,** Cholesteric phase. Note the corkscrew-like arrangement of the layers. **C,** Smectic phase. A rectangular volume of the phase shows the more orderly stacking of layers.

Molecules that form liquid crystal phases can exhibit various types of order. Three common types are nematic, cholesteric, and smectic:

- In a *nematic* phase, the molecules lie in the same direction but their ends are not aligned, much like a school of fish swimming in synchrony (Figure 12.43A). The nematic phase is the least ordered type of liquid crystal phases.
- In a *cholesteric* phase, which is somewhat more ordered, the molecules lie in layers that each exhibit nematic-type ordering. Rather than lying in parallel fashion, however, each layer is rotated by a fixed angle with respect to the next layer. The result is a helical (corkscrew) arrangement, so a cholesteric phase is often called a *twisted nematic phase* (Figure 12.43B).
- In a *smectic* phase, which is the most ordered, the molecules lie parallel to each other, *with* their ends aligned, in layers that are stacked directly over each other, much like a supermarket display of shelves filled with identical bottles (Figure 12.43C). The long molecular axis has a well-defined angle (shown in the figure as 90°) with respect to the plane of the layer. The molecules in Figure 12.42 are typical of those that form nematic or smectic phases. Liquid crystal–type phases appear in many biological systems (Figure 12.44).

In some cases, a substance that forms a given liquid crystal phase under one set of conditions forms other phases under different conditions. Thus, a given thermotropic liquid crystal substance can pass from disordered liquid through a series of distinct liquid crystal phases to an ordered crystal through a decrease in temperature. A lyotropic substance can undergo similar changes through an increase in concentration.

Applications of Liquid Crystals The ability to control the orientation of the molecules in a liquid crystal allows us to produce materials with high strength or unique optical properties.

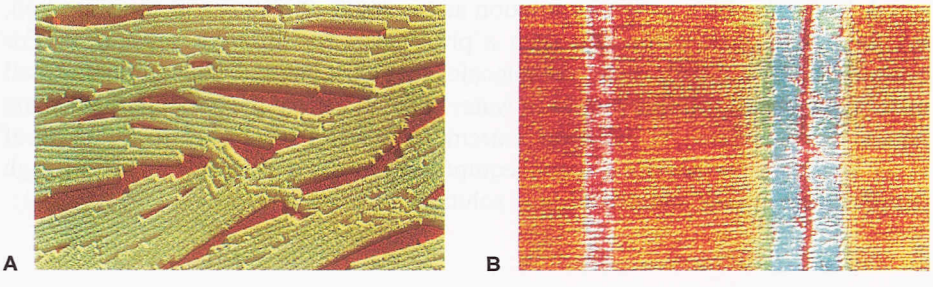

Figure 12.44 Liquid crystal–type phases in biological systems. A, Nematic arrays of tobacco mosaic virus particles within the fluid of a tobacco leaf. **B,** The orderly arrangement of actin and myosin protein filaments in voluntary muscle cells.

High-strength applications involve the use of extremely long molecules called *polymers*. While in a thermotropic liquid crystal phase and during their flow through the processing equipment, these molecules become highly aligned, like the fibers in wood. Cooling solidifies them into fibers, rods, and sheets that can be shaped into materials with superior mechanical properties in the direction of the long molecular axis. Sporting equipment, supersonic aircraft parts, and the sails used in the America's Cup races are fabricated from these polymeric materials. (We discuss the structure and physical behavior of polymers later in this section and their synthesis in Chapter 15.)

Far more important in today's consumer market are the liquid crystal displays (LCDs) used in watches, calculators, cell phones, and computers. All depend on *changes in molecular orientation in an electric field*. The most common type, called a *twisted nematic* display, is shown schematically in Figure 12.45 as a small portion of a wristwatch LCD. The liquid crystal phase consists of layers of nematic phases sandwiched between thin glass plates that incorporate transparent electrodes. As a result of a special coating process, the long molecular axis lies parallel to the plane of the glass plates. The distance between the plates (6–8 μm) is chosen so that the molecular axis within each succeeding layer twists just enough for the molecular orientation at the bottom plate to be 90° from that at the top plate. Above and below this "sandwich" are thin polarizing filters (like those used in Polaroid lenses or camera sunlight filters), which allow light waves oriented in only one direction to pass through. The filters are placed in a "crossed" arrangement, so that light passing through the top filter must twist 90° to pass through the bottom filter. The orientation and optical properties of the molecules twist the orientation of the light by exactly this amount. This whole grouping of filters, plates, and liquid crystal phase lies on a mirror.

A current generated by the watch battery controls the orientation of the molecules within the phase. With the current on in one region of the display, the molecules become oriented *toward* the field, and thus block the light from passing through to the bottom filter, so that region appears dark. With the current off in another region, light passes through the molecules and bottom filter to the mirror and back again, so that region appears bright.

Cholesteric liquid crystals are used in applications that involve color changes with temperature. The twisted molecular orientation in these phases "unwinds" with heating, and the extent of the unwinding determines the color. Liquid crystal thermometers that include a mixture of substances to widen their range of temperatures use this effect. Newer and more important uses include "mapping" the area of a tumor, detecting faulty connections in electronic circuit boards, and nondestructive testing of materials under stress.

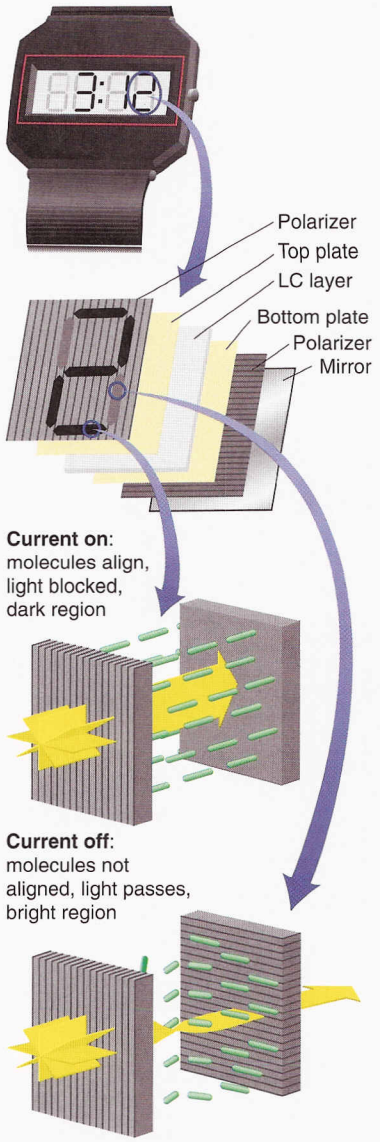

Figure 12.45 Schematic of a liquid crystal display (LCD). A close-up of the "2" on a wristwatch LCD reveals two polarizers sandwiching two glass plates, which sandwich a liquid crystal (LC) layer, all lying on a mirror. When light waves oriented in all directions enter the first polarizer, only waves oriented in one direction emerge to enter the LC layer. Enlarging a dark region of the numeral *(top blow-up)* shows that with the current on, the LC molecules are aligned and the light cannot pass through the other polarizer to the mirror; thus, the viewer sees no light. Enlarging a bright region *(bottom blow-up)* shows that with the current off, the LC molecules lie in a twisted nematic arrangement, which rotates the plane of the light waves and allows them to pass through the other polarizer to the mirror. Reflecting and retracing this path (not shown), the light reaches the viewer.

Ceramic Materials

First developed by Stone Age people, **ceramics** are defined as nonmetallic, nonpolymeric solids that are hardened by heating to high temperatures. Clay ceramics consist of silicate microcrystals suspended in a glassy cementing medium. In "firing" a ceramic pot, for example, a kiln heats the object made of an aluminosilicate clay, such as kaolinite, to 1500°C and the clay loses water:

$$Si_2Al_2O_5(OH)_4(s) \longrightarrow Si_2Al_2O_7(s) + 2H_2O(g)$$

During the heating process, the structure rearranges to an extended network of Si-centered and Al-centered tetrahedra of O atoms (Section 14.6).

Bricks, porcelain, glazes, and other clay ceramics are useful because of their hardness and resistance to heat and chemicals. Today's high-tech ceramics incorporate these traditional characteristics in addition to superior electrical and magnetic properties (Table 12.7, on the next page). As just one example, consider the unusual electrical behavior of certain zinc oxide (ZnO) composites. Ordinarily a

Table 12.7 Some Uses of Modern Ceramics and Ceramic Mixtures

Ceramic	Applications
SiC, Si_3N_4, TiB_2, Al_2O_3	Whiskers (fibers) to strengthen Al and other ceramics
Si_3N_4	Car engine parts; turbine rotors for "turbo" cars; electronic sensor units
Si_3N_4, BN, Al_2O_3	Supports or layering materials (as insulators) in electronic microchips
SiC, Si_3N_4, TiB_2, ZrO_2, Al_2O_3, BN	Cutting tools, edge sharpeners (as coatings and whole devices), scissors, surgical tools, industrial "diamond"
BN, SiC	Armor-plating reinforcement fibers (as in Kevlar composites)
ZrO_2, Al_2O_3	Surgical implants (hip and knee joints)

semiconductor, ZnO can be doped so that it becomes a conductor. Imbedding particles of the doped oxide into an insulating ceramic produces a variable resistor: at low voltage, the material conducts poorly, but at high voltage, it conducts well. Best of all, the changeover voltage can be "preset" by controlling the size of the ZnO particles and the thickness of the insulating medium.

Preparing Modern Ceramics Among the important modern ceramics are silicon carbide (SiC) and nitride (Si_3N_4), boron nitride (BN), and the superconducting oxides. They are prepared by standard chemical methods that involve driving off a volatile component during the reaction.

The SiC ceramics are made from compounds used in silicone polymer manufacture (we'll discuss their structures and uses in Section 14.6):

$$n(CH_3)_2SiCl_2(l) + 2nNa(s) \longrightarrow 2nNaCl(s) + [(CH_3)_2Si]_n(s)$$

This product is heated to 800°C to form the ceramic:

$$[(CH_3)_2Si]_n \longrightarrow nCH_4(g) + nH_2(g) + nSiC(s)$$

SiC can also be prepared by direct reaction of Si and graphite under vacuum:

$$Si(s) + C(\text{graphite}) \xrightarrow{\sim 1500^\circ C} SiC(s)$$

The nitride is also prepared by reaction of the elements:

$$3Si(s) + 2N_2(g) \xrightarrow{>1300^\circ C} Si_3N_4(s)$$

The formation of a BN ceramic begins with the reaction of boron trichloride or boric acid with ammonia:

$$B(OH)_3(s) + 3NH_3(g) \longrightarrow B(NH_2)_3(s) + 3H_2O(g)$$

Heat drives off some of the bound nitrogen as NH_3 to yield the ceramic:

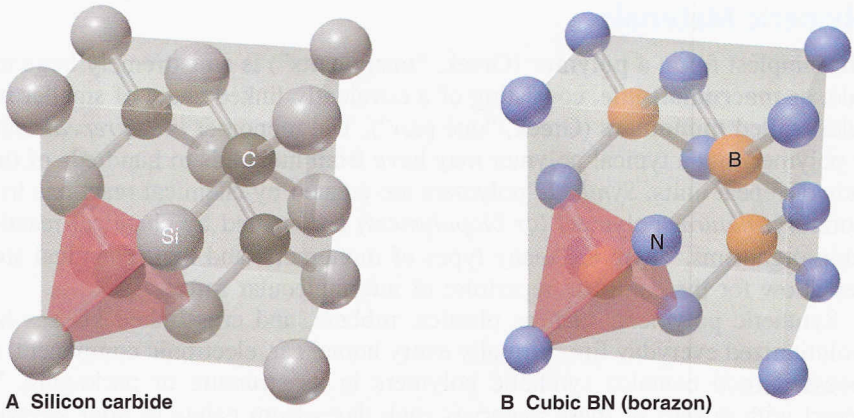
$$B(NH_2)_3(s) \xrightarrow{\Delta} 2NH_3(g) + BN(s)$$

One of the common high-temperature superconducting oxides is a ceramic made by heating a mixture of barium carbonate and copper and yttrium oxides, followed by further heating in the presence of O_2:

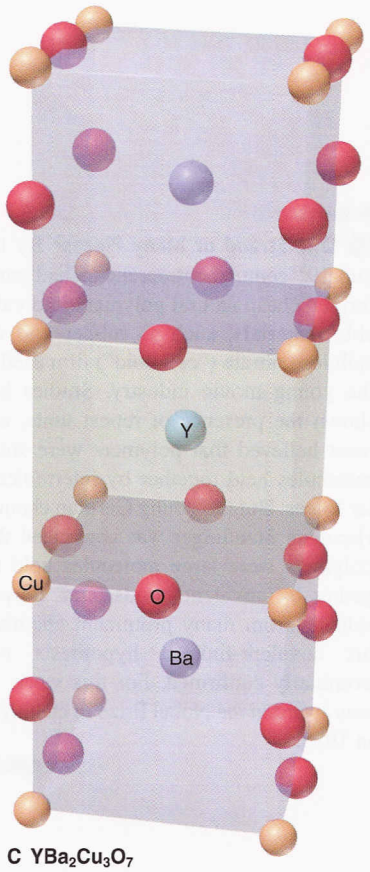
$$4BaCO_3(s) + 6CuO(s) + Y_2O_3(s) \xrightarrow{\Delta} 2YBa_2Cu_3O_{6.5}(s) + 4CO_2(g)$$

$$YBa_2Cu_3O_{6.5}(s) + \tfrac{1}{4}O_2(g) \xrightarrow{\Delta} YBa_2Cu_3O_7(s)$$

Ceramic Structures and Uses Structures of several ceramic materials are shown in Figure 12.46. Note the diamond-like structure of silicon carbide. Network covalent bonding gives this material great strength. Silicon carbide is made into thin fibers, called *whiskers*, to reinforce other ceramics in a composite structure and prevent cracking, much like steel rods reinforcing concrete. Silicon nitride is



A Silicon carbide B Cubic BN (borazon)



C $YBa_2Cu_3O_7$

Figure 12.46 Unit cells of some modern ceramic materials. SiC **(A)** and the high-pressure form of BN **(B)** both have a crystal structure similar to that of diamond and are extremely hard. $YBa_2Cu_3O_7$ **(C)** is one of the high-temperature superconducting oxides.

virtually inert chemically, retains its strength and wear resistance for extended periods above 1000°C, is dense and hard, and acts as an electrical insulator. Japanese and American automakers are testing it in high-efficiency car and truck engines because it allows an ideal combination of low weight, high operating temperature, and little need for lubrication.

The BN ceramics exist in two structures (Section 14.5), analogous to the common crystalline forms of carbon. In the graphite-like form, BN has extraordinary properties as an electrical insulator. At high temperature and very high pressure (1800°C and 8.5×10^4 atm), it converts to a diamond-like structure, which is extremely hard and durable. Both forms are virtually invisible to radar.

Earlier, we mentioned some potential uses of the superconducting oxides. In nearly every one of these ceramic materials, copper occurs in an unusual oxidation state. In $YBa_2Cu_3O_7$, for instance, assuming oxidation states of +3 for Y, +2 for Ba, and −2 for O, the three Cu atoms have a total oxidation state of +7. This is allocated as $Cu(II)_2Cu(III)$, with one Cu in the unusual +3 state. X-ray diffraction analysis indicates that a distortion in the structure makes four of the oxide ions unusually close to the Y^{3+} ion, which aligns the Cu ions into chains within the crystal. It is suspected that a specific half-filled 3*d* orbital in Cu oriented toward a neighboring O^{2-} ion may be associated with superconductivity, although the process is still poorly understood. Because of their brittleness, it has been difficult to fashion these ceramics into wires, but methods for making superconducting films and ribbons have recently been developed.

Research in ceramic processing is beginning to overcome the inherent brittleness of this entire class of materials. This brittleness arises from the strength of the ionic-covalent bonding in these solids and their resulting inability to deform. Under stress, a microfine crystal defect widens and lengthens until the material cracks. One new method forms defect-free ceramics using controlled packing and heat-treating of extremely small, uniform oxide particles coated with organic polymers. Another method is aimed at arresting a widening crack. These ceramics are embedded with zirconia (ZrO_2), whose crystal structure expands up to 5% under the mechanical stress of a crack tip: the moment the advancing crack reaches them, the zirconia particles effectively pinch it shut. Very recently, a third method was reported. Japanese researchers prepared a ceramic material made of precisely grown single crystals of Al_2O_3 and $GdAlO_3$, which become entangled during the solidification process. The material bends without cracking at temperatures above 1800 K.

Despite the technical difficulties, chemical ingenuity will continue to develop new ceramic materials and apply their amazing and useful properties well into the 21st century.

Polymeric Materials

In its simplest form, a **polymer** (Greek, "many parts") is an extremely large molecule, or **macromolecule**, consisting of a covalently linked chain of smaller molecules, called **monomers** (Greek, "one part"). The monomer is the *repeat unit* of the polymer, and a typical polymer may have from hundreds to hundreds of thousands of repeat units. *Synthetic* polymers are created by chemical reactions in the laboratory; *natural* polymers (or *biopolymers*) are created by chemical reactions within organisms. There are many types of monomers, and their chemical structures allow for the complete repertoire of intermolecular forces.

One Strand or Many Pieces? By the mid-19th century, entrepreneurs had transformed cheap natural polymers into valuable materials, such as rubber and the cellulose nitrate ("celluloid") film used in the young movie industry. Studies had shown the presence of repeat units, and most believed that polymers were small molecules held together by intermolecular forces. But the young German chemist Hermann Staudinger was convinced that polymers were large molecules held together by covalent bonds, and, despite ridicule from many prominent chemists, his covalent-linkage hypothesis was eventually confirmed. For this work, he was awarded the Nobel Prize in chemistry in 1953.

Synthetic polymers, such as plastics, rubbers, and crosslinked glasses have revolutionized everyday life. Virtually every home, car, electronic component, and processed food contains synthetic polymers in its structure or packaging. You interact with dozens of these materials each day—from paints to floor coverings to clothing to the additives and adhesives in this textbook. Some of these materials, like those used in food containers, are very long-lived in the environment and have created a serious waste-disposal problem. Others are being actively recycled into the same or other useful products, such as garbage bags, outdoor furniture, roofing tiles, and even marine pilings and roadside curbs. Still others, such as artificial skin, heart valve components, and hip joints, are designed to have as long a life as possible.

In this section, we'll examine the physical nature of synthetic polymers and explore the role intermolecular forces play in their properties and uses. In Chapter 15, we'll examine the types of monomers, look at the preparation of synthetic polymers, and then focus on the structures and vital functions of the biopolymers.

Dimensions of a Polymer Chain: Mass, Size, and Shape

Because of their great lengths, polymers are unlike smaller molecules in several important ways. Let's see how chemists describe the mass, size, and shape of a polymer chain and how the chains exist in a sample. We'll focus throughout on polyethylene, by far the most common synthetic polymer.

1. *Polymer mass.* The molar mass of a polymer chain ($\mathcal{M}_{polymer}$, in g/mol, often referred to as the *molecular weight*) depends on two parameters—the molar mass of the repeat unit ($\mathcal{M}_{repeat}$) and the **degree of polymerization (*n*)**, or the number of repeat units in the chain:

$$\mathcal{M}_{polymer} = \mathcal{M}_{repeat} \times n$$

For example, the molar mass of the ethylene repeat unit is 28 g/mol. If an individual polyethylene chain in a plastic grocery bag has a degree of polymerization of 7100, the molar mass of that particular chain is

$$\mathcal{M}_{polymer} = \mathcal{M}_{repeat} \times n = (28 \text{ g/mol})\ (7.1\times10^3) = 2.0\times10^5 \text{ g/mol}$$

Table 12.8 shows some other examples.

Table 12.8 Molar Masses of Some Common Polymers

Name	$\mathcal{M}_{polymer}$ (g/mol)	*n*	Uses
Acrylates	2×10^5	2×10^3	Rugs, carpets
Polyamide (nylons)	1.5×10^4	1.2×10^2	Tires, fishing line
Polycarbonate	1×10^5	4×10^2	Compact discs
Polyethylene	3×10^5	1×10^4	Grocery bags
Polyethylene (ultrahigh molecular weight)	5×10^6	2×10^5	Hip joints
Poly(ethylene terephthalate)	2×10^4	1×10^2	Soda bottles
Polystyrene	3×10^5	3×10^3	Packing, coffee cups
Poly(vinyl chloride)	1×10^5	1.5×10^3	Plumbing

However, even though any *given* chain within a sample of a polymer has a fixed molar mass, the degree of polymerization often varies considerably from chain to chain. As a result, *all samples of synthetic polymers have a distribution of chain lengths*. For this reason, polymer chemists use various definitions of *average* molar mass, and a common one is the *number-average molar mass*, $\mathcal{M}_n$:

$$\mathcal{M}_n = \frac{\text{total mass of all chains}}{\text{number of moles of chains}}$$

Thus, even though the number-average molar mass of the polyethylene in grocery bags is, say, 1.6×10^5 g/mol, the chains may vary in molar mass from about 7.0×10^4 to 3.0×10^5 g/mol.

2. *Polymer size and shape*. The long axis of a polymer chain is called its *backbone*. The length of an *extended* backbone is simply the number of repeat units (degree of polymerization, n) times the length of each repeat unit (l_0). For instance, the length of an ethylene repeat unit is about 250 pm, so the extended length of our particular grocery-bag polyethylene chain is

$$\text{Length of extended chain} = n \times l_0 = (7.1\times10^3)\ (2.5\times10^2 \text{ pm}) = 1.8\times10^6 \text{ pm}$$

Comparing this length with the thickness of the chain, which is only about 40 pm, gives a good picture of the threadlike dimensions of the extended chain.

It's very important to understand, however, that a polymer molecule, whether pure or in solution, doesn't exist as an extended chain but, in fact, is far more compact. To picture the actual shape, polymer chemists assume, as a first approximation, that the shape of the chain arises as a result of free rotation around all of its single bonds. Thus, as each repeat unit rotates randomly, the chain continuously changes direction, turning back on itself many times and eventually arriving at the **random coil** shape that most polymers adopt (Figure 12.47). In reality, of course, rotation is not completely free because, as one portion of a chain bends and twists near other portions of the same chain or of other nearby chains, they attract each other. Thus, the nature of intermolecular forces between chain

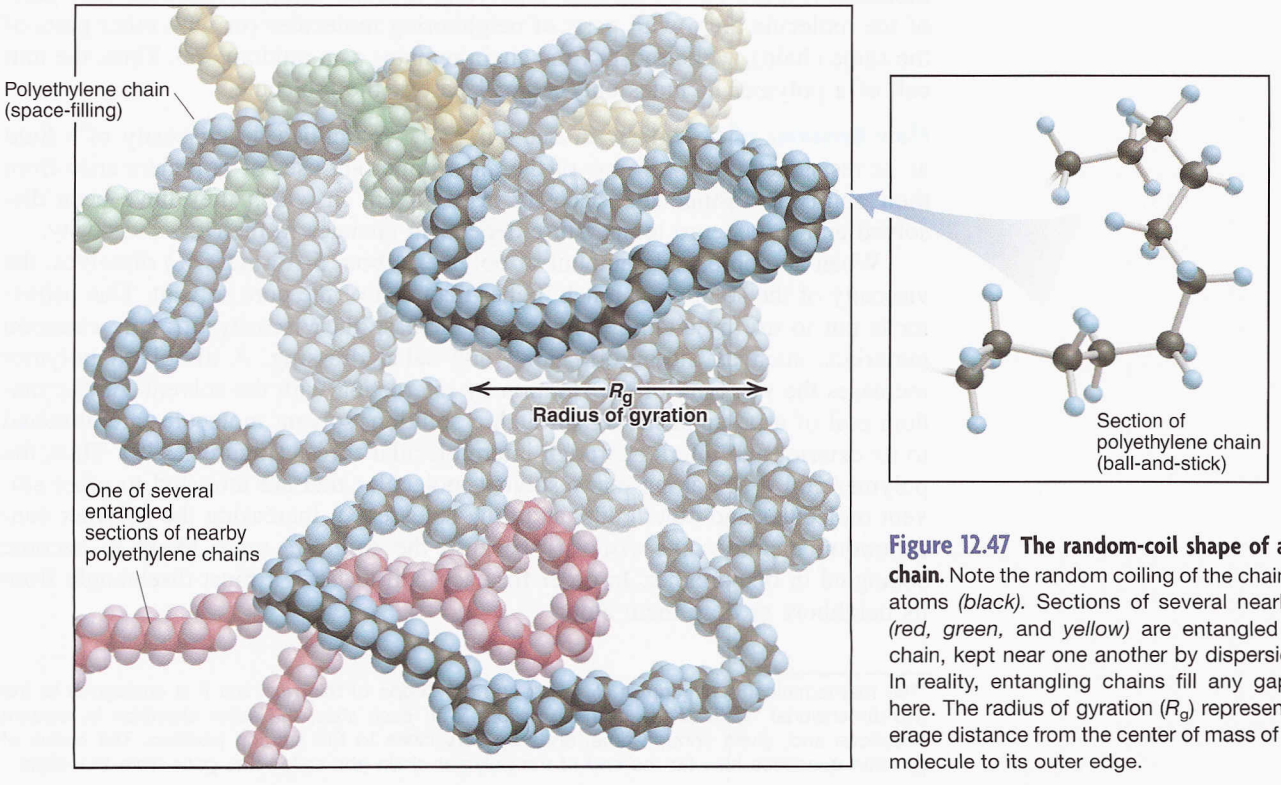


Figure 12.47 The random-coil shape of a polymer chain. Note the random coiling of the chain's carbon atoms *(black)*. Sections of several nearby chains *(red, green,* and *yellow)* are entangled with this chain, kept near one another by dispersion forces. In reality, entangling chains fill any gaps shown here. The radius of gyration (R_g) represents the average distance from the center of mass of the coiled molecule to its outer edge.

portions, between different chains, and/or between chain and solvent becomes a key factor in establishing the actual shape of a polymer chain.

The size of the coiled polymer chain is expressed by its **radius of gyration, R_g**, the average distance from the center of mass to the outer edge of the coil (Figure 12.47). Even though R_g is reported as a single value for a given polymer, it represents an average value for many chains. The mathematical expression for the radius of gyration considers the length of each repeat unit and its randomized direction in space, as well as the bond angles between atoms in a unit and between adjacent units:*

$$R_g = \sqrt{\frac{nl_0^2}{6}}$$

As we would expect, the radius of gyration increases with the degree of polymerization, and thus with the molar mass as well. Most importantly, light-scattering experiments and other laboratory measurements correlate with the calculated results, so for many polymers the radius of gyration can be determined experimentally.

For our grocery-bag polyethylene chain, we have

$$R_g = \sqrt{\frac{nl_0^2}{6}} = \sqrt{\frac{(7.1\times10^3)\,(2.5\times10^2\ \text{pm})^2}{6}} = 8.6\times10^3\ \text{pm}$$

Doubling the radius gives a diameter of 1.7×10^4 pm, less than one-hundredth the length of the extended chain!

3. *Polymer crystallinity*. You may get the impression from the discussion so far that a sample of a given polymer is just a disorderly jumble of chains, but this is often not the case. If the molecular structure allows neighboring chains to pack together and if the chemical groups lead to favorable dipole-dipole, H-bonding, or dispersion forces, portions of the chains can align regularly and exhibit crystallinity.

However, the crystallinity of a polymer is very different from the crystal structures of the simple compounds we discussed earlier. There, the orderly array extends over many molecules, and the unit cell includes at least one molecule. In contrast, the orderly regions of a polymer rarely, if ever, involve even one whole molecule (Figure 12.48). At best, a polymer is *semicrystalline,* because only parts of the molecule align with parts of neighboring molecules (or with other parts of the same chain), while most of the chain remains as a random coil. Thus, the unit cell of a polymer includes only a small part of the molecule.

Flow Behavior of Polymers. In Section 12.4, we defined the viscosity of a fluid as its resistance to flow. Some of the most important uses of polymers arise from their ability to change the viscosity of a solvent in which they have been dissolved and to undergo temperature-dependent changes in their own viscosity.

When an appreciable amount of polymer (about 5–15 mass %) dissolves, the viscosity of the solution is much higher than that of the pure solvent. This behavior is put to use by adding polymers to increase the viscosity of many common materials, such as motor oil, paint, and salad dressing. A dissolved polymer increases the viscosity of the solution by interacting with the solvent. As the random coil of a polymer moves through a solution, solvent molecules are attracted to its exterior and interior through intermolecular forces (Figure 12.49). Thus, the polymer coil drags along many solvent molecules that are attracted to other solvent molecules and other coils, and flow is lessened. Increasing the polymer concentration increases the viscosity because the coils are more likely to become entangled in one another. In order for each coil to flow, it must disentangle from its neighbors or drag them along.

*The mathematical derivation of R_g is beyond the scope of this text, but it is analogous to the two-dimensional "walk of the drunken sailor." With each step, the sailor stumbles in random directions and, given enough time, ends up very close to the starting position. The radius of gyration quantifies how far the end of the polymer chain (the sailor) has gone from the origin.

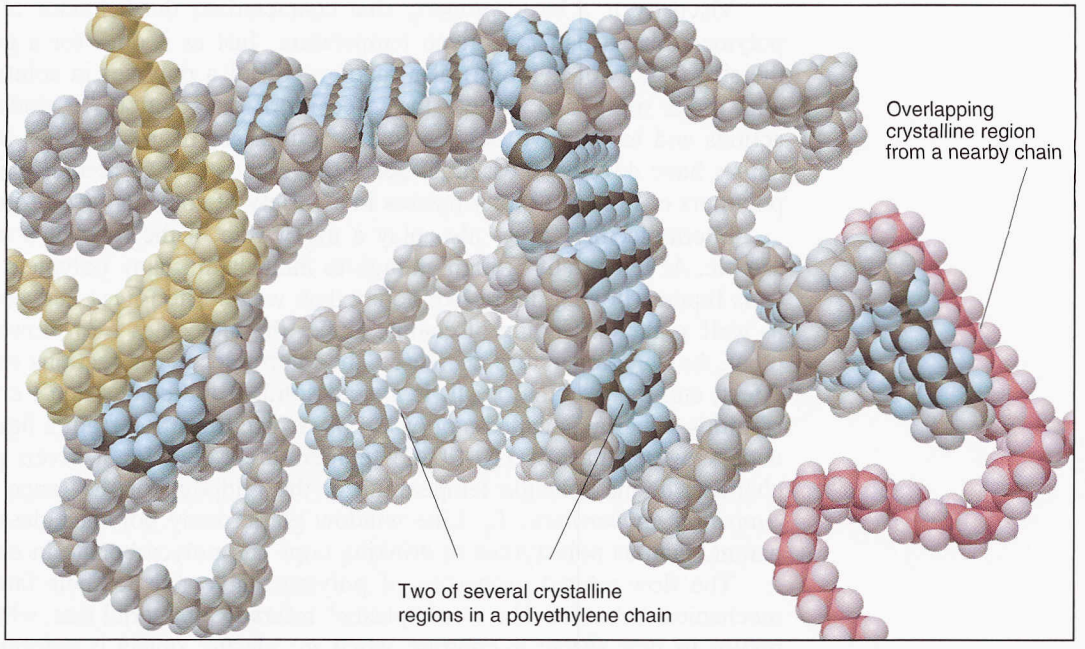

Figure 12.48 The semicrystallinity of a polymer chain. This depiction of polyethylene highlights several ordered regions (*darker color*) with random coils between them. Ordered regions from nearby chains (*red* and *yellow*) are shown overlapping those in the main chain.

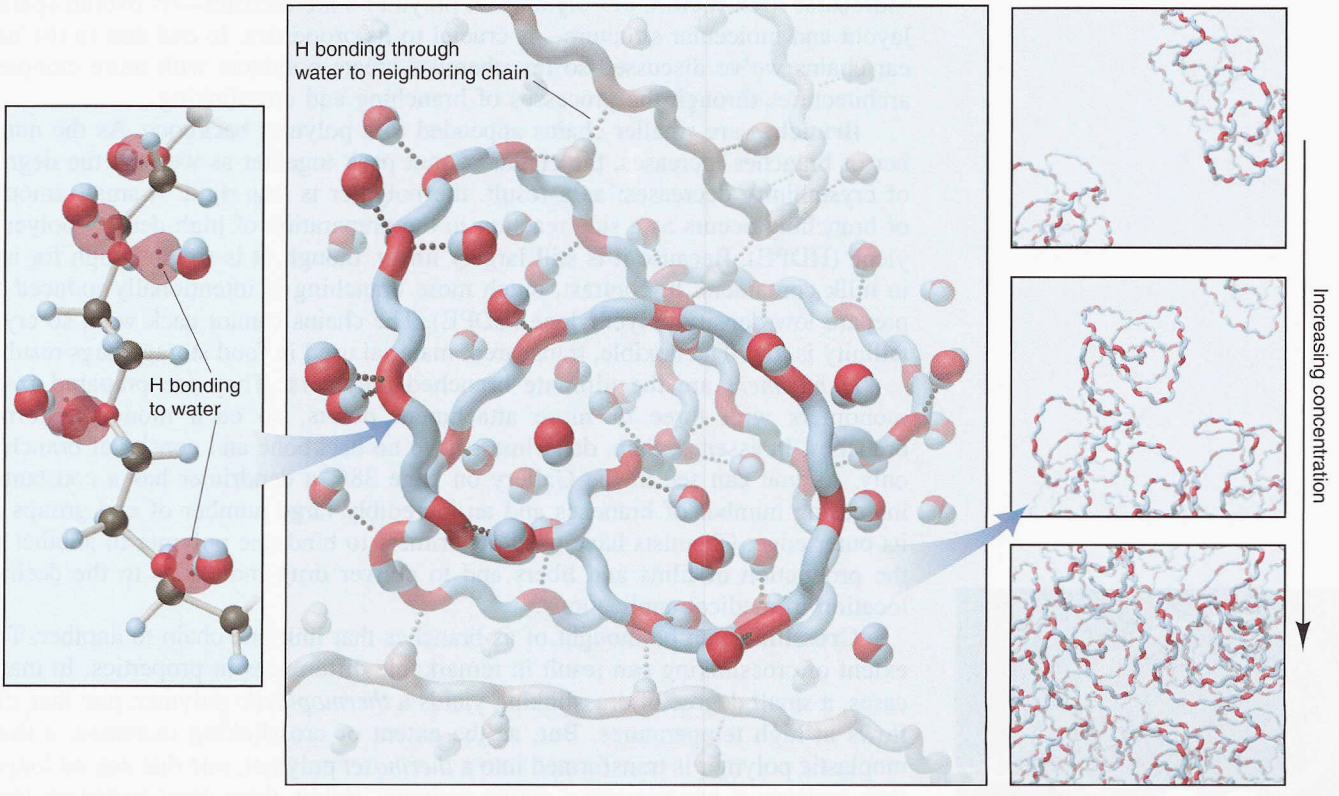

Figure 12.49 The viscosity of a polymer in solution. A ball-and-stick model of a section (*left panel*) of a poly(ethylene oxide) chain in water shows the H bonds that form between the lone pairs of the chain's O atoms and the H atoms of solvent molecules. The polymer chain, depicted as a blue and red coiled rod (*center panel*), forms many H bonds with solvent molecules. Note the H bonds to water molecules that allow one chain to interact with others nearby. As the concentration of polymer increases (*three right panels*), the viscosity of the solution increases because the movement of each chain is restricted through its interactions with solvent and with other chains.

Viscosity is a basic property that characterizes the behavior of a particular polymer-solvent pair at a given temperature. Just as it does for a pure polymer, the size (radius of gyration) of a random coil of a polymer in solution increases with molar mass, and so does the viscosity of the solution. To study basic interactions and to improve polymer manufacture, chemists and other industrial scientists have developed essential quantitative equations to predict the viscosity of polymers of different molar masses in a variety of solvents (see Problem 12.149).

Intermolecular forces also play a major role in the flow of a pure polymer sample. At temperatures high enough to melt them, many polymers exist as viscous liquids, flowing more like honey than water. The forces between the chains, as well as the entangling of chains, hinder the molecules from flowing past each other. As the temperature decreases, the intermolecular attractions exert a greater effect, and the eventual result is a rigid solid. If the chains don't crystallize, the resulting material is called a *polymer glass*. The transition from a liquid to a glass occurs over a narrow (10–20°C) temperature range for a given polymer, but chemists define a single temperature at the midpoint of the range as the *glass transition temperature,* T_g. Like window glass, many polymer glasses are transparent, such as polystyrene in drinking cups and polycarbonate in compact discs.

The flow-related properties of polymers give rise to their familiar **plastic** mechanical behavior. The word "plastic" refers to a material that, when deformed, retains its new shape; in contrast, when an "elastic" object is deformed, it returns to its original shape. Many polymers can be deformed (stretched, bent, twisted) when warm and retain their deformed shape when cooled. In this way, they are made into countless everyday objects—milk bottles, car parts, and so forth.

Molecular Architecture of Polymers A polymer's architecture—its overall spatial layout and molecular structure—is crucial to its properties. In addition to the linear chains we've discussed so far, chemists create polymers with more complex architectures through the processes of branching and crosslinking.

Branches are smaller chains appended to a polymer backbone. As the number of branches increases, the chains cannot pack together as well, so the degree of crystallinity decreases; as a result, the polymer is less rigid. A small amount of branching occurs as a side reaction in the preparation of high-density polyethylene (HDPE). Because it is still largely linear, though, it is rigid enough for use in milk containers. In contrast, much more branching is intentionally induced to prepare low-density polyethylene (LDPE). The chains cannot pack well, so crystallinity is low. The flexible, transparent material used in food storage bags results.

Dendrimers are the ultimate branched polymers. They are prepared from monomers with three or more attachment points, so each monomer forms branches. In essence, then, dendrimers have no backbone and consist of branches only. As you can see in the Gallery on page 386, a dendrimer has a constantly increasing number of branches and an incredibly large number of end groups at its outer edge. Chemists have used dendrimers to bind one polymer to another in the production of films and fibers and to deliver drug molecules to the desired location in medical applications.

Tennis racket containing a thermoset polymer.

Crosslinks can be thought of as branches that link one chain to another. The extent of crosslinking can result in remarkable differences in properties. In many cases, a small degree of crosslinking yields a *thermoplastic* polymer, one that still flows at high temperatures. But, as the extent of crosslinking increases, a thermoplastic polymer is transformed into a *thermoset* polymer, one that can no longer flow because it has become a single network. Below their glass transition temperatures, some thermosets are extremely rigid and strong, making them ideal as matrix materials in high-strength composites (see photo).

Above their glass transition temperatures, many thermosets become **elastomers**, polymers that can be stretched and immediately spring back to their ini-

Table 12.9 Some Common Elastomers

Name	T_g (°C)	Uses
Poly(dimethyl siloxane)	−123	Breast implants
Polybutadiene	−106	Rubber bands
Polyisoprene	−65	Surgical gloves
Polychloroprene (neoprene)	−43	Footwear, medical tubing

tial shapes when released, like the net under a trapeze artist or a common rubber band. When you stretch a rubber band, individual polymer chains flow for only a short distance before the connectivity of the network returns them to their original positions. Table 12.9 lists some elastomers.

Differences in monomer sequences often influence polymer properties as well. A *homopolymer* consists of one type of monomer (A—A—A—A—A—. . .), whereas a **copolymer** consists of two or more types. The simplest copolymer is called an *AB block copolymer* because a chain (block) of monomer A and a chain of monomer B are linked at one point:

. . . —A—A—A—A—A—B—B—B—B—B— . . .

If the intermolecular forces between the A and B portions of the chain are weaker than those between different regions within each portion, the A and B portions form their own random coils. This ability makes AB block copolymers ideal adhesives for joining two polymer surfaces covalently. An ABA block copolymer has A chains linked at each end of a B chain:

. . . —A—A—A—B—$(B)_n$—B—A—A—A— . . .

Some of these block copolymers act as *thermoplastic elastomers*, materials shaped at high temperature that become elastomers at room temperature; not surprisingly, some of these materials have revolutionized the footwear industry.

Polymer chemists tailor polymers to control properties such as viscosity, strength, toughness, and flexibility. The effect of intermolecular forces on their physical properties is only part of the story of these remarkably useful materials. Silicone polymers are described in the Gallery in Chapter 14 (p. 581), and organic reactions that form polymer chains from monomers are examined in Chapter 15.

Nanotechnology: Designing Materials Atom by Atom

At the frontier of interdisciplinary science and expanding at an incredible pace, the exciting new field of *nanotechnology* is joining researchers from physics, materials science, chemistry, biology, environmental science, medicine, and many branches of engineering. International conferences, scientific journals, and an ever-growing list of university and industrial web sites herald the enormous potential impact of nanotechnology on society.

Nanotechnology is the science and engineering of nanoscale systems—those whose sizes range from 1 to 50 nm. Until recently, physical scientists had focused primarily on atoms, which are smaller (around 1×10^{-1} nm), or on crystals, which are larger (around 1×10^{5} nm and up). Working between these size extremes, nanotechnologists examine the chemical and physical properties of nanostructures, manipulating atoms one at a time to synthesize particles, clusters, and layers with properties very different from either individual molecules or their bulk phases. The scanning tunneling microscope (see Tools of the Laboratory, p. 456) and the similar scanning probe and atomic force microscopes are among the precise tools required to place individual atoms, molecules, and clusters into the positions required to build a structure or cause a desired reaction.

The key to this futuristic technology lies in two features of nanoscale construction that occur routinely in nature. The first is *self-assembly*, the ability of smaller, simpler parts to organize themselves into a larger, more complex whole. On the molecular scale, self-assembly refers to atoms or small molecules aggregating through intermolecular forces, especially dipole-dipole, H-bonding, and dispersion forces. Oppositely charged regions on two such particles make contact to form a larger particle, which in turn forms a still larger one. The other feature is *controlled orientation*, the positioning of two molecules near each other long enough for intermolecular forces to take effect. Some industrial catalysts and all biological catalysts (enzymes) function through controlled orientation. (Catalysts, discussed in Chapter 16, are substances that speed reactions.) Common strategies for nanoscale construction include approaches that mimic biological self-assembly, sophisticated precipitation methods, and a variety of physical and chemical aerosol techniques for making nanoclusters and then manipulating them into more consolidated structures.

Because the field is evolving so rapidly, it is possible to provide only a very general overview of some current research directions in nanotechnology. The National Nanotechnology Initiative describes worldwide efforts in many key areas—four of which are dispersions and coatings, high-surface-area materials, functional devices, and consolidated materials.

Dispersions and Coatings Nanostructuring is being used in a wide range of optical, thermal, and electrical applications of dispersions and coatings, including products related to printing, photography, and pharmaceuticals. Some examples are thermal and optical barriers, sunscreens, image enhancers, ink-jet materials, coated abrasive slurries, and information-recording layers. Highly ordered, iron/platinum nanoparticles of extremely uniform size and exceptional magnetic properties may be adapted as coatings for high-density information storage, holding a million times as much data per unit of surface area as current materials. Another exciting application involves highly ordered, one-molecule-thick films—in effect, two-dimensional crystals—that can be coated on a variety of surfaces. One approach is to layer light-sensitive molecules that change reversibly from one form to another. A finely focused laser could trigger the change in the molecular form to create specific patterns, thus storing information at the density of one bit of data per molecule!

High-Surface-Area Materials These applications take advantage of the incredibly large surface areas of nanoscale building blocks. For example, a particle 5 nm in diameter has about half of its atoms on its surface. When such nanoparticles are assembled, the resulting surface area is enormous. Current projects include porous membranes for water purification and batteries, drug-delivery systems, and multilayer films that incorporate photosynthetic molecules for high-efficiency solar cells. There is great potential for molecule-specific sensors. Certain biosensors allow detection of as little as 10^{-14} mol of DNA using color changes in gold nanoparticles. In another development, 50-nm gold particles sense slight differences in two portions of DNA; such sensitivity may allow detection of subtle genetic mutations. An eventual goal is to develop biosensors that could circulate freely in the bloodstream, measure levels of specific disease-related molecules, and deliver drugs to individual cells, even individual genes.

Functional Devices The need for ever smaller machines is the driving force in this area of research, and the nanoscale computer is the dream. The ongoing race for faster, smaller traditional computers will soon hit a fundamental "brick wall." Since the 1960s, computing speeds have doubled about every two years as the light-etched rules between transistors and diodes on the silicon chip were made closer and closer. Currently, UV photolithography makes rules less than 180 nm apart. As this distance approaches 50 nm, however, doping inconsistencies, heat

generation, and other inherent limitations arise, and the silicon-based chip reaches its lower size limit. Imagine the potential impact of ongoing work to develop supercomputers consisting of molecule-sized diodes and transistors bound to an organic surface—the ultimate reduction in size and, thus, increase in speed.

To realize this dream, one of the major research efforts focuses on developing the single-electron transistor (SET). SETs will be made into arrays using methods similar to biological self-assembly. Such nanoscale devices must have nanoscale connections, and a related research area involves the fabrication of nanowires. In one method, a metal is electroplated from solution [such as cobalt from a solution of $Co(NO_3)_2$] to fill uniform nanopores created by controlled oxidation of aluminum surfaces. But the greatest research activity is focused on carbon nanotubes (see the Gallery, p. 386). These can be single or nested tubes with insulating, semiconducting, or metallic properties. Produced by high-temperature (800°–1000°C) reduction of a hydrocarbon or by electron-beam irradiation of fullerenes, nanotubes are then physically separated according to size and properties, using an atomic force or scanning tunneling microscope. Adding specific chemical groups to the nanotubes expands their applications further (Figure 12.50).

Consolidated Materials It is known that mechanical, magnetic, and optical properties change dramatically when bulk materials are consolidated from nanoscale building blocks. Nanostructuring will greatly increase the hardness and strength of metals and the ductility and plasticity of ceramics. Nanoparticle fillers can yield nanocomposites with unique properties—soft magnets, tough cutting tools, ultrastrong ductile cements, magnetic refrigerants, and a wide range of nanoparticle-filled elastomers, thermoplastics, and thermosets.

A, The tip of an atomic force microscope, one of the key tools used to build nanodevices. **B,** This atomic force micrograph shows a carbon nanotube "wire" (*blue*) on platinum electrodes (*yellow*). The nanotube is 1.5 nm (10 atoms) across and was made by using a laser to join fullerene molecules into a tube. (Magnification ×120,000.)

SECTION SUMMARY

Doping increases the conductivity of semiconductors and is essential to modern electronic materials. Doping silicon with Group 5A atoms introduces negative sites (n-type) by adding valence electrons to the conduction band, whereas doping with Group 3A atoms adds positive holes (p-type) by emptying some orbitals in the valence band. Placing these two types of doped Si next to one another forms a p-n junction. Sandwiching a p-type portion between two n-type portions forms a transistor. Liquid crystal phases flow like liquids but have molecules ordered like crystalline solids. Typically, the molecules have rodlike shapes, and their intermolecular forces keep them aligned. Thermotropic phases are prepared by heating the solid; lyotropic phases form when the solvent concentration is varied. The nematic, cholesteric, and smectic types of liquid crystals differ in their molecular order. Liquid crystal applications depend on controlling the orientation of the molecules. Ceramics are very resistant to heat and chemicals. Most are network covalent solids formed at high temperature from simple reactants. They add lightweight strength to other materials. Polymers are extremely large molecules that adopt the shape of a random coil as a result of intermolecular forces. A polymer sample has an average molar mass because it consists of a range of chain lengths. The high viscosity of a polymer arises from attractions between chains or, in the case of a dissolved polymer, between the chain and the solvent molecules. By varying the degrees of branching, crosslinking, and ordering (crystallinity), chemists tailor polymers with remarkable properties. Nanoscale materials can be made one atom or molecule at a time through construction processes involving self-assembly and controlled orientation of molecules.

Chapter Perspective

Our central focus—macroscopic behavior resulting from molecular behavior—became still clearer in this chapter, as we built on earlier ideas of bonding, molecular shape, and polarity to understand the intermolecular forces that create the properties of liquids and solids. In Chapter 13, we'll find many parallels to the key ideas in this chapter: the same intermolecular forces create solutions, temperature influences solubility just as it does vapor pressure, and the equilibrium state also underlies the properties of solutions.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. How the interplay between kinetic and potential energy underlies the properties of the three states of matter and their phase changes (12.1)
2. The processes involved, both within a phase and during a phase change, when heat is added or removed from a pure substance (12.2)
3. The meaning of vapor pressure and how phase changes are dynamic equilibrium processes (12.2)
4. How temperature and intermolecular forces influence vapor pressure (12.2)
5. The relation between vapor pressure and boiling point (12.2)
6. How a phase diagram shows the phases of a substance at differing conditions of pressure and temperature (12.2)
7. The distinction between bonding and intermolecular forces on the basis of Coulomb's law and the meaning of the van der Waals radius of an atom (12.3)
8. The types and relative strengths of intermolecular forces acting in a substance (dipole-dipole, H-bonding, dispersion), the impact of H bonding on physical properties, and the meaning of polarizability (12.3)
9. The meanings of surface tension, capillarity, and viscosity and how intermolecular forces influence their magnitudes (12.4)
10. How the important macroscopic properties of water arise from atomic and molecular properties (12.5)
11. The meaning of *crystal lattice* and the characteristics of the three types of cubic unit cells (12.6)
12. How packing of spheres gives rise to the hexagonal and cubic unit cells (12.6)
13. Types of crystalline solids and how their intermolecular forces give rise to their properties (12.6)
14. How band theory accounts for the properties of metals and the relative conductivities of metals, nonmetals, and metalloids (12.6)
15. The structures, properties, and functions of modern materials (doped semiconductors, liquid crystals, ceramics, polymers, and nanostructures) on the atomic scale (12.7)

Master These Skills

1. Calculating the overall enthalpy change when heat is added to or removed from a pure substance (12.2)
2. Using the Clausius-Clapeyron equation to examine the relationship between vapor pressure and temperature (SP 12.1)
3. Using a phase diagram to predict the physical state and/or phase change of a substance (12.2)
4. Determining whether a substance can form H bonds and drawing the H-bonded structures (SP 12.2)
5. Predicting the types and relative strength of the intermolecular forces acting within a substance from its structure (SP 12.3)
6. Finding the number of particles in a unit cell (12.6)
7. Calculating atomic radius from the density and crystal structure of an element (SP 12.4)

Key Equations and Relationships

12.1 Using the vapor pressure at one temperature to find the vapor pressure at another temperature (two-point form of the Clausius-Clapeyron equation) (433):

$$\ln\frac{P_2}{P_1} = \frac{-\Delta H_{vap}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

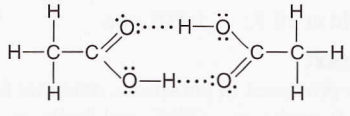
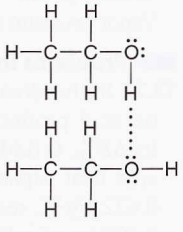
Brief Solutions to Follow-up Problems

12.1
$$\ln\frac{P_2}{P_1} = \left(\frac{-40.7\times10^3\ \text{J/mol}}{8.314\ \text{J/mol·K}}\right) \times \left(\frac{1}{273.15 + 85.5\ \text{K}} - \frac{1}{273.15 + 34.1\ \text{K}}\right)$$
$$= (-4.90\times10^3\ \text{K})(-4.66\times10^{-4}\ \text{K}^{-1}) = 2.28$$
$$\frac{P_2}{P_1} = 9.8;\ \text{thus, } P_2 = 40.1\ \text{torr} \times 9.8 = 3.9\times10^2\ \text{torr}$$

12.2 (a)



(b)



(c) No H bonding

12.3 (a) Dipole-dipole, dispersion; CH_3Br
(b) H bonds, dipole-dipole, dispersion; $CH_3CH_2CH_2OH$
(c) Dispersion; C_3H_8

12.4
$$\text{Avogadro's no.} = \frac{1\ \text{cm}^3}{7.874\ \text{g Fe}} \times \frac{55.85\ \text{g Fe}}{1\ \text{mol Fe}} \times 0.68 \times \frac{1\ \text{Fe atom}}{8.38\times10^{-24}\ \text{cm}^3}$$
$$= 5.8\times10^{23}\ \text{Fe atoms/mol Fe}$$

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

An Overview of Physical States and Phase Changes

Concept Review Questions

12.1 How does the energy of attraction between particles compare with their energy of motion in a gas and in a solid? As part of your answer, identify two macroscopic properties that differ between a gas and a solid.

12.2 What types of forces, intramolecular or intermolecular,
(a) prevent ice cubes from adopting the shape of their container?
(b) are overcome when ice melts?
(c) are overcome when liquid water is vaporized?
(d) are overcome when gaseous water is converted to hydrogen gas and oxygen gas?

12.3 (a) Why are gases more easily compressed than liquids?
(b) Why do liquids have a greater ability to flow than solids?

12.4 (a) Why is the heat of fusion (ΔH_{fus}) of a substance smaller than its heat of vaporization (ΔH_{vap})?
(b) Why is the heat of sublimation (ΔH_{subl}) of a substance greater than its ΔH_{vap}?
(c) At a given temperature and pressure, how does the magnitude of the heat of vaporization of a substance compare with that of its heat of condensation?

Skill-Building Exercises *(grouped in similar pairs)*

12.5 Which forces are intramolecular and which intermolecular?
(a) Those preventing oil from evaporating at room temperature
(b) Those preventing butter from melting in a refrigerator
(c) Those allowing silver to tarnish
(d) Those preventing O_2 in air from forming O atoms

12.6 Which forces are intramolecular and which intermolecular?
(a) Those allowing fog to form on a cool, humid evening
(b) Those allowing water to form when H_2 is sparked
(c) Those allowing liquid benzene to crystallize when cooled
(d) Those responsible for the low boiling point of hexane

12.7 Name the phase change in each of these events:
(a) Dew appears on a lawn in the morning.
(b) Icicles change into liquid water.
(c) Wet clothes dry on a summer day.

12.8 Name the phase change in each of these events:
(a) A diamond film forms on a surface from gaseous carbon atoms in a vacuum.
(b) Mothballs in a bureau drawer disappear over time.
(c) Molten iron from a blast furnace is cast into ingots ("pigs").

Problems in Context

12.9 Liquid propane, a widely used fuel, is produced by compressing gaseous propane at 20°C. During the process, approximately 15 kJ of energy is released for each mole of gas liquefied. Where does this energy come from?

12.10 Many heat-sensitive and oxygen-sensitive solids, such as camphor, are purified by warming under vacuum. The solid vaporizes directly, and the vapor crystallizes on a cool surface. What phase changes are involved in this method?

Quantitative Aspects of Phase Changes

(Sample Problem 12.1)

Concept Review Questions

12.11 Describe the changes (if any) in potential energy and in kinetic energy among the molecules when gaseous PCl_3 condenses to a liquid at a fixed temperature.

12.12 When benzene is at its melting point, two processes occur simultaneously and balance each other. Describe these processes on the macroscopic and molecular levels.

12.13 Liquid hexane (bp = 69°C) is placed in a closed container at room temperature. At first, the pressure of the vapor phase increases, but after a short time, it stops changing. Why?

12.14 Explain the effect of strong intermolecular forces on each of these parameters: (a) critical temperature; (b) boiling point; (c) vapor pressure; (d) heat of vaporization.

12.15 At 1.1 atm, will water boil at 100.°C? Explain.

12.16 A liquid is in equilibrium with its vapor in a closed vessel at a fixed temperature. The vessel is connected by a stopcock to an evacuated vessel. When the stopcock is opened, will the final pressure of the vapor be different from the original value if (a) some liquid remains; (b) all the liquid is first removed? Explain.

12.17 The phase diagram for substance A has a solid-liquid line with a positive slope, and that for substance B has a solid-liquid line with a negative slope. What macroscopic property can distinguish A from B?

12.18 Why does water vapor at 100°C cause more severe burns than liquid water at 100°C?

Skill-Building Exercises *(grouped in similar pairs)*

12.19 From the data below, calculate the total heat (in J) needed to convert 12.00 g of ice at −5.00°C to liquid water at 0.500°C:

mp at 1 atm:	0.0°C	ΔH^0_{fus}:	6.02 kJ/mol
c_{liquid}:	4.21 J/g·°C	c_{solid}:	2.09 J/g·°C

12.20 From the data below, calculate the total heat (in J) needed to convert 0.333 mol of gaseous ethanol at 300°C and 1 atm to liquid ethanol at 25.0°C and 1 atm:

bp at 1 atm:	78.5°C	ΔH^0_{vap}:	40.5 kJ/mol
c_{gas}:	1.43 J/g·°C	c_{liquid}:	2.45 J/g·°C

12.21 A liquid has a ΔH^0_{vap} of 35.5 kJ/mol and a boiling point of 122°C at 1.00 atm. What is its vapor pressure at 109°C?

12.22 Diethyl ether has a ΔH^0_{vap} of 29.1 kJ/mol and a vapor pressure of 0.703 atm at 25.0°C. What is its vapor pressure at 95.0°C?

12.23 What is the ΔH^0_{vap} of a liquid that has a vapor pressure of 641 torr at 85.2°C and a boiling point of 95.6°C at 1 atm?

12.24 Methane (CH_4) has a boiling point of −164°C at 1 atm and a vapor pressure of 42.8 atm at −100°C. What is the heat of vaporization of CH_4?

12.25 Use these data to draw a qualitative phase diagram for ethylene (C_2H_4). Is $C_2H_4(s)$ more or less dense than $C_2H_4(l)$?

bp at 1 atm:	−103.7°C
mp at 1 atm:	−169.16°C
Critical point:	9.9°C and 50.5 atm
Triple point:	−169.17°C and 1.20×10^{-3} atm

12.26 Use these data to draw a qualitative phase diagram for H_2. Does H_2 sublime at 0.05 atm? Explain.

mp at 1 atm:	13.96 K
bp at 1 atm:	20.39 K
Triple point:	13.95 K and 0.07 atm
Critical point:	33.2 K and 13.0 atm
Vapor pressure of solid at 10 K:	0.001 atm

Problems in Context

12.27 Sulfur dioxide is produced in enormous amounts for sulfuric acid production. It melts at −73°C and boils at −10.°C. Its ΔH^0_{fus} is 8.619 kJ/mol and its ΔH^0_{vap} is 25.73 kJ/mol. The specific heat capacities of the liquid and gas are 0.995 J/g·K and 0.622 J/g·K, respectively. How much heat is required to convert 2.500 kg of solid SO_2 at the melting point to a gas at 60.°C?

12.28 Butane is a common fuel used in cigarette lighters and camping stoves. Normally supplied in metal containers under pressure, the fuel exists as a mixture of liquid and gas, so high temperatures may cause the container to explode. At 25.0°C, the vapor pressure of butane is 2.3 atm. What is the pressure in the container at 150.°C (ΔH_{vap} = 24.3 kJ/mol)?

12.29 Use Figure 12.9A, p. 435, to answer the following:
(a) Carbon dioxide is sold in steel cylinders under pressures of approximately 20 atm. Is there liquid CO_2 in the cylinder at room temperature (~20°C)? At 40°C? At −40°C? At −120°C?
(b) Carbon dioxide is also sold as solid chunks, called *dry ice*, in insulated containers. If the chunks are warmed by leaving them in an open container at room temperature, will they melt?
(c) If a container is nearly filled with dry ice and then sealed and warmed to room temperature, will the dry ice melt?
(d) If dry ice is compressed at a temperature below its triple point, will it melt?
(e) Will liquid CO_2 placed in a beaker at room temperature boil?

Types of Intermolecular Forces

(Sample Problems 12.2 and 12.3)

Concept Review Questions

12.30 Why are covalent bonds typically much stronger than intermolecular forces?

12.31 Even though molecules are neutral, the dipole-dipole force is one of the most important interparticle forces that exists among them. Explain.

12.32 Oxygen and selenium are members of Group 6A(16). Water forms H bonds, but H_2Se does not. Explain.

12.33 In solid I_2, is the distance between the two I nuclei of one I_2 molecule longer or shorter than the distance between two I nuclei of adjacent I_2 molecules? Explain.

12.34 Polar molecules exhibit dipole-dipole forces. Do they also exhibit dispersion forces? Explain.

12.35 Distinguish between *polarizability* and *polarity*. How does each influence intermolecular forces?

12.36 How can one nonpolar molecule induce a dipole in a nearby nonpolar molecule?

Skill-Building Exercises *(grouped in similar pairs)*

12.37 What is the strongest interparticle force in each substance?
(a) CH_3OH (b) CCl_4 (c) Cl_2

12.38 What is the strongest interparticle force in each substance?
(a) H_3PO_4 (b) SO_2 (c) $MgCl_2$

12.39 What is the strongest interparticle force in each substance?
(a) CH_3Br (b) CH_3CH_3 (c) NH_3

12.40 What is the strongest interparticle force in each substance?
(a) Kr (b) BrF (c) H_2SO_4

12.41 Which member of each pair of compounds forms intermolecular H bonds? Draw the H-bonded structures in each case:
(a) $CH_3\underset{\displaystyle OH}{\underset{|}{C}}HCH_3$ or CH_3SCH_3 (b) HF or HBr

12.42 Which member of each pair of compounds forms intermolecular H bonds? Draw the H-bonded structures in each case:
(a) $(CH_3)_2NH$ or $(CH_3)_3N$ (b) $HOCH_2CH_2OH$ or FCH_2CH_2F

12.43 Which forces oppose vaporization of each substance?
(a) hexane (b) water (c) $SiCl_4$

12.44 Which forces oppose vaporization of each substance?
(a) Br_2 (b) SbH_3 (c) CH_3NH_2

12.45 Which has the greater polarizability? Explain.
(a) Br^- or I^- (b) $CH_2{=}CH_2$ or $CH_3{-}CH_3$ (c) H_2O or H_2Se

12.46 Which has the greater polarizability? Explain.
(a) Ca^{2+} or Ca (b) CH_3CH_3 or $CH_3CH_2CH_3$ (c) CCl_4 or CF_4

12.47 Which member in each pair of liquids has the *higher* vapor pressure at a given temperature? Explain.
(a) C_2H_6 or C_4H_{10} (b) CH_3CH_2OH or CH_3CH_2F
(c) NH_3 or PH_3

12.48 Which member in each pair of liquids has the *lower* vapor pressure at a given temperature? Explain.
(a) $HOCH_2CH_2OH$ or $CH_3CH_2CH_2OH$
(b) CH_3COOH or $(CH_3)_2C{=}O$ (c) HF or HCl

12.49 Which substance has the *higher* boiling point? Explain.
(a) LiCl or HCl (b) NH_3 or PH_3 (c) Xe or I_2

12.50 Which substance has the *higher* boiling point? Explain.
(a) CH_3CH_2OH or $CH_3CH_2CH_3$ (b) NO or N_2 (c) H_2S or H_2Te

12.51 Which substance has the *lower* boiling point? Explain.
(a) $CH_3CH_2CH_2CH_3$ or $\begin{matrix}CH_2{-}CH_2\\ |\quad\ \ |\\ CH_2{-}CH_2\end{matrix}$ (b) NaBr or PBr_3
(c) H_2O or HBr

12.52 Which substance has the *lower* boiling point? Explain.
(a) CH_3OH or CH_3CH_3 (b) FNO or ClNO
(c)  or

Problems in Context

12.53 For pairs of molecules in the gas phase, average H-bond dissociation energies are 17 kJ/mol for NH_3, 22 kJ/mol for H_2O, and 29 kJ/mol for HF. Explain this increase in H-bond strength.

12.54 Dispersion forces are the only intermolecular forces present in motor oil, yet it has a high boiling point. Explain.

12.55 Why does the antifreeze ingredient ethylene glycol ($HOCH_2CH_2OH$; $\mathcal{M}$ = 62.07 g/mol) have a boiling point of 197.6°C, whereas propanol ($CH_3CH_2CH_2OH$; $\mathcal{M}$ = 60.09 g/mol), a compound with a similar molar mass, has a boiling point of only 97.4°C?

Properties of the Liquid State

Concept Review Questions

12.56 Before the phenomenon of surface tension was understood, physicists described the surface of water as being covered with a "skin." What causes this skinlike phenomenon?

12.57 Small, equal-sized drops of oil, water, and mercury lie on a waxed floor. How does each liquid behave? Explain.

12.58 Why does an aqueous solution of ethanol (CH_3CH_2OH) have a lower surface tension than water?

12.59 Why are units of energy per area (J/m^2) used for surface tension values?

12.60 Does the *strength* of the intermolecular forces in a liquid change as the liquid is heated? Explain. Why does liquid viscosity decrease with rising temperature?

Skill-Building Exercises *(grouped in similar pairs)*

12.61 Rank the following in order of *increasing* surface tension at a given temperature, and explain your ranking:
(a) $CH_3CH_2CH_2OH$ (b) $HOCH_2CH(OH)CH_2OH$
(c) $HOCH_2CH_2OH$

12.62 Rank the following in order of *decreasing* surface tension at a given temperature, and explain your ranking:
(a) CH_3OH (b) CH_3CH_3 (c) $H_2C{=}O$

12.63 Rank the compounds in Problem 12.61 in order of *increasing* viscosity at a given temperature; explain your ranking.

12.64 Rank the compounds in Problem 12.62 in order of *decreasing* viscosity at a given temperature; explain your ranking.

Problems in Context

12.65 Soil vapor extraction (SVE) is used to remove volatile organic pollutants, such as chlorinated solvents, from soil at hazardous waste sites. Vent wells are drilled, and a vacuum pump is applied to the subsurface. (a) How does this remove pollutants? (b) Why does heating combined with SVE speed the process?

12.66 Use Figure 12.1, p. 427 to answer the following: (a) Does it take more heat to melt 12.0 g of CH_4 or 12.0 g of Hg? (b) Does it take more heat to vaporize 12.0 g of CH_4 or 12.0 g of Hg? (c) What is the principal intermolecular force in each sample?

12.67 Pentanol ($C_5H_{11}OH$; $\mathcal{M}$ = 88.15 g/mol) has nearly the same molar mass as hexane (C_6H_{14}; $\mathcal{M}$ = 86.17 g/mol) but is more than 12 times as viscous at 20°C. Explain.

The Uniqueness of Water

Concept Review Questions

12.68 For what types of substances is water a good solvent? For what types is it a poor solvent? Explain.

12.69 A water molecule can engage in as many as four H bonds. Explain.

12.70 Warm-blooded animals have a narrow range of body temperature because their bodies have a high water content. Explain.

12.71 What property of water keeps plant debris on the surface of lakes and ponds? What is the ecological significance of this?

12.72 A drooping plant can be made upright by watering the ground around it. Explain.

12.73 Describe the molecular basis of the property of water responsible for the presence of ice on the surface of a frozen lake.

12.74 Describe in molecular terms what occurs when ice melts.

The Solid State: Structure, Properties, and Bonding

(Sample Problem 12.4)

Concept Review Questions

12.75 What is the difference between an amorphous solid and a crystalline solid on the macroscopic and molecular levels? Give an example of each.

12.76 How are a solid's unit cell and crystal structure related?

12.77 For structures consisting of identical atoms, how many atoms are contained in the simple, body-centered, and face-centered cubic unit cells? Explain how you obtained the values.

12.78 An element has a crystal structure in which the width of the cubic unit cell equals the diameter of an atom. What type of unit cell does it have?

12.79 What specific difference in the positioning of spheres gives a crystal structure based on the face-centered cubic unit cell less empty space than one based on the body-centered cubic unit cell?

12.80 Both solid Kr and solid Cu consist of individual atoms. Why do their physical properties differ so much?

12.81 What is the energy gap in band theory? Compare its size in superconductors, conductors, semiconductors, and insulators.

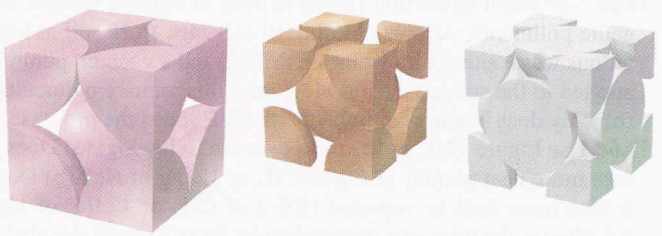
12.82 Predict the effect (if any) of an increase in temperature on the electrical conductivity of (a) a conductor; (b) a semiconductor; (c) an insulator.

12.83 Besides the type of unit cell, what information is needed to find the density of a solid consisting of identical atoms?

Skill-Building Exercises *(grouped in similar pairs)*

12.84 What type of crystal lattice does each metal form? (The number of atoms per unit cell is given in parentheses.)
(a) Ni (4) (b) Cr (2) (c) Ca (4)

12.85 What is the number of atoms per unit cell for each metal?
(a) Polonium, Po (b) Iron, Fe (c) Silver, Ag



12.86 Of the five major types of crystalline solid, which does each of the following form: (a) Sn; (b) Si; (c) Xe?

12.87 Of the five major types of crystalline solid, which does each of the following form: (a) cholesterol ($C_{27}H_{45}OH$); (b) KCl; (c) BN?

12.88 Of the five major types of crystalline solid, which does each of the following form, and why: (a) Ni; (b) F_2; (c) CH_3OH?

12.89 Of the five major types of crystalline solid, which does each of the following form, and why: (a) SiC; (b) Na_2SO_4; (c) SF_6?

12.90 Zinc oxide adopts the zinc blende crystal structure (Figure P12.90). How many Zn^{2+} ions are in the ZnO unit cell?

12.91 Calcium sulfide adopts the sodium chloride crystal structure (Figure P12.91). How many S^{2-} ions are in the CaS unit cell?

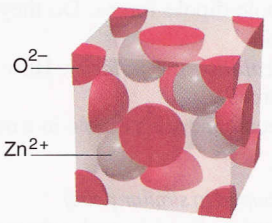


Figure P12.90

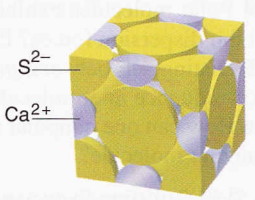

Figure P12.91

12.92 Zinc selenide (ZnSe) crystallizes in the zinc blende structure and has a density of 5.42 g/cm^3.
(a) How many Zn and Se ions are in each unit cell?
(b) What is the mass of a unit cell?
(c) What is the volume of a unit cell?
(d) What is the edge length of a unit cell?

12.93 An element crystallizes in a face-centered cubic lattice and has a density of 1.45 g/cm^3. The edge of its unit cell is 4.52×10^{-8} cm.
(a) How many atoms are in each unit cell?
(b) What is the volume of a unit cell?
(c) What is the mass of a unit cell?
(d) Calculate an approximate atomic mass for the element.

12.94 Classify each of the following as a conductor, insulator, or semiconductor: (a) phosphorus; (b) mercury; (c) germanium.

12.95 Classify each of the following as a conductor, insulator, or semiconductor: (a) carbon (graphite); (b) sulfur; (c) platinum.

12.96 Predict the effect (if any) of an increase in temperature on the electrical conductivity of (a) antimony, Sb; (b) tellurium, Te; (c) bismuth, Bi.

12.97 Predict the effect (if any) of a decrease in temperature on the electrical conductivity of (a) silicon, Si; (b) lead, Pb; (c) germanium, Ge.

Problems in Context

12.98 Polonium, the Period 6 member of Group 6A(16), is a rare radioactive metal that is the only element with a crystal structure based on the simple cubic unit cell. If its density is 9.142 g/cm^3, calculate an approximate atomic radius for polonium.

12.99 The coinage metals—copper, silver, and gold—crystallize in a cubic closest packed structure. Use the density of copper (8.95 g/cm^3) and its molar mass (63.55 g/mol) to calculate an approximate atomic radius for copper.

12.100 One of the most important enzymes in the world—nitrogenase, the plant protein that catalyzes nitrogen fixation—contains active clusters of iron, sulfur, and molydenum atoms. Crystalline molybdenum (Mo) has a body-centered cubic unit

cell (d of Mo = 10.28 g/cm^3). (a) Determine the edge length of the unit cell. (b) Calculate the atomic radius of Mo.

12.101 Tantalum (Ta; d = 16.634 g/cm^3 and $\mathcal{M}$ = 180.9479 g/mol) has a body-centered cubic structure with a unit-cell edge length of 3.3058 Å. Use these data to calculate Avogadro's number.

Advanced Materials

Concept Review Questions

12.102 When tin is added to copper, the resulting alloy (bronze) is much harder than copper. Explain.

12.103 In the process of doping a semiconductor, certain impurities are added to increase its electrical conductivity. Explain this process for an n-type and a p-type semiconductor.

12.104 State two molecular characteristics of substances that typically form liquid crystals. How is each of them related to function?

12.105 Distinguish between isotropic and anisotropic substances. To which category do liquid crystals belong?

12.106 How are the properties of high-tech ceramics the same as those of traditional clay ceramics, and how are they different? Refer to specific substances in your answer.

12.107 Why is the average molar mass of a polymer sample different from the molar mass of an individual chain?

12.108 How does the random coil shape relate to the radius of gyration of a polymer chain?

12.109 What factor(s) influence the viscosity of a polymer solution? What factor(s) influence the viscosity of a molten polymer? What is a polymer glass?

12.110 Use an example to show how branching and crosslinking can affect the physical behavior of a polymer.

Skill-Building Exercises (grouped in similar pairs)

12.111 Silicon and germanium are both semiconducting elements from Group 4A(14) that can be doped to improve their conductivity. Would each of the following form an n-type or a p-type semiconductor: (a) Ge doped with P; (b) Si doped with In?

12.112 Would each of the following form an n-type or a p-type semiconductor: (a) Ge doped with As; (b) Si doped with B?

12.113 The repeat unit in a polystyrene coffee cup has the formula $C_6H_5CHCH_2$. If the molar mass of the polymer is 3.5×10^5 g/mol, what is the degree of polymerization?

12.114 The monomer of poly(vinyl chloride) has the formula C_2H_3Cl. If there are 1565 repeat units in a single chain of the polymer, what is the molecular mass (in amu) of that chain?

12.115 The polypropylene (repeat unit CH_3CHCH_2) in a plastic toy has a molar mass of 2.5×10^5 g/mol and a repeat unit length of 0.252 pm. Calculate the radius of gyration.

12.116 The polymer that is used to make 2-L soda bottles [poly(ethylene terephthalate)] has a repeat unit with molecular formula $C_{10}H_8O_4$ and length 1.075 nm. Calculate the radius of gyration of a chain with molar mass of 2.30×10^4 g/mol.

Comprehensive Problems

12.117 A 0.75-L bottle is cleaned, dried, and closed in a room where the air is 22°C and 44% relative humidity (that is, the water vapor in the air is 0.44 of the equilibrium vapor pressure at 22°C). The bottle is brought outside and stored at 0.0°C.
(a) What mass of liquid water condenses inside the bottle?
(b) Would liquid water condense at 10°C? (See Table 5.3, p. 197.)

12.118 In an experiment, 4.00 L of N_2 is saturated with water vapor at 22°C and then compressed to half its volume. (a) What is the partial pressure of H_2O in the compressed gas mixture? (b) What mass of water vapor condenses to liquid?

12.119 Which forces are overcome when the following events occur: (a) NaCl dissolves in water; (b) krypton boils; (c) water boils; (d) CO_2 sublimes?

12.120 Changes in pressure cause phase changes analogous to the changes with temperature shown in Figure 12.3, p. 429.
(a) Refer to Figure 12.9B (p. 435) and draw a curve of pressure vs. time for water similar to Figure 12.3; label the phase changes as the pressure is continuously *increased* at 2°C.
